AMERICAN SOCIETY OF CLINICAL ONCOLOGY

2015 EDUCATIONAL BOOK

"Illumination & Innovation: Transforming Data into Learning"

A PEER-REVIEWED, INDEXED PUBLICATION

51st Annual Meeting | May 29-June 2, 2015 | Chicago, Illinois | Volume 35

ASCO®

Making a world of difference in cancer care

American Society of Clinical Oncology Educational Book

The American Society of Clinical Oncology assumes no responsibility for errors or omissions in this publication. The reader is advised to check the appropriate medical literature and the product information currently provided by the manufacturer of each drug to be administered to verify the dosage, the method and duration of administration, or contraindications. It is the responsibility of the treating physician or other health care professional, relying on the independent experience and knowledge of the patient, to determine drug dosages and the best treatment for the patient.

PRINTED WITH SOY INK

Contents

INVITED ARTICLES

BREAST CANCER

Challenging Issues in Metastatic Disease

The *2015 ASCO Educational Book* is published online at asco.org/edbook. Articles can also be accessed from the Attendee Resource Center at am.asco.org/ARC. Articles that are included in this print edition include a page number reference in the table of contents.

GENITOURINARY CANCER

Beyond Tyrosine Kinase Inhibitor Therapy: Incorporating Immunotherapy and Metastasectomy into Renal Cell Carcinoma Management

Controversies in the Management of Germ Cell Tumors

Debate on Chemotherapy and Radium 223 for the Optimal Treatment of Advanced Prostate Cancer

Immunotherapy for Genitourinary Tumors: Are We Ready for Prime Time?

Integrating New Approaches in Complicated Bladder Cancer

GYNECOLOGIC CANCER

Cervical Cancer from Diagnosis to Survivorship

PATIENT AND SURVIVOR CARE

TUMOR BIOLOGY

Implications of Intratumor Heterogeneity for Personalized Therapy

New Strategies to Understand and Target Initiation of Aggressive Cancers

Targeting Cancer Metabolism

2015 ASCO Annual Meeting Disclosure

ASCO's commitment to balance, objectivity, and scientific rigor has been reflected in its responsible management of financial interactions with for-profit health care companies that could create real or perceived conflicts of interest. To help attendees, faculty, and the Society continue to manage these interactions appropriately, ASCO has updated its conflict of interest policy and launched a new Conflict of Interest Disclosure Management System.

In the past, disclosures applied to individual activities and separate forms were completed for each one. With the updated policy and new disclosure management system, one disclosure will apply to all activities. Members and participants in activities will use coi.asco.org to disclose all interactions with companies; this disclosure will be kept on file and can be confirmed or updated with each new activity.

The full ASCO Policy for Relationships with Companies and frequently asked questions are available at asco.org/rwc. Please email coi@asco.org with specific questions or concerns.

2014–2015 Cancer Education Committee

The Cancer Education Committee assesses the need for, plans, develops, and initiates the education programs of the Society, with special emphasis on the Annual Meeting.

Letter from the Editor

On behalf of my Associate Editor, Dr. Nate Pennell, I welcome you to the 2015 American Society of Clinical Oncology (ASCO) Annual Meeting. It is my heartfelt privilege as well to present to you the 35th volume of the NLM-indexed *ASCO Educational Book*. The theme of the 2015 Annual Meeting is "Illumination and Innovation: Transforming Data into Learning." The Cancer Education Committee, helmed by Dr. John Vernon Cox, has assembled a comprehensive education program that illustrates how creative transformation of data into knowledge, and knowledge into learning, can change the lives of our patients in a sustainable and scalable manner.

Long after the halls of McCormick Place have emptied and the echoes of our colleagues' lectures have faded from our ears, the 2015 *ASCO Educational Book* will remain as an enduring source of this shared knowledge. We are indebted to the over 100 authors who generously took the time to write and, in some cases, revise, the articles in this volume. In addition, I want to recognize our truly remarkable volunteer peer reviewers who dedicated their time and effort to careful, thorough, and thoughtful reviews. I strongly believe this collaborative effort has resulted in articles that are not only highly informative, but worthy of indexing in the National Library of Medicine. Thank you for your efforts and for your commitment to education and ASCO's mission. Special thanks also go out to Lindsay Pickell at ASCO, for whom none of this could ever have been put together.

In the spirit of this year's theme, Nate and I have included in this printed volume a curated selection of articles that most embody the transformative power of data into learning. As with the 2014 *ASCO Educational Book*, this edition includes invited articles from thought leaders who played leadership roles in ASCO's many thematic and specially focused meetings. Each invited author was tasked with bringing forward an article that represented their area of oncology and also spoke to one of the major themes of the 2015 Annual Meeting. I am proud to say each author delivered high-caliber work that will stand as a major contribution to the field of oncology.

It is our honor to invite you to read through the exceptional contributions that comprise the 2015 volume, only a selection of which are found in the print edition. For access to all of the 2015 *ASCO Educational Book* articles, as well as access to past volumes, please visit www.asco.org/edbook.

Nate and I welcome your feedback and suggestions on how we can improve the content, so please contact us at edbook@asco.org with your comments.

Don S. Dizon, MD
Editor

INVITED ARTICLES

This year's invited articles come from a few of the many oncology thought leaders who played leadership roles in ASCO's thematic and specially focused meetings during 2014 and early 2015. These articles represent each author's oncology specialty as it relates to one or more of the major themes of the 2015 ASCO Annual Meeting. Articles cover topics such as big data, clinical trials, value from the perspective of the patient, value from the perspective of the institute/national policy, geriatrics, and quality, and ethics.

The Changing Landscape of Phase I Trials in Oncology

Kit Man Wong, MD, Anna Capasso, MD, and S. Gail Eckhardt, MD

There has been an exponential rise in the number of novel anticancer drugs in development over the last decade. Our improved understanding of the molecular mechanisms of tumorigenesis has driven the discovery of molecularly targeted agents (MTAs) that inhibit specific proteins or pathways. However, although over 750 anticancer drugs are presently in development,[1] only 5% of these ultimately demonstrate sufficient efficacy for regulatory approval and clinical application.[2] For example, from 1998 to 2014, the failure-to-success ratio of investigational agents for melanoma was 14:1, whereas only 10 of 177 agents for lung cancer were approved.[3] Furthermore, the drug developmental process in oncology is estimated to take 1.5 years longer than in other diseases.[4] This highlights the need to maximize the efficiency and cost-effectiveness of early clinical trials, given the vast resources and time involved.

A phase I trial represents the critical transition of a novel compound from the preclinical to clinical stage, and thus provides the foundation for an efficacious drug development program. Several aspects of phase I trials have evolved in the era of MTAs that span multiple facets, from the overarching goals of phase I studies to trial design and the regulatory process, with consequent implications for participating institutions and investigators. This article summarizes the changing landscape of phase I trials in oncology, new challenges, and future directions.

TRIAL DESIGN

The conventional goals of phase I trials are to characterize the safety, tolerability, and maximum tolerated dose (MTD) of a novel agent by enrolling patients with a wide range of advanced cancers refractory to standard therapy. With the emergence of MTAs, new approaches related to dose escalation, patient selection, and study endpoints are making their way into current phase I studies.

Dose Escalation

The classic 3 + 3 design is a simple algorithmic method consisting of a set of predefined dose escalation rules based on the observed rate of dose-limiting toxicities (DLTs) within a specified window of assessment, typically 28 to 30 days. This approach enrolls cohorts of three patients at each dose level based on an algorithm (Table 1). The MTD is defined as the dose level at which the DLT rate is less than 33% and is usually the recommended phase II dose (RP2D) for further study. This design is well suited for cytotoxic agents, which are characterized by a positive correlation between dose, toxicity, and efficacy, and the highest dose with acceptable toxicity is desired.[5]

Although the 3 + 3 design is simple to implement, it may lead to suboptimal treatment in a large number of patients.[6] The estimated MTD may be imprecise because of the small cohort size and the nature of a rule-based approach.[7] Furthermore, MTAs may demonstrate delayed or cumulative mechanism-based toxicities that are not captured within the DLT assessment window. In these cases, the maximally administered dose is determined instead of the MTD.[6] In a systematic review of more than 450 phase I trials, the MTD was identified for 64% of MTAs compared with 99% of cytotoxic agents.[8] It is estimated that 20% of dose reductions with MTAs occur beyond cycle 1, the usual DLT assessment period.[9] Indeed, there is great heterogeneity in the DLT definition across published phase I trials of MTAs, particularly with respect to the window of assessment and severity.[10] In fact, the RP2D of MTAs should incorporate toxicity data from all cycles of therapy and symptomatic grade 2 toxicities.[9,11]

New strategies for dose escalation were developed to address these issues, including accelerated titration and model-based designs (Table 1). The accelerated titration design (ATD) as originally proposed consists of an accelerated phase of 100% dose escalation steps in successive single-patient cohorts, until DLT or substantial toxicity occurs during any cycle, at which point the trial reverts to the standard

3 + 3 scheme with smaller dose increments.[12] Not only does the ATD enable faster dose escalation without increased toxicity, it also allows more patients to be treated at the therapeutic dose.[12,13]

Model-based adaptive designs were devised to capture delayed toxicities without prolonging patient accrual. The continual reassessment method (CRM) requires a priori estimation of the dose-toxicity model, which is continuously updated by incorporating the cumulative toxicity data from all treated patients to compute the optimal dose for the next cohort.[5,14] Therefore, late onset toxicities are considered in subsequent dose level determinations. Several modifications have been made to the original CRM to further enhance safety or flexibility, such as sequencing 3 + 3 and CRM,[15] the quasi-CRM for nondichotomized toxicity grades,[16] the time-to-event CRM for very late toxicities as observed postradiation,[17] and other extensions to handle subject heterogeneity or varying treatment schedules.[18] Although the CRM is advocated, it requires a close collaboration between the investigator and biostatistician throughout the dose escalation phase.

The efficiency of novel dose escalation designs was demonstrated in a study of 84 phase I trials from 2000 to 2010. Compared with the traditional strategy, new designs explored a greater number of dose levels (median of 6, 8, and 10 levels for 3 + 3, ATD, and modified CRM, respectively) and achieved a higher mean MTD-to-starting dose ratio (ratios of 9, 22, and 30, respectively).[19]

The changes in dose escalation in phase I trials have resulted in fewer patients enrolled per dose level. This presents a challenge to multi-institutional studies, as individual sites

enroll very few patients, not only preventing investigators from gaining adequate experience with a drug and its toxicities, but also limiting the number of patients sampled for pharmacokinetic (PK) and pharmacodynamic (PD) studies. Greater communication between sites also is necessary to completely capture the toxicity data for dose escalation decisions. Therefore, in some respects, the multisite nature of current phase I trials may drive the continued use of more traditional designs.

Patient Selection

Rather than a single dominant gene, it is now recognized that most cancers arise from multiple somatically mutated oncogenes, each contributing a small effect, which accumulate during tumor progression. Thus, even within the same cancer type, individual tumors are driven by distinct sets of genes and pathways.[20] It is this genetic heterogeneity that underlies the observed variable responses to MTAs.

In most cases, an MTA is active only in a subgroup of patients who may be identified using predictive biomarkers, such as the expression level of a gene or protein, or the presence of a gene mutation, amplification, or translocation. Phase I trials increasingly are used as a platform to explore biomarkers and enrich molecular subsets of patients most likely to respond to specific MTAs. When used appropriately, this can improve the efficiency and safety of drug development.[21] For instance, the successful use of biomarker-driven patient selection was exemplified by the phase I trials of crizotinib (PF-02341066) in EML4-ALK rearranged non-small cell lung cancer[22] and vemurafenib (PLX4032) in BRAF V600E mutant melanoma,[23] in which the remarkable responses in these patient subsets helped to accelerate their approval.

However, challenges are inherent in incorporating biomarkers in early drug development.[5] As most cancers have multiple genetic aberrations, sensitivity to an MTA is likely modulated by many factors. Also, identifying a reliable biomarker may be less feasible when an agent has several targets, as is the case with most tyrosine kinase inhibitors. Since the misapplication of predictive biomarkers can potentially be over-restrictive and exclude patients who might benefit from an MTA, establishing a very strong scientific basis for the biomarker with preclinical validation is a prerequisite, as is acceptable sample collection, assay performance, reproducibility, and standardization.[24-28] For these reasons, biomarkers typically are investigated as exploratory objectives.

The increasing use of biomarker-based patient selection has transformed the enrollment process of phase I trials. First, patients must be molecularly screened to determine their eligibility. Where the biomarker of interest has a low prevalence, many patients must be screened to identify a few potential candidates, and more studies have to open at a single center to accommodate all patients wishing to enter a trial. Phase I teams must be highly organized to obtain archival tissue or fresh biopsies in a timely manner and be prepared to manage patient anxiety from invasive screening procedures and negative results. Furthermore, since many

---

KEY POINTS

- Several aspects of phase I trials have evolved in the current era of molecular targeted agents to adapt to the changing nature of anticancer therapy and to increase the efficiency of drug development.
- Current phase I designs are increasingly integrating novel dose-escalation approaches and biomarker-driven selection of patients, as well as expanding study objectives to include the evaluation of efficacy and pharmacodynamics/pharmacokinetics in addition to safety.
- Changes to the regulatory approval process have helped to expedite drug development, particularly for novel agents with a strong biologic rationale and proof of concept, validated predictive biomarker, and clear evidence of efficacy in early trials.
- As a result of the substantial changes in phase I trial goals and conduct, there is a parallel shift toward multi-institutional trials and central study management by clinical research organizations.
- The use of multi-institutional trials has a significant impact on the structure of phase I programs and the experience of investigators, particularly because of limited patient enrollment at each site.

Table 1. Comparison of Dose Escalation Designs

	Algorithmic Design (3 + 3)	Accelerated Titration Design	Model-Based Design (Continual Reassessment Method)
Dose levels	Predefined starting dose level (considered safe in humans based on data from animal models) and DE steps	Predefined starting dose level (considered safe in humans based on data from animal models); DE steps determined by occurrence of DLT	Starting dose level based on a prior dose-toxicity curve and target DLT rate; dose of next cohort determined by the updated model using the same target DLT rate
Number of patients per cohort	3 patients in each cohort; 6 patients in an expanded cohort	1 patient in each cohort during the accelerated titration phase; 3 or 6 patients in each cohort once DE reverts to standard 3 + 3	Number specified by the investigator, typically 2 patients per cohort
DE scheme	Patients are enrolled (3 at a time) in each successive cohort. When 1 out of 3 patients has DLT, the cohort is expanded to 3 more patients at the same dose level. If 2 or 3 patients in a cohort have DLTs, the next lower dose level is expanded to 3 more patients.	During the accelerated phase, DE steps occur at 100% increments until one DLT or two moderate toxicities occur at any cycle. Then, DE reverts to the standard 3 + 3 design with 40% DE steps.	The dose-toxicity model is updated on an ongoing basis using the cumulative toxicity rate from all previously treated patients to determine the optimal dose level of the next cohort using the same target DLT rate
MTD	Dose level at which there is ≤ 1 DLT out of 6 patients (< 33%)	Dose level at which there is ≤ 1 DLT out of 6 patients (< 33%)	Dose corresponding to the predefined target DLT rate based on the final updated model
Advantages	- Simple, easy to implement	- More patients treated at the therapeutic dose	- More patients treated at the therapeutic dose
	- Does not require statistical modeling	- Faster DE and MTD reached with the same number of patients	- Model-based approach allows more accurate estimation of MTD
	- Allows conservative DE for drugs with narrow therapeutic index		- Takes into account delayed toxicities
Disadvantages	- Many patients may be treated at subtherapeutic doses	- May not be appropriate for agents with narrow therapeutic index	- Continual modeling by a biostatistician is needed
	- MTD may be imprecise		
	- May not be appropriate for MTAs with no or delayed toxicities		

Abbreviations: DE, dose escalation; DLT, dose-limiting toxicity; MTA, molecularly targeted agent; MTD, maximum tolerated dose.

biomarkers are disease-specific, centers must be able to rapidly screen large numbers of patients for disease-specific expansion cohorts, which may pose a challenge when the phase I program is not well integrated with subspecialty clinics. Finally, each patient in need of an experimental therapy has to be considered for multiple studies at the same time to avoid delays in entering a trial in the event of a screen fail. Strategies to facilitate the inclusion of molecularly selected patients are needed, such as molecular prescreening programs for all metastatic patients to ease the transition to a phase I trial on disease progression.[29]

Endpoints

The conventional primary endpoint of phase I trials has been toxicity, with efficacy as only a secondary outcome. However, with the new breakthrough therapy designation created by the U.S. Food and Drug Administration (FDA) to expedite drug development, obtaining early evidence of efficacy is now an important component of phase I studies. This has increased the use of tumor-specific expansion cohorts to further characterize both safety and clinical response at the RP2D,[30] which is associated with a higher success rate of phase II trials and faster drug approval.[31] As mentioned above, the organization of some phase I centers also has been restructured around disease-specific investigators and clinics.

Moreover, in the MTA setting, the use of toxicity as the primary determinant of the RP2D has been called into question.[32] Unlike cytotoxic agents, the efficacy of MTAs may not be reliably predicted by either dose or toxicity. Increasingly recognized for MTAs are mechanism-based toxicities that relate to the presence of the target on normal tissues and cause chronic toxicities.[33] Although not always dose-limiting, the latter may nonetheless be compliance-limiting (e.g., rash, diarrhea, fatigue). These and other physiological adverse effects of MTAs (e.g., hypothyroidism, hypertension) require the parallel development of supportive care regimens and collaboration with other medical specialists for optimal clinical development.[34-37]

For MTAs, alternate endpoints reflecting target modulation may be more relevant surrogates of efficacy when determining the RP2D, and they may assist in prioritizing drug candidates for further development.[38] Therefore, the PD analysis of MTAs has become an integral part of phase I trials. Common correlative endpoints include protein expression in tumor tissue by immunohistochemistry before and after treatment, which requires invasive tissue acquisition procedures, as well as less invasive assays of serum proteins, peripheral blood mononuclear cells, and imaging biomarkers.[5,6] Circulating tumor cells and DNA will likely play an important role in the future as liquid biopsies.[39,40] Moreover, PK endpoints are often simultaneously analyzed to charac-

terize the PK-PD and PK-toxicity relationships, which can guide the selection of the RP2D when the plasma drug concentration for maximal biologic effects is known.[32,41] Well-planned correlative endpoints can significantly improve the efficiency of drug development and reduce overall costs.[38]

Therefore, although the evaluation of safety remains the primary goal of early phase studies, assessment of efficacy and PD/PKs also are key objectives in this new era of drug development. This, in turn, is transforming the landscape of phase I trials, with greater emphasis on disease-focused clinicians, tissue acquisition and assay performance, multidisciplinary supportive care, and radiological expertise in functional imaging.

REGULATORY CHANGES

The development of a successful drug from first-in-human study to approval normally takes about 7 years, during which its safety and efficacy are thoroughly and rigorously assessed.[42] However, in the case of MTAs with a clearly established biologic mechanism backed by proof of concept, unprecedented clinical responses with minimal toxicity, and availability of a strong predictive biomarker, many argue that the approval process should be shortened, especially when promising results are observed in early phase. Strategies to expedite drug development were proposed in the FDA Safety and Innovation Act of 2012. Thus, the new breakthrough therapy designation for investigational drugs was added to FDA's armamentarium of programs that also include the fast-track designation, accelerated approval pathway, and priority-review designation (Table 2).[43]

The opportunity to exploit such pathways has a substantial effect on phase I trial conduct. Not only are efficacy end-points emphasized in the design, the quality of data is increasingly scrutinized because it may be used for a new drug application. In fact, trials frequently are now managed by large clinical research organizations (CROs) to standardize trial conduct and data collection.

PRACTICAL IMPLICATIONS

Over the past decade, phase I trials have evolved from single-/oligo-site studies to increasingly large multi-institutional efforts with the goal of expediting patient accrual. In the latter, three or more institutions typically enroll patients, and slots in each cohort are assigned by the sponsor or filled on a competitive first-come first-served basis.

Multi-institutional trials have several implications, including limited slot availability per site, thus requiring more trials to be opened at a center to accommodate the same number of patients. Moreover, additional staff, resources, and frequent conference calls among participating sites are needed to enable real-time notification of adverse events and DLTs. These factors have led to greater reliance on CROs for study management. Further, the desire to accelerate patient recruitment results in the selection of sites based on their ability to enroll rather than on the experience and quality of the phase I program.

Similarly, the experience of phase I investigators has been influenced by multi-institutional trials. An individual investigator at one site can only gain limited clinical experience with a novel agent and its spectrum of toxicities.[8] Moreover, since sponsors and/or CROs are usually responsible for overseeing the operations of current phase I trials, it is a challenge for trainees and junior faculty to obtain comprehensive training in early drug development. Consequently, many years

Table 2. Main Features of the FDA's Expedited Programs for Serious Conditions

	Qualifying Criteria	Features
Fast track designation	A drug that is intended to treat a serious condition AND nonclinical or clinical data demonstrate the potential to address unmet medical need	- Actions to expedite development and review
		- Rolling review
Breakthrough therapy designation	A drug that is intended to treat a serious condition AND preliminary clinical evidence indicates that the drug may demonstrate substantial improvement on clinically significant endpoint(s) over available therapies	- Intensive guidance on efficient drug development
		- Organizational commitment
		- Rolling review
		- Other actions to expedite review
Accelerated approval pathway	A drug that treats a serious condition AND generally provides a meaningful advantage over available therapies AND demonstrates an effect on a surrogate endpoint that is reasonably likely to predict clinical benefit or on a clinical endpoint that can be measured earlier than IMM that is reasonably likely to predict an effect on IMM or other clinical benefit (i.e., an intermediate clinical endpoint)	- Approval based on an effect on a surrogate endpoint or an intermediate clinical endpoint that is reasonably likely to predict a drug's clinical benefit
Priority review designation	An application (original or efficacy supplement) for a drug that treats a serious condition AND, if approved, would provide a significant improvement in safety or effectiveness	- Shorter time for review of marketing application (6 months compared with the 10-month standard review)

Abbreviations: FDA, U.S. Food and Drug Administration; IMM, irreversible morbidity or mortality.
Adapted from: U.S. Department of Health and Human Services, Food and Drug Administration. Guidance for industry: expedited programs for serious conditions-drugs and biologics. May 2014. www.fda.gov/Drugs/GuidanceComplianceRegulatoryInformation/Guidances/default.htm. Accessed December 27, 2014.

of experience may be required before they are fully competent in designing and carrying out phase I studies, highlighting the importance of strong mentorship in this setting. At the same time, it has become more difficult for junior faculty to be truly independent investigators of phase I trials and advance their academic careers. This is especially true at smaller centers that lack the capacity to compete for enrollment. Therefore, although multisite trials have the advantage of improving efficiency, these issues have led some to suggest that no more than three centers participate.[5]

CONCLUSION

Phase I trials are the cornerstone of developmental therapeutics, and they are playing an expanding role in the changing landscape of cancer drug development. In the era of MTAs, they have evolved into complex studies that provide much more information than merely safety. With different dose es-

calation designs, molecular patient selection, and alternate endpoints, not only can current well-designed phase I trials better determine the RP2D of an MTA, they can also provide an opportunity to demonstrate proof of concept, characterize PD/PKs, define predictive biomarkers, and explore early efficacy that may potentially expedite drug approval. Importantly, this has led to a shift toward multi-institutional trials and CROs, greater demand on individual sites in terms of patient screening and enrollment, and the need to open more studies at each center.

Coupled with FDA initiatives to accelerate drug approval, current phase I studies can greatly advance the drug development process, as evidenced by the success of recently approved MTAs. In fact, the landscape of phase I oncology trials is ever-changing. As we continue to discover new molecular targets and better therapies, phase I trials must continue to evolve to efficiently translate these innovative therapies from bench to bedside.

Genomics, Personalized Medicine, and Supportive Cancer Care

Stephen T. Sonis, DMD, DMSc

The successes of the Human Genome Project catalyzed the transition of genomics from the laboratory to the clinic. Over the past decade, there has been a proliferation of studies demonstrating the potential utility of various applications of genomics as a conduit to accelerate drug development, understand mechanism(s) of action, and personalize treatment. For patients with cancer, genomics-informed medicine has largely focused on issues associated with patients' malignancies. But with the recognition that genomics is also a pivotal contributor to risk of regimen-related toxicities and how patients respond to treatment, the chances for applying genomics to comprehensive cancer care are increasing.

BACKGROUND

The application of genomics as a tool to personalize cancer care is not new. Headlines about individualizing oncology treatment have been heralded in both the lay and scientific press. The use of *Oncotype* DX to predict the course and guide treatment of early estrogen-receptor positive breast cancers has made its way into both the American Society of Clinical Oncology and National Comprehensive Cancer Network guidelines.[1,2] However, individualized cancer care based on genomics is still only having a marginal effect on the vast majority of oncology patients. Although the emphasis of oncologic-associated genomics primarily has focused on defining tumor risk, biology, and response, the potential opportunities associated with the application of genomics to supportive cancer care are just evolving.

Few patients avoid toxicities and side effects of cytotoxic and targeted anticancer regimens. The list of complications is extensive and diverse. Treatment can result in specific tissue injury (e.g., mucositis, pneumonitis, dermatitis, diarrhea, nausea and vomiting, and neuropathy) or more generalized consequences (e.g., fatigue, cognitive dysfunction, and cachexia). As every oncologist has observed, not all patients are equally threatened for specific treatment-related side effects. Although overall risk is, to some degree, associated with regimen selection, drug or radiation dose, and route of admin-

istration, patient-centric variables are major contributors. Why do two patients of the same sex, same weight, with the same malignancy, and treated with the same drug regimen differ so significantly in their response? It continues to become increasing clear that genomics play a pivotal role in determining an individual's risk of developing adverse responses to chemotherapy or radiation therapy.

The ultimate objective of therapy is the eradication of primary and secondary disease with as little collateral damage (toxicity) as possible. In fact, data suggest that patients overwhelmingly indicate a tolerance for a risk of treatment side effects in favor of a better chance of tumor cure.[3] However, it is also becoming more evident that there is a point at which the extent and nature of the toxicity risk tips patient decision making in favor of less aggressive cancer therapy. Furthermore, as we respond to patients' desire to be involved in treatment choices, we must provide information on the projected efficacy of regimen options and the probability of associated toxicities.[4]

Pharmacogenomics offer providers and patients individualized outputs that describe a comprehensive assessment of the likelihood of both treatment success and the specific probability of specific toxicities. Data from recent studies confirm that patients are overwhelmingly supportive of genetic testing that provides meaningful information about tumor response and toxicity risk.[5] These results, however, also demonstrate substantial gaps in patient and provider perceptions of treatment complication effects and how information is conveyed about toxicities.

Do patients really understand what they are getting into with toxicities? It is hard to believe that patient decision making around toxicity tolerance would not be colored if they better understood the differential ramifications of acute and chronic toxicities, if they were aware of toxicity treatment options, or if they were able to appreciate their individual risk for specific side effects. Data gathered from women with breast and ovarian cancers indicate[6,7] a huge variance in how patients weigh side effects. Nausea and vomiting, sensory neuropathy, and mucositis are examples of least acceptable side effects, whereas alopecia and fatigue seem to be most acceptable. Im-

portantly, patients were able to make treatment preference decisions based on their understanding of toxicity risk within the context of cancer therapy treatment outcomes.

From the standpoint of integrating genomics into a comprehensive management paradigm that includes supportive care, a genomic test that addresses the inclusive risks of toxicities has most value when it is interpreted in the context of a specific anticancer regimen. For example, if a patient with breast cancer can be effectively treated for her disease with either Regimen A or Regimen B and the risk of the toxicity profile associated with each regimen can be defined, the patient and the oncologist can choose one over the other based on patient preference. If, on the other hand, Regimen A is not as effective as Regimen B, but the toxicity risk profile is more tolerable to the patient, there may be a trade-off point at which the patient determines that the risk and scope of side effects outweigh the selection of the potentially more effective cancer treatment.

A second value in understanding a patient's toxicity risk focuses on the chance to individualize and target the use of medications that prevent or treat specific side effects. For example, approximately 40% of patients treated with certain conditioning regimens for hematopoietic stem cell transplant develop severe oral mucositis with all of its consequent comorbidities. Palifermin, keratinocyte growth factor-1, is approved to prevent its development.[8] To be effective, palifermin must be administered for 3 days before the infusion of the conditioning regimen, a time in which there is no evidence of mucosal injury. Not only does this schedule add days to care, it also incurs substantial financial costs. Both are well worth the price for the individual at risk of mucositis, but there is more to be lost than gained for the remaining 60% of patients. Thus to administer palifermin to everyone does not make sense at multiple levels. However, if one could predict with reasonable certainty which patients were at risk for developing mucositis, the agent could be given selectively and more economically.

In addition to risk prediction, at least two other potential applications for genomics as it relates to personalization of supportive cancer care are available. In the current paradigm of drug development, success or failure is defined as an assessment of the mean.[9] Criteria for efficacy are set around a one-size-fits-all vision in which it is presumed that all patients have an equivalent response to a drug. Since the response rate for drugs ranges dramatically (90% of drugs work in only 30% to 50% of patients),[10] we know this is not the case. There is clearly individuality in how any population with cancer responds to a drug. Clinicians often deal with this variance by adjusting dose or through trial and error. However, genomic differences often define response/nonresponse and the ability to dichotomize patients prospectively offers a great opportunity to personalize their care and create hierarchies for toxicity intervention. For example, if multiple agents to treat chemotherapy-induced nausea and vomiting are available, knowing which one was most active in a prospective patient makes prescribing more efficient and cost-effective.

Finally, genomics provides an important tool in drug development— discovery through clinical trials. Both radiation and chemotherapy stimulate changes in gene expression that trigger the pathobiologic events that produce toxicities. Identifying and defining the sequence of gene activation that underlies regimen-related injury provides specific targets for intervention. In addition, by mapping the inter-relationships between cooperative groups of genes and organizing these into networks, the hubs at the center of the network can be targeted and disrupted. This approach mimics what happens to the United Airlines flight schedule when there's a snowstorm in Chicago.

PHARMACOGENOMICS AND TOXICITY-RISK PREDICTION AND TREATMENT
Pharmacokinetic Risk Assessment

Genomic contribution to chemotherapy-associated toxicity risk is governed by two components: one associated with the concentration and availability of the drug (pharmacokinetics [PK]), and the other on how the drug affects the biology that underlies the pathogenesis of the toxicity. Drug dosing typically is determined on a one-size-fits-all notion (recommended dose) that typically has been determined by dose escalation in clinical trials based on the mean response of the study population. Although dosing is adjusted based on patient size, variable efficacy and toxicity outcomes are common. This should not be a surprise because we now know that patients do not handle drugs in a uniform way. Drug metabolism is affected by enzymes, and enzymes are controlled by genes. Too much enzyme production and the drug's tumoricidal effects are minimized, but toxicity risk is low. Too little enzyme production and there is an effective overdose with a large toxicity risk.

A classic example of a PK-related pharmacogenomic marker of toxicity-risk prediction is the catabolic enzyme, dihydropyrimidine dehydrogenase (DPD), which plays a critical role in fluorouracil (5-FU) metabolism.[11] Insufficient DPD activity results in toxic levels of 5-FU and is associated with increases in both hematologic and nonhematologic toxicities. Variants in the *DPYD* gene affect DPD activity. At least two variants, DPYD*2A and D949V,[12] have been identified, largely through a candidate gene approach, as being associated with increased toxicity risk. Furthermore, additional DPYD variants have been uniquely described in black patients, a finding that emphasizes the importance of broad demographic inclusion criteria in any study aimed at identifying genes affecting PK.[13] DPD currently is the only genomic marker for 5-FU risk prediction that the U.S. Food and Drug Administration (FDA) recognizes and for which a commercial test exists.[14] Not surprisingly, not all tests have equivalent value.[15]

An association between gene-based changes, pharmacokinetics, and toxicity risk also has been described for many chemotherapeutic agents,[16] including methotrexate, platinum drugs, taxanes, and anthracyclines.[17-19] Results of these studies have been largely inconsistent. Whether the variance in findings is a consequence of small sample size, inconsistent study design, differences in candidate gene or SNP selection, or variability in toxicity definitions is unclear. But the disparity in conclusions is remarkable. For example, two studies of the genomic PK toxicity association in pediatric patients

treated with methotrexate for acute lymphoblastic leukemia (ALL) reached totally different conclusions. Den Hoed et al[20] found no association between either methotrexate (MTX) levels or single nucleotide polymorhphisms (SNPs) commonly associated with metabolic genes and a sentinel toxicity (mucositis). However, Csordas et al reported a link between increased MTX levels, novel metabolic genes, and acute toxicity.[21]

The majority of genomic/PK studies have two common methodological themes that might contribute to their inconsistent findings. First, they are generally based on the premise that individual genes govern PK risk, rather than considering the possibility that multiple, synergistically functioning genes may be more significant. Second, largely in concert with the previous point, they rely almost exclusively on a candidate gene or SNP approach to form a suspect list, as opposed to an open, learned method to identify genes of interest.

Although more work must be done to frame accurately the application of genomics to pharmacokinetic-associated toxicity risk, it is important to note that even in the case of DPD and 5-FU toxicity, the percentage of patients who have frank DPD deficiency does not exceed 10%, and the percentage of patients with even partial deficiencies is even less. This observation raises a critical question: How does genomics contribute to toxicity risk outside of a PK mechanism? Likewise, how can genomics assist in the prediction of radiation therapy–associated toxicities in which drug metabolism is not a consideration?

PHARMACODYNAMIC RISK ASSESSMENT

The pathogenesis of regimen-related toxicities is more biologically complex and dynamic than imagined several decades ago. The concept that tissue injury associated with chemotherapy or radiotherapy is simply the result of the indiscriminant death of rapidly dividing normal cells that has been replaced by findings detailing sequential activation of molecular and cellular pathways that mediate damage.[22] Systemic side effects of treatment have been associated with increased levels of biologic active drivers of symptoms.[23] Further, genes noted to be expressed in diseases with comparable phenotypes have been identified in patients with cancer with symptoms of diarrhea (inflammatory bowel disease), fatigue (chronic fatigue syndrome), and cognitive dysfunction (Alzheimer's).[24]

Consequently, investigators have been drawn to assess the possibility that genes that control pathways or proteins thought to be toxicity mediators could be used to predict risk. In general, two investigational approaches have been used for these studies: candidate gene/SNP protocols and genome-wide association studies. Since there have been accumulating reports indicating that inflammatory and profibrotic cytokines, and mediators of oxidative stress are implicated in the pathogenesis of regimen-related normal tissue injury, genes and SNPs associated with variations in patients' production of these proteins are among the most studied using candidate gene/SNP methodologies.

The candidate gene approach is based on targeting those genes or SNPs that have been reported to be implicated in the production of the protein of interest and linked to mecha-

nisms that lead to the toxicity of interest.[25,26] The investigator picks a gene or SNP based on prior knowledge (usually from the literature) and then tests only for them. This approach is economical, but relies highly on what is already known and presumes a one gene– one phenotype determination. Among genes or SNPs that have been implicated as risk predictors using this approach are polymorphisms for TNF,[27] TGF-beta,[28] DNA DSB repair,[29] and VEGF.[30]

Unfortunately, the results of candidate gene studies have been disappointingly difficult to validate. In a study of over 1,500 patients with breast or prostate cancer, Barnett et al were unable to validate any of the genes or SNPs reported to be associated with late toxicities of radiation therapy.[31] Why is this? The most obvious reason is that the key predictive gene or SNP was selected incorrectly. To compensate for this, some investigators have looked at panels of genes that are reportedly associated with variations in biologic activity. However, even this approach has failed to provide consistent results.

The availability of gene and especially SNP array technology led to an opportunity for a vastly more comprehensive approach, genome-wide association studies (GWAS). Genome-wide association studies allow the investigator to fish for correlations between SNPs (and associated genes) and phenotypes of interest, usually using a case-control approach in which differences in SNP expression are determined between patients who develop toxicities of interest and those who do not.[32] Associations are done in a sequential analysis between one SNP at a time and the phenotype using traditional association studies.[33] The number of SNPs available on arrays has proliferated dramatically over the past few years— current chips contain over 4 million SNPs. Given that number, the probability that some association will be discovered is extremely high. The probability is so high that conventional statistical parameters of significance are of little value. To compensate, a statistical penalty is applied to these studies, or, more recently, measures of false discovery. The need for such measures became obvious because of the high false positive rates which were typical of these studies. In addition, modest subject numbers often contributed to the high rate of false positives. Nonetheless, the literature contains a number of reports identifying SNPs predictive of regimen-related toxicities. To date, validating studies are few.

Similar to candidate gene studies, GWAS have largely been driven by the objective of trying to identify *the* gene or SNP associated with toxicity risk. These studies largely presume that the functional relationship of a SNP to a gene is critical to its potential importance as a risk predictor. It turns out that neither of these concepts optimizes the potential utility of genomic risk predictors.

Genes often act synergistically to affect function. This concept has been defined biologically by the identification of ontological and functional pathways. Furthermore, since not all genes or polymorphisms may contribute equally, a hierarchical model can be developed that helps to define contribution. Similar to a championship sports team, the clinical and biologic effect of a group of genes may be more dependent on how each member of the team contributes to the aggregate, rather than the performance of a single star. Importantly, the predictive value of the

elements of a cluster of polymorphisms is greater than the contribution of any of the contributing parts. This principle was demonstrated by Tucker et al in studies of radiation-induced pneumonitis.[34] Their evaluation of 16 polymorphisms associated with 10 genes demonstrated the increasing predictive value of multiple SNPs over fewer numbers. Additionally, although SNPs occurring outside of genes were mockingly referred to as junk DNA, it has now become evident that such polymorphisms have value, not only as effective genetic markers, but as functional modifiers.[35]

Whereas the single SNP approach suffers from its inability to identify associations because of the simultaneous presence of multiple variants in different DNA regions,[36] GWAS often identify too many associations (false positives) as a result of dependencies between SNPs in contiguous regions (linkage disequilibrium) and the dependency between SNPs on different chromosomes.[37]

Amalgamating these findings leads to the conclusion that the optimal way to identify genomic risk predictors should provide for a learned outcome in which (1) the genomic results dictate the genes or SNPs of interest, (2) there is a mechanism to filter those genes or SNPs that are extraneous without diluting the ultimate prognostic significance or pool, (3) there is a way to identify and define those polymorphisms and genes that function synergistically to contribute to risk in as precise a way as possible, and (4) there is a high degree of sensitivity and specificity. Multivariate statistical models circumvent many of the limitations noted above by examining the overall dependency structure between genotypes, phenotype, and nongenetic variables.

There is now a growing list of other analytic options that seem to meet the above criteria and seek to identify groups of SNPs or genes that are defined probabilistically by their combined ability to predict risk. We have used two analytic approaches to identify predictive gene networks or clusters. In one method, we used a Bayesian approach to identify SNP-based gene networks that were predictive of oral mucositis in autologous stem cell recipients.[38]

The first step is to whittle down the total output from a typical SNP microarray (1 to 4 million depending on the size of the array) by filtering out those SNPs that are highly unlikely to contribute to the predictive value of the Bayesian network. This is done using a simple chi-square statistic to identify the top 200,000 SNPs associated with the phenotype of interest (mucositis, in our case). Using another heuristic, the number of SNPs likely to contribute to risk differential is further filtered to identify the 4,000 SNPs from which a Bayesian network can be discovered. Unlike classical methods of identifying the important genes or SNPs based on an expression threshold, the Bayesian approach does not conduct significance tests, but ranks alternative models of association on the basis of posterior probability (to provide for inference). As such, no threshold is needed to select the most probable network. The predictive strength of the network is learned so it becomes stronger as more data are entered. As with any study of this type, a key component is testing the predictive validity of the network using an independent group of patients.

Another method that is defined by self-learning and the generation of a predictive team of genes also uses a series of statistical filters to determine the team of genes with the highest probabilistic chance of being associated with toxicity risk.[39] Like the method described above, the first sets of filters provide a large, but effective, net to capture those genes most likely to be in play and to discard those that are probably extraneous. This technique proved to be effective in identifying a group of genes that discriminated patients with prostate cancer who were at risk for radiation therapy–associated fatigue from those patients who were unlikely to be hampered with the same side effect. Then, by testing the effect of each gene on its contribution to the predictive value of the team, a highly discriminating list of predictive genes could be described.

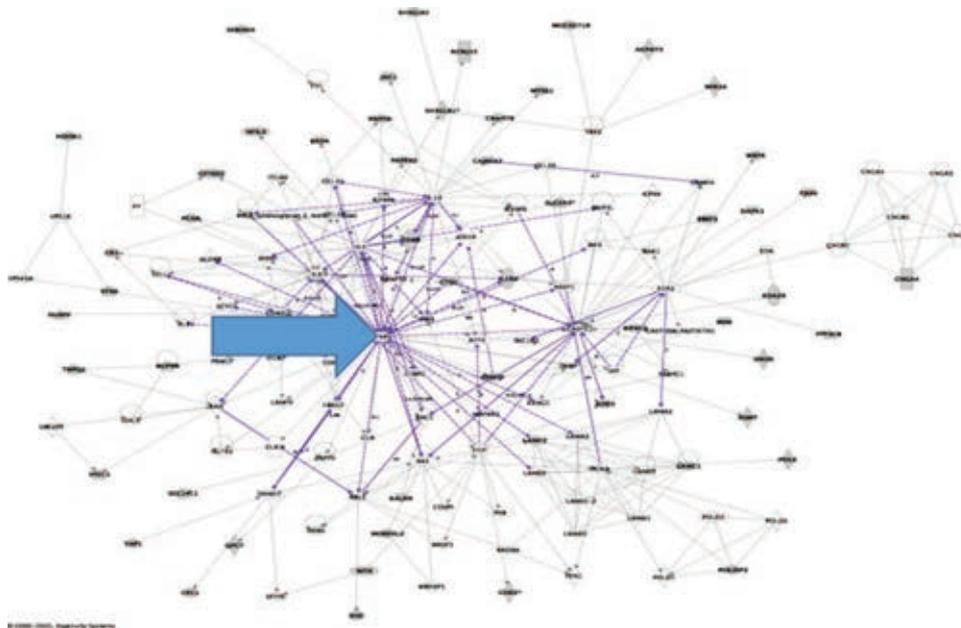
Since most studies that generate predictive genomic endpoints are largely designed around some form of internal validation, it is imperative that an external set of subjects be tested against the prognostic criteria to assure their legitimacy.

GENOMICS AND DRUG DEVELOPMENT FOR SUPPORTIVE CARE INDICATIONS

Gene analytics can expedite the recognition of drug targets for supportive care indications. By defining the sequence and organization of genes expressed in response to chemotherapy or radiation therapy as they relate to the development of toxicity, key regulators of the process can be identified and targeted. As such, regimen-related toxicities provide substantial advantages over most chronic diseases because genomic studies that characterize the pathogenesis of cancer treatment side effects provide a baseline state at which the phenotype of interest, and presumably the genes associated with its development, are absent. The oncologist then flips the switch to start the biologic cascade that leads to the toxicity, thereby permitting investigators to sample time points leading up to, during, and after the toxicity is present. Compare that to the patient with ongoing disease (e.g., asthma, IBD, or arthritis) for whom there is never an opportunity to evaluate baseline gene expression. Performing studies in patients with an existing disease means that the malady is already ongoing when the patient first presents for evaluation. In the patient with cancer, the changes in gene expression are expressly associated with antitumor treatment and can be directly compared to levels at a time when the patient is treatment-naive.

PHARMACOGENOMIC APPLICATIONS FOR DRUG DEVELOPMENT

Once changes in gene expression are discovered following treatment, and correlated with the development of specific toxicities, questions around both toxicity pathogenesis and identification of interventional targets can be answered. Using genes selected (learned) with a Bayesian analytic algorithm, functional pathways whose differential activation best explains the differences between patients with and without the toxicity can be identified using established databases

FIGURE 1. Differentially Expressed Genes Defined by Signaling Functions


Major roles for TNF-alpha have been suggested in pathoetiology of radiation-induced toxicities, including mucositis and fatigue. The formation of a network based on differentially expressed genes in patients who developed mucositis confirms a central role for TNF, illustrates its effect on connected nodes, and provides a potential target for pharmacologically-based intervention.[40]

such as Ingenuity Pathways Analysis (Ingenuity Systems). Network analyses identify the biologic functions and canonical pathways that are most significant to the genes in the network (Fig. 1).[40]

This methodology has been used to provide an abundance of mechanistic data to define regimen-related tissue injury. Canonical pathways associated with NF-kappa B signaling, Toll-like receptor signaling, P13K/AKT signaling, interleukin-6 signaling, and p38 MAPK signaling are among examples that are consistent with proposed mechanisms by which toxicities, such as mucosal injury, occur. From the viewpoint of drug development, the key roles played by each pathway suggest that each is a potential therapeutic target.

An analysis of canonical pathways may also provide hints to the global symptomatic response of patients to cancer therapy. For example, although overexpression of genes within the glutamate signaling pathway has been associated with central nervous system activity, recent analyses suggest broadened activity, including a role as a signal mediator.[23] This conclusion has implications in drug development and might favor and inform formulation and/or route of administration strategies.

The fact that genetics can play a key role in determining a patient's response to a drug creates opportunities for both expediting drug development and individualizing care. By identifying a genetic signature that differentiates the likelihood of response or nonresponse to a drug, developers would have the ability to enrich clinical trials with groups of patients who were most likely to benefit, and, at the same time, spare genetically-defined nonresponders from the risks and inconvenience of receiving an experimental agent. Once approved, compounds that effectively mitigated regimen-related toxicities could be selectively administered to the most appropriate patients, favorably affecting the physiological and financial costs of treating nonresponders.

ECONOMIC, POLICY IMPLICATIONS, AND CHALLENGES FOR THE APPLICATION OF GENOMICS TO SUPPORTIVE CANCER CARE

For a clinical genomics test to achieve acceptability by patients, clinicians, payers, and regulators, it has to successfully answer two questions: Does it work and is it worth the cost?[41] How to answer the first question has been a topic addressed in a variety of forums. In 2004, the Centers for Disease Control and Prevention launched the Evaluation of Genomic Applications in Practice and Prevention (EGAPP) initiative. The group defined four evaluation criteria: analytic validity (how well does the test measure what it is supposed to measure); clinical validity (how well does the test predict its specified outcome); clinical utility (how well does the test improve or harm outcomes to patients); and ethical, legal, and social issues.[42]

In general, the efficacy of genomic tests as toxicity-risk predictors using the validity criteria cited above requires data drawn from large populations of patients. As noted earlier in this article, results of studies using either candidate gene or GWAS approaches have been notoriously difficult to replicate, and, in the case of GWAS, prone to false-positive signals. Fortunately new big data methods and the integration of multifaceted analytics provide a platform from which genomic parameters with toxicity risk can be determined. Based on past experiences, such studies likely will be most effective if they are prospective and if they provide a strict template for the capture of accurate toxicity data.

Defining the clinical utility of a genomic test in the context of supportive care may turn out to be complex. Toxicities rarely occur as singular events. Rather, patients develop simultaneous clusters of toxicities[43] often related by common biologic underpinnings. This may be advantageous from the potential of testing because there may be pathways (and genes) that are shared by more than one toxicity. Compartmentalizing genomic risk testing (i.e., toxicity by toxicity) ultimately is less attractive than a comprehensive toxicity panel, especially with respect to adding meaningful information for clinician-patient decision making. A test's true utility will be derived from cases in which patients can select equally effective anticancer regimens based on their toxicity preferences.

Economics play an increasing role in health care decision making today. Aside from patients, health economic stakeholders include providers, payers, and government. It initially appears that a sound fiscal argument can be developed in favor of genomic testing for supportive care indications, as long as it results in an actionable outcome that affects toxicity risk, prevention, or effective management. Numerous studies have demonstrated increased costs and increased health resource use attributable to specific toxicities.[44,45] However, these data might be underestimates. In many cases, only severe forms of adverse events have been evaluated, even though it is likely that toxicity of any grade affects cost.[46] The incremental financial effect of toxicities has also been differentially described for direct costs (those costs associated with the costs of managing the toxicity) or indirect costs (lost opportunity costs, caregiver costs, etc.). For the most part, direct costs have been delineated for acute toxicities, whereas indirect costs are often attributed to chronic adverse events (i.e., the effect of cancer treatment–related fatigue on inability to return to work).

As noted above, the finding that patients most often develop multiple, simultaneous toxicities mandates that true cost assessment be done in a comprehensive way, rather than toxicity by toxicity. It also places an obligation to develop genomic assessments that, in a single test, capture comprehensive toxicity risk and link those to alternative regimens for the same cancer. The recent report by Hurvitz et al[47] of a large number of patients with metastatic breast cancer provides a rationale for such an approach. Using an extensive claims database, they first identified the 22 most common adverse events associated with common chemotherapy regimens. They computed and compared the comprehensive monthly costs per number of adverse events. The results were dramatic. Increases in average monthly costs ranged from $854 to $5,320 depending on chemotherapy regimen.

Consequently, even considering the additional costs of testing (including test development), the prospective identification of risk that results in the avoidance of toxicity either by guiding regimen selection, or by targeted toxicity prophylaxis, certainly should provide overall cost savings. For example, if an effective preventive agent were available for radiation-induced mucositis in patients with head and neck cancer, the projected savings could be calculated by deducting the cost of the intervention from the incremental cost (about $17,000) of mucositis.[48]

Not surprisingly, third-party payers have been reluctant to provide either coverage or reimbursement for genomic risk prediction, often still considering such tests to be investigational. Perhaps with broader test platforms— one test for multiple toxicities—and increasing validation of clinical utility, this stance will change. As the largest provider of health insurance in the United States, the government has established several initiatives to evaluate genomic tests and, in particular, to figure out ways to provide reimbursement. Although multiple U.S. agencies are involved in these efforts, those led by the National Human Genome Research Institute are noteworthy. From the patients' perspective, the value of genomic risk prediction seems recognized as patients have expressed a willingness to pay for information that better guides their treatment.

CONCLUSION

The application of genomics to cancer supportive care holds multiple opportunities to improve our understanding of the biology of regimen-related toxicities, to develop effective interventions, and, most importantly, to guide treatment decisions. A critical challenge to clinical implementation of this data will be ensuring that providers and patients understand what the data mean and how they can be used. Organizing and presenting data in such a way that results are actionable will be key. Provider education has been identified as a priority as genomics moves from the laboratory to the clinic.

Clinical Research in Metastatic Prostate Cancer: A Focus on Impact and Value

Maha Hussain, MD, FACP, FASCO, and Robert S. DiPaola, MD

Despite substantial and continued reduction in mortality, prostate cancer continues to be a major cause of cancer death in men in the United States, with an estimated 27,540 deaths in 2015.[1] Historically, prostate cancer was one of the earliest examples of success in targeted therapy. More than 7 decades ago the key biologic and therapeutic breakthrough by Huggins et al established that prostate cancer is an androgen receptor (AR) pathway–driven and androgen-dependent disease, and that surgical or medical castration can induce substantial and prolonged regressions for patients with prostate cancer.[2,3] Despite a high response rate with androgen deprivation, most patients with metastatic disease progress to castration resistance, with a median survival in the prostate-specific antigen (PSA) era of about 4 years.[4]

In cancer therapy development, cytotoxic chemotherapy was one of the major products of the "war on cancer" during the past 4 decades. With androgen deprivation therapy (ADT) as a backbone of treatment for metastatic prostate cancer, efforts were directed at adding cytotoxic agents following castration resistance. Several chemotherapeutic agents were tested without a major breakthrough until 2004, with the approval of docetaxel, the first nonhormone agent that demonstrated a survival benefit in patients with metastatic castration-resistant prostate cancer (mCRPC), thus establishing a new benchmark and validating the role of targeting the microtubule in this disease.[5,6] Subsequent investments in prostate cancer research over the last 2 decades have led to major biologic discoveries with many targets and agents, resulting in several U.S. Food and Drug Administration (FDA) approvals (Table 1)[7] and additional testing in clinical trials.

ANDROGEN RECEPTOR SIGNALING CONTINUES TO MATTER BUT IS NOT THE WHOLE STORY

Perhaps one of the most important biologic discoveries was the understanding that progression to castration resistance is partly an adaptive process. Furthermore, despite clear evidence to support AR-independent mechanisms, unlike prior dogmas, AR-dependent signaling continues to be relevant.[8] Biologic data on the importance of AR signaling was the basis for developing several agents targeting AR or relevant enzymatic pathways. The principle was validated by results from phase III trials with abiraterone and enzalutamide that demonstrated survival improvements in patients with mCRPC.[9,10] The biologic discoveries regarding progression to castration resistance led to studies of several other experimental agents targeting additional pathways.[8,11-13] Efforts to target the immune system and bone have led to survival improvement with sipuleucel-T and radium 223 dichloride.[7] Therefore, in 2015, oncologists have several standard treatment options with proven clinical benefits to offer patients, both docetaxel-naive (sipuleucel-T, abiraterone/prednisone, radium 223 dichloride, enzalutamide) and docetaxel-treated patients (cabazitaxel/prednisone, abiraterone, enzalutamide, radium 223 dichloride), as well as an array of additional opportunities for clinical trials.

SO ARE WE THERE YET?

Over the past 2 decades, we have witnessed unprecedented progress in the understanding of the biology of prostate cancer and substantial returns on investment in research with the development of therapies for patients with mCRPC. This is reflected by multiple approvals that FDA has issued since 1996. These approvals were based on positive phase III trials for agents that have demonstrated an effect on overall survival, pain, or skeletal-related events—all clinical benefit outcomes relevant for managing this group of patients. However, in a similar time period, more phase III trials proved negative despite very promising biologic, preclinical, and phase II trial data (Table 2).[14-27] Surprisingly, multiple large studies that attempted to build on docetaxel by adding targeted therapy (DN101, GVAX, atrasentan, zibotenan, bev-

	Docetaxel + aflibercept
	Docetaxel + lenalidomide
	Sunitinib

acizumab, dasatinib, aflibercept, and lenalidomide) were negative, which raises concerns about the adequacy and depth of current preclinical, diagnostic, and early clinical evaluation strategies and highlights the importance of the disease's biologic context.

Although these agents with demonstrated efficacy have been valuable to date, there is little question that current therapies have substantial limitations, including the fact that their effect on survival continues to be very modest (2 to 5 months' improvements).[7] Clearly, not all patients benefit. Furthermore, unlike many other solid tumors, we still use a one-size-fits-all treatment approach with no predictive biomarkers to maximize chance for benefit and reduce treatment burden on patients, both physical and monitory. Furthermore, although some trials were positive, these predominantly were conducted in an era in which essentially only one major treatment choice (docetaxel) existed. Also, many nonchemotherapy trials reported to date had a placebo control arm, which was a low bar to cross. Therefore, the true efficacy of current therapies in the current clinical context in which patients have undergone multiple prior treatments is unclear. In fact, several anecdotal and ob-

servational data are emerging on the suboptimal response to sequential AR pathway targeting with current agents.[28] The latter is an area that must be addressed considering all the implications.

THERAPY COST IS ESCALATING

"Price is what you pay. Value is what you get," is one of Warren Buffett's favorite admonitions, highlighting that price and value are not always the same. Perceived expectations, quality, value, effectiveness, and side effects are critical factors in a patient's satisfaction with his or her treatment. Historically, physicians, professional societies, and regulatory bodies in the United States have shied away from discussing financial costs of care. However, this discussion is very timely and critical. We owe it to our patients and society that therapy development must take into account the cost relative to the true benefit, value, and effect of the specific therapy. Table 3 highlights the average wholesale price of current agents. Although this may vary somewhat by vendor, or actual charge, the overall financial effect in the context of partial clinical activity calls for much needed improvement and reform of our current processes surrounding clinical trials and drug approval. The recent data on the detection of AR-V7 in circulating tumor cells from patients with castration-resistant prostate cancer and its association with resistance to enzalutamide and abiraterone,[29] if validated, is an example of the potential for better individualized selection of therapy to maximize benefit and reduce cost.

THE CHARGE MOVING FORWARD: A FOCUS ON TRUE IMPACT AND VALUE

Albert Einstein said, "Most of the fundamental ideas of science are essentially simple, and may, as a rule, be expressed in

> **KEY POINTS**
>
> - Several therapies targeting the androgen receptor and other pathways have improved survival and quality of life for patients with metastatic prostate cancer.
> - Many costly therapeutic clinical trial efforts have failed to improve outcomes.
> - Prostate cancer is a complex disease. Its biologic heterogeneity warrants that future clinical trials be carefully designed to achieve higher levels of clinical impact by attention to targeting more critical pathways; integrating improved diagnostics; well-designed and powered clinical trials using multi-targeted strategies; and optimized timing of therapy.

Table 3. Treatment Costs for Approved Agents[38]

Drug	Dose/Route	AWP Cost per Cycle (Drug Only)	Number of Cycles	Survival
Docetaxel	150 mg IV (75 mg/m^2 × 2 m^2)	$1,583.00	Median: 6	Yes
Cabazitaxel	50 mg IV (25 mg/m^2 × 2 m^2)	$10,797.68	Median: 6	Yes
Abiraterone	1,000 mg PO (30-d)	$8,852.02	Median: 8 ms	Yes
Enzalutamide	160 mg PO (30-d)	$10,026.04	Median: 8 ms	Yes
Sipuleucel-T	IV	$44,162.40	3 cycles	Yes
Radium 223 dichloride	IV	$22,126.80	6 cycles	Yes
Denusomab	120 mg SC	$2,115.72	Monthly	No
Zoledronic acid	4 mg IV	$838.29	Monthly	No

Abbreviations: AWP, average wholesale price; IV, intravenously; PO, orally; ms, months; SC, subcutaneously.

a language comprehensible to everyone." As a simple fundamental rule, therefore, our next efforts in clinical research must maximize clinical value and effect on patients, perhaps by simply using new technology to identify, critically evaluate, and target multiple critical pathways/targets simultaneously (or sequentially).

In the last 2 decades, the course of metastatic prostate cancer has evolved with improved management of age-associated comorbidities, PSA-driven stage migration, improved imaging, and the expansion of novel therapies. Therefore, the focus of therapy also must evolve and, much like other cancers, a cure should be the overarching objective. Short of a cure, there is a clear need for greater sustained therapeutic benefit. The latter necessitates substantially more investment in high-quality research and a critical review of our drug approval standards in this country, which currently do not incorporate major impact and value or cost of therapy relative to benefit. The latter, coupled with the cost of conducting clinical trials, does not necessarily encourage multitargeted combination therapy strategies; comparative effectiveness trials, with obvious clinical questions such as a comparison of competitor drug (e.g., abiraterone vs. enzalutamide efficacy in the same disease setting); nor moving therapeutics into earlier stages of the disease in which the therapeutic benefit is likely to be much greater.

The optimal development of studies with a higher effect must consider targeting multiple critical targets; utilization of improved technology, such as next generation sequencing; and new preclinical models with the potential to develop drug combinations and predictive biomarkers with analytic validity and greater clinical utility. Although the chromosomal translocation of *BCR* and *ABL* in chronic myeloid leukemia has served as an effective biomarker for a molecularly targeted therapy, it has become apparent that most other cancers have multiple driver alterations and adaptations thus requiring combinations of therapies for greater effectiveness. As additional potential driver mutations are now identified in prostate cancer through enhanced diagnostic technologies, such as next generation sequencing, we have new opportunities to design multitargeted approaches, perhaps aided by preclinical models to select best therapeutic combinations for clinical trials.[30-32] New models include the development of patient-derived tumor xenograft (PDX) models that allow testing of targeted agents, resistance mechanisms, and combinations in the preclinical setting in parallel with clinical trials in patients.[33] Recently, organoids have been created from patients with prostate cancer, allowing the potential for a novel preclinical model to test combination therapy.[34-36]

Taken together, an overall paradigm to create higher effect for value should include attention to (1) strong science that identifies critical targets and combinations in preclinical models; (2) optimization of combinations to target multiple critical pathways preclinically and clinically, with more precise selection of patients most likely to benefit using improved diagnostics; and (3) consideration to timing of therapy, with a rationale that therapy in earlier stages of disease may have more effect on outcome. A possible clue to the potential success of using both a multitargeted strategy and earlier introduction of therapy may be exemplified by the recently reported National Cooperative Group study, which study demonstrated improved survival by the concomitant use of docetaxel chemotherapy and ADT as compared to ADT only in patients with newly diagnosed metastatic prostate cancer.[38] The magnitude of survival improvement with early combination therapy (all patients, 57.6 vs. 44 months; high-volume disease patients, 49.2 vs. 32.2 months, as initially reported at the American Society of Clinical Oncology Plenary Session, 2014) represents multiples of those observed with current approved therapies in mCRPC.

CONCLUSION

The landscape of therapy and biologic understanding of metastatic prostate cancer is infinitely better compared to a decade ago, and it continues to evolve exponentially. However, the long list of negative trials clearly underscores the need that therapy development must focus on the totality of disease biology, including comprehensive molecular understanding of disease states; thorough validation of candidate targets/pathways/biomarkers of response and resistance; and multitargeted approaches to maximize therapeutic effects.

As oncologists, we owe it to our patients to raise the bar for future trials by requiring greater therapeutic efficacy; mini-

mizing use of placebo; avoiding artificial disease contexts such as pre- and post-docetaxel setting; avoiding artificial clinical benefit endpoints such as time to chemotherapy; developing multitargeted treatment strategies; and evaluating and maximizing cost-effectiveness. The latter strategies are not unique to prostate cancer. However, prostate cancer is a disease in which patient survival is measured in years, and although it continues to improve, it can become the model to begin to tackle and control the escalating costs of therapy while maximizing benefit. With smarter research and a higher bar for clinical trial expectations, we can raise the standards so that the return on investment for patients has more of an impact when patients are weighing their treatment options.

The Future of Molecular Medicine: Biomarkers, BATTLEs, and Big Data

Edward S. Kim, MD, FACP

When I first entered the field of lung cancer, the seminal study published in the *New England Journal of Medicine* was a four-arm chemotherapy doublet study that showed no difference in effectiveness. Conclusions: All the drugs are the same, so use what you like for patients with advanced non–small cell lung cancer (NSCLC).[1]

Times have changed, and personalized medicine has become a reality. The era of "molecular medicine" has truly blossomed. Over the last decade, approximately 40 drug approvals were based on specific tumor biomarkers.[2] Options for patients have changed dramatically, from cytotoxic chemotherapy to molecularly targeted therapy. This concept has been standard for almost 2 decades for those treating patients with breast cancer (targeting HER2 and/or hormone receptors), but now patients with melanoma and lung cancer are included in this discussion. It is astounding how far treatments for each of these tumor types have progressed in the past 10 years. Melanoma treatment consisted of chemotherapy or interleukin-2 and now consists of RAF inhibitors and targeted immunotherapy, both of which have improved patient outcomes substantially: response rates and progression-free survivals have more than doubled. In fact, the progression-free survivals for molecularly targeted therapies exceed the overall survival numbers reported for chemotherapies. Lung cancer treatment has evolved from administration of chemotherapy yielding poor outcomes to biomarker assessments such as *EGFR, ALK,* and *ROS1.* Treatment with *EGFR* inhibitors (gefitinib, erlotinib, afatinib)[3-5] and *ALK*-based therapies (crizotinib, ceritinib)[6,7] have dramatically improved efficacy and quality-of-life outcomes. The notion that a patient with advanced lung cancer could be treated on oral biologic therapy for over 2 years without undergoing intravenous chemotherapy is astounding. For example, a patient with an *EGFR* mutation present in their tumor is treated with an *EGFR* tyrosine kinase inhibitor (TKI). Then the patient develops a *T790* mutation in the tumor and is treated with a *T790* TKI.[8]

As our desire for continued discoveries in tumor genetics increases, more and more data are generated and captured. Larger organized trials that prospectively capture biomarker and treatment data have emerged, and data analysis of these trials has become more complex. Adaptive trial designs, such as umbrella and basket trials, have become commonplace across academic cancer institutes and are emerging at community-based cancer institutes. As biopsies to obtain adequate amounts of testing for molecular studies are now the norm, repeat biopsies are now part of the armamentarium of procedures to best assess the tumor in real time following treatment. With electronic data capture processes (including electronic health records [EHRs] and national databases) also evolving, medicine is now faced with the concept of "Big Data": how to collect it, maintain it, integrate EHR big data with genomic big data, and thus, utilize it.

BIOMARKERS

The principle of identifying biomarkers to help guide patient treatment has been a longstanding research initiative. Early biomarkers and panels were largely classified as prognostic or predictive. They were not associated with a specific biologic therapy but rather defined the tumor characteristics, including response to therapy. Examples include Ki-67, carcinoembryonic antigen (CEA), and prostate-specific antigen (PSA). Breast cancer markers, such as hormone receptor status and HER2, were some of the earliest markers related directly to therapy. In lung cancer, validated markers associated with therapy began with elucidating that *EGFR* mutations were more prevalent in patients with adenocarcinoma, Asian ethnicity, and nonsmoking status and were correlated with high activity of *EGFR* TKIs (gefitinib, erlotinib, afatinib). However, more information was desired by researchers and treating physicians, and, more importantly, correlation with specific treatments was sought. Tumor registries were created to collect tissue and test utilizing evolving molecular

panels. Such strategies have been developed across academic institutions, private enterprises, and government. Numerous cancer consortiums were developed in the 2000s that required submission of patient tissue along with clinical data.

The Lung Cancer Mutation Consortium (LCMC) is one of these efforts (www.golcmc.com). The LCMC, an initiative of the National Cancer Institute (NCI), comprises 16 leading cancer centers across the country, with the goal of providing clinicians with information on the types and frequency of mutations. Once identified, the mutations are matched with associated treatments and/or clinical trials, giving physicians more options to better care for patients with advanced NSCLC. Testing these mutations with various treatments could lead to identification of actionable mutations (tumors with a mutation that responds to specific treatments), which would expedite potential drug development. Over 1,000 patients (stage IIIB/IV, performance status 0 to 2) have been enrolled in the LCMC. The group has detected an actionable mutation in 64% of tumors from prospectively studied patients with lung adenocarcinoma.[9]

DIRECTOR'S CHALLENGE CONSORTIUM

The Director's Challenge Lung Study comprises gene expression profiles acquired on Affymetrix microarray chips from more than 400 specimens of early-stage lung cancer, with associated clinical and pathologic annotation available to the public for analysis.[10] The investigators reported a large, training-testing, multisite, blinded validation study to characterize the performance of several prognostic models based on gene expression for 442 lung adenocarcinomas. The hypotheses proposed examined whether microarray measurements of gene expression, either alone or combined with basic clinical covariates (stage, age, sex), could be used to predict overall survival in lung cancer subjects. Several models examined produced risk scores that substantially correlated with actual subject outcome. Most methods performed better with clinical data, supporting the combined use of clinical and molecular information when building prognostic models for early-stage lung cancer.[10] This has not yet translated into clinical practice, but highlighted that clinical information is still very important. This study also provides the largest available set of microarray data with extensive pathologic and clinical annotation for lung adenocarcinomas.

GENOME-WIDE ASSOCIATION STUDIES

Early efforts to collect large amounts of comprehensive data included genome-wide association studies (GWA study, or GWAS), also known as whole genome association study (WGA study, or WGAS). These studies involve rapidly scanning markers across the complete sets of DNA, or genomes, of many people to find genetic variations associated with a particular disease. The magnitude of data involved with GWAS requires thousands to tens of thousands of markers, compared to genomics that could require few to hundreds.

Other limitations of GWAS include the potential for high false-positive rates, which next-generation sequencing (NGS) may be able to overcome, and perhaps at a more economical scale. However, this is debatable until sufficiently larger data sets can be analyzed.

This method searches the genome for small variations, called single nucleotide polymorphisms (SNPs), which occur more frequently in people with a particular disease than in people without the disease. Information generated from these analyses can pinpoint genes that may contribute to a person's risk of developing a certain disease—including cardiovascular, pulmonary, or neurologic ailments, or cancer—or even determine an individual's sensitivity to drug metabolism. The National Institutes of Health (NIH) has developed a Database of Genotypes and Phenotypes (dbGaP; www.ncbi.nlm.nih.gov/gap) to archive and distribute the results of studies that have investigated the interaction of genotype and phenotype.

UMBRELLA TRIALS

Identifying a patient population that has the best chance for improved outcomes with therapy allows better assessment of safety and risk. Realizing phenotypic characteristics are limited in nature, clinical trials have focused more than ever on acquiring blood, tissue, and other biospecimens to identify biomarkers of response. However, the idea of finding the appropriate molecular phenotype/genotype of a patient and matching it with a molecularly tailored drug that will in turn lead to an overall survival advantage is still in the research and testing stage for the majority of patients with cancer. Clinicians have patients in whom impressive results have occurred on a mostly case-by-case basis. The best drugs or combinations of drugs for individual patients are still speculative.

BATTLE

My colleagues and I initiated the BATTLE trial (Biomarker-Based Approaches of Targeted Therapy for Lung Cancer Elimination) in 2005. In the study, patients with previously diagnosed and treated lung cancer underwent a new real-time biopsy to assess biomarkers. These biomarkers were utilized in an adaptive manner to select treatment recommendations with one of several biologic agents. BATTLE was conducted before any drugs were approved with companion diagnostic biomarkers. The trial provided an important proof of principle that repeat biopsies could be performed safely and expeditiously in patients who were previously treated for lung cancer.[11] Subsequent BATTLE trials have been initiated based on our initial trial.

I-SPY 1 and I-SPY 2

Other trials have utilized similar concepts across a variety of disease types (Table 1). The I-SPY breast cancer studies were sponsored by a combination of public and private organizations, including the Foundation for the National Institutes of Health, NCI, U.S. Food and Drug Administration (FDA),

TABLE 1. Selected Umbrella and Master Trials

Title	Short Name	Sponsor	Accrual Dates	Estimated Enrollment	Cancer Types	Treatment	Biomarkers
Biomarker-Integrated Approaches of Targeted Therapy for Lung Cancer Elimination	BATTLE	MD Anderson Cancer Center	2006-2015	250	Non-small cell lung	Erlotinib, sorafenib, vandetanib, erlotinib + bexarotene	EGFR, KRAS, BRAF, CCND1, VEGF, VEGFR-2, RXRs, cyclin D-1
BATTLE-2 Program: A Biomarker-Integrated Targeted Therapy Study	BATTLE-2	MD Anderson Cancer Center	2011-2017	450	Non-small cell lung	Erlotinib, AZD6244, MK-2206, sorafenib	EGFR, KRAS, EML4/ALK
Lung Cancer Master Protocol	Lung-MAP	Southwest Oncology Group	2014-2022	Up to 10,000 screened	Squamous cell lung	MEDI4736, GDC-0032, palbociclib isethionate, AZD4547, rilotumumab, docetaxel, erlotinib hydrochloride	PIK3CA, CCND1, D2, CDK4, FGFR
Investigation of Serial Studies to Predict Your Therapeutic Response with Imaging And Molecular Analysis 1	I-SPY1	National Cancer Institute	2002-2010	356	Stage II-III breast	Standard neoadjuvant anthracycline-based chemotherapy, with or without a taxane	Hormone and HER2 expression
Investigation of Serial Studies to Predict Your Therapeutic Response with Imaging And Molecular Analysis 2	I-SPY2	QuantumLeap Healthcare Collaborative	2010-2015	800	Locally advanced breast	Standard therapy, AMG 386, AMG 479 (ganitumab) + metformin, MK-2206 with or without trastuzumab, AMG 386 + trastuzumab, T-DM1 + pertuzumab, pertuzumab + trastuzumab, ganetespib	Hormone and HER2 expression
Molecular Analysis for Therapy Choice	NCI MATCH	National Cancer Institute	Opening early 2015	Up to 3,000 screened for biomarkers, approximately 1,000 treated	Advanced solid tumors, lymphoma	20-25 targeted agents (e.g., imatinib, erlotinib, crizotinib, trastuzumab, vemurafenib)	EGFR, HER2, MET, BRAF, NF1, GNAQ, GNA11, TSC1/2, PTEN, Patch, NF2, ALK, ROS, FGFR
Initiative for Molecular Profiling in Advanced Cancer Therapy (IMPACT) Trial, An Umbrella Protocol	IMPACT	MD Anderson Cancer Center	2009-2016	Approximately 5,000	Advanced cancers	None	EGFR, VEGF, HIF-1α, PI3K, RAS, RAF, MEK, cytokines, interleukins
Molecular Profiling-Based Assignment of Cancer Therapeutics	NCI MPACT	National Cancer Institute	2014-2017	700 to be screened, 180 to be enrolled on treatment	Advanced cancers	Temozolomide, everolimus, carboplatin, trametinib DMSO, ABT-888, MK-1775	DNA repair pathways, PI3K, or RAS/RAF/MEK
Adjuvant Lung Cancer Enrichment Marker Identification and Sequencing Trial	ALCHEMIST	National Cancer Institute	2014-2020	Up to 8,000 screened	Early-stage non-small cell lung	Erlotinib hydrochloride, crizotinib	EGFR, ALK

Safeway Foundation, Biomarkers Consortium, Quintiles, and QuantumLeap Health Care Collaborative. The goal of I-SPY 1 was to identify predictors of response to neoadjuvant chemotherapy for women with stage II/III cancer. A total of 356 women were enrolled; biomarker information and MRI results were obtained. Researchers found that certain tumor profiles responded better than others to particular drugs. Results from I-SPY 1 guided the design of I-SPY 2, an adaptive, randomized trial that uses early data to guide treatment decisions for those enrolled later in the trial. Approximately 800 women will be enrolled in this trial of multiple drugs.[12]

ALCHEMIST

The NCI has launched initiatives to study patients with unique biomarkers and targeted therapy in both early- and advanced-stage cancer settings. The Adjuvant Lung Cancer Enrichment Marker Identification and Sequencing Trial (ALCHEMIST) series is focused on patients diagnosed with early-stage lung cancer. The series of trials consists of a screening trial and two treatment trials (*EGFR*-targeted therapies and *ALK*-targeted therapies). Approximately 6,000 to 8,000 patients will be enrolled in the screening trial over the next 5 to 6 years with the goal of determining if selection of therapy based on these molecular markers leads to improved survival. Tumor biopsies from these patients will be evaluated for *EGFR* and *ALK* abnormalities. Patients whose tumors harbor one of these mutations will be directed into the appropriate biologic treatment trial (erlotinib if *EGFR* is mutated and crizotinib if *ALK* is abnormal vs. placebo). Each treatment trial is expected to enroll approximately 400 patients.[13]

MASTER STUDIES
NCI MATCH

Another NCI-sponsored study, NCI MATCH (The NCI Molecular Analysis for Therapy Choice Trial), will enroll patients with advanced solid tumors (gastrointestinal stromal tumor, NSCLC, breast, gastric, melanoma, thyroid) and lym-

phomas. Biopsies from approximately 3,000 patients will undergo testing for abnormalities that may respond to targeted drug therapies. Of these patients, up to 1,000 will then participate in phase II clinical trials of targeted drug therapies. The patients will be matched to the drug based solely on the genetic abnormality, not on the type of cancer. NCI MATCH is a master trial, meaning that new drugs can be added to the trial at any time. The primary endpoint for this trial is response, however, progression-free survival will also be assessed.[14]

A new public/private cooperative effort is Lung-MAP (Lung Master Protocol). This study will enroll 500 to 1,000 patients diagnosed with advanced, previously treated squamous cell lung cancer each year. The molecular profiling is done with a central commercial panel and places patients into different arms with biologic therapies. One feature of this study is that patients who do not meet the criteria for treatment with a targeted therapy are placed into a trial involving a nontargeted investigational treatment. The primary objective of this trial is to determine if the efficacy of targeted therapy is better than that of standard therapy.[15]

M-PACT

In the NCI-sponsored M-PACT (Molecular Profiling–Based Assignment of Cancer Therapeutics trial), patients with advanced tumors that have progressed on at least one line of standard therapy undergo tumor biopsy to determine if a mutation is present. Those who do not have an identifiable mutation are removed from the trial. Those who do have a mutation are randomly assigned to receive either treatment with a drug known to target their mutation or treatment with a drug not known to target their mutation. Cross-over is allowed for those who experience disease progression after receiving treatment with a drug not known to target their mutation. Tumor response and 4-month progression-free survival are the endpoints in this trial. Accrual to this trial began in 2014 and approximately 700 patients are expected to be screened, with over 150 to be enrolled in a treatment arm. The goal is to determine whether therapies targeting a mutation can work in the metastatic setting.[16]

There is a need to test the approach in different settings, leading to many umbrella and master studies required to answer the overarching question of whether therapies targeting molecular aberrations lead to better outcomes for patients over standard chemotherapy, and in what types of patients, tumors, or aberrations these treatments work (or do not work). The importance of these efforts is not only the testing of the specific targeted therapies, but the collection and storage of centralized tissue and molecular data. These collections will allow large amounts of data to be analyzed with the hope of someday developing predictive treatment models for patients.

BIG DATA

Big data is defined as any voluminous amount of structured, semi-structured, and unstructured data that has the potential to be mined for information. More specifically, big data is any

data whose scale, diversity, and complexity require new architecture, techniques, algorithms, and analytics to manage it as well as to extract value and hidden knowledge from it. Big data expands across four fronts: velocity, variety, volume, and veracity (Table 2).[17,18]

Capturing big data in databases may help formulate hypotheses for testing. Statistical testing can be performed on pre-existing data to facilitate this process. However, big data collection can be compromised by bias in medical records, lack of data validity and reliability, and technology challenges. The potential for misinterpretation of the data is paramount. Additionally, the structure of electronic medical records may be poorly suited for adequate data abstraction and are certainly not suited for numerous secondary analyses. Many institutions also have different platforms, which can impede data integration. Attention to privacy, sharing, transparency, and stewardship are all guiding principles for big data collection and analysis.

Medicine, specifically cancer medicine, is encountering this dilemma. As the amount of information exponentially increases (patient clinical information, pathology, biomarkers, treatment outcomes, and patient questionnaires), the prospect of harnessing and processing this data is daunting. However, the potential rewards make it worth the effort. Numerous companies and researchers are working to integrate and interrogate these data sets with expectations that they will identify new opportunities for treatment, diagnosis, prognosis, and prevention. Nontraditional groups are joining the foray into this area, including Google and financial institutions, because of their ability to collect a variety of data on inordinately large numbers of individuals and variables (e.g., search, purchasing, and other behaviors).

ASCO CANCERLINQ

The American Society of Clinical Oncology (ASCO) has established an important initiative called CancerLinQ™ (www.CancerLinQ.org), a health information technology

TABLE 2. The Four Fronts of Big Data

Fronts	Description
Velocity	The velocity of cancer medicine is ever increasing as the number of patient encounters, molecular tests, and treatments grows.
Variety	Data platforms in cancer medicine continue to rapidly evolve. The electronic health record is becoming a better resource as a database. More and more hospital systems are incorporating telemedicine which enlist mobile connectivity. Archived data mining is now becoming active data searches.
Volume	The amount of information that is being generated by cancer medicine is being measured in the scope of peta- and exabytes. Storage solutions must be forward-thinking, including current cloud sourcing.
Veracity	The reliability of data sources in the health care setting is not always ideal, as most systems are not set up for research. Large data sets can be subject to bias. We should be prepared to acknowledge the limitations of our data.

platform that plans to collect information from the experiences of patients with cancer. The goal of this big data collection will be to improve the quality and value of cancer care. Data will be collected from the electronic health records of patients across the United States and will be restructured and stored into one single database that will be able to provide clinical decision-making support for health care providers. The information from patients and providers will be continuously collected, thus enabling further refinement of the decision-making algorithm. ASCO has currently created a prototype platform and has initiated 15 practice sites to collect data from over 500,000 patient experiences.[19]

Big data projects like CancerLinQ include strategic, technical, and regulatory challenges, but ASCO has established a robust external advisory structure to guide its development. An example of clinical utility could be in immunotherapy treatment. As melanoma, renal cell, and lung cancer have immunotherapy as treatment options, harnessing numerous patient encounters and clinical data could create guidance for clinicians in managing not only the disease process, but also side effects from the treatment. This type of data would be valuable in helping predict responders and nonresponders, perhaps predict who will experience side effects, and more importantly, help keep patients on treatment longer, which may translate into better survival and quality of life.

PRECISION MEDICINE INITIATIVE

In his 2015 State of the Union Address, President Barack Obama proposed a new initiative aimed at increasing our capacity to research, and ultimately deliver, precision medicine across disease types. President Obama has designated over $215 million to support the collaborative efforts of the NIH, FDA, and Office of the National Coordinator for Health Information Technology on this Precision Medicine Initiative. With the initial focus on cancer, the President has proposed to create a research cohort (partially through the use of existing resources and partially through upwards of 1 million new accruals) in which patient tissues and clinical data will be collected, stored, and analyzed. This big data will be used to enhance our existing knowledge of molecular medicine and develop individualized, molecular approaches to cancer treatment. The President's new initiative is clearly at the intersection of biomarkers and big data.[20,21]

CONCLUSION

The era of personalized medicine continues at a rapid pace. The practice of medicine now requires not only a clinical examination, but also molecular testing, novel therapeutics, research trial awareness, and perhaps utilization of information obtained from big data in the near future. Integration of these tools will enable providers to deliver better, more comprehensive care. Much work still needs to be performed, and more tools needs to be developed and refined, to help providers and clinicians achieve the best results.

Towards a Personalized Treatment of Head and Neck Cancer

Andrew M. Gross, CPhil, and Ezra E.W. Cohen, MD

There is increasing excitement surrounding the surge of data that has emerged throughout various sectors of oncology research, which often seems like hyperbole. Although the use of data to inform decision making is far from novel, the emergence of inexpensive and ubiquitous computing power and storage has bolstered our ability to produce data-driven insights and has ushered in the era of "big data." The essence of the big data paradigm is simple: given enough data, machines can generate insights equivalent to or sometimes even exceeding experts in the field. One example of the application of this paradigm lies in the field of natural language processing where the use of giant collections of text provide better results with much simpler models and less expert input.[1] In contrast, notable failures exist including the buildup and subsequent implosion of Google Flu Trends to predict the onset of the flu season.[2,3]

Alongside these developments, the field of cancer has seen a bolus of data emerging from a combination of old and new sources. The digitization of hospitals and the spread of electronic medical records have created large archives of traditional data, making meta-analyses of large patient cohorts almost facile. Furthermore, the adoption of high-throughput molecular profiling and the plummeting costs of genetic sequencing are creating new opportunities to probe the inner-workings of healthy and diseased cells. Although the idea of personalized medicine is clearly not new, our ability to accurately quantify the defining characteristics of an individual patient's tumor lends hope that a targeted attack against its specific biology is possible.

In head and neck squamous cell carcinoma (HNSCC), such molecular biology has proven pivotal to our understanding of the disease. Starting with targeted studies of mRNA, protein expression, and analysis of chromosomal gains and losses, the field slowly pieced together a model in which epidermal growth factor receptor (*EGFR*) expression is activated and chromosomal abnormalities accumulate, often alongside mutations to the *TP53* gene.[4-6] As cohorts became larger and more high-throughput analysis such as microarrays and sequencing technologies became available, it became clear that the picture was far more complex and that there exist different subtypes of the disease.

As data acquisition becomes readily available with the rise of high-throughput sequencing, our understanding of tumor biology is actually beginning to blur. Although more and more driver genes are being discovered, it is exceedingly clear that the molecular characteristics of no two tumors are identical and that the biology driving tumor initiation and progression may be far more complex than originally envisioned. As genomic profiling in cancer becomes ubiquitous, the promise of the big data paradigm may affect patients with HNSCC by enabling personalized monitoring, diagnosis, and treatment of this disease. Although the dystopian vision of machines treating patients is not likely to become a reality anytime soon, the ability to use systematic data to inform better patient treatment is all but inevitable.

MOLECULAR STRATIFICATION OF HEAD AND NECK CANCER

In the late 1990s, the convergence of epidemiological and molecular studies on the influence of HPV in cancers of the oropharynx led to the first molecular stratification of head and neck cancers. The ability within the research community to detect HPV DNA by sequencing-based methods allowed for comparison of HPV-positive and HPV-negative groups with other molecular measurements and clinically obtained variables. In parallel, analysis of increasingly large molecularly characterized cohorts has enabled a more refined understanding of the heterogeneity of this disease. The rise of such cohorts alongside the continued use of model systems has allowed for exquisite understanding of the key events that drive HNSCC and even how these events interact with each other. Whereas the molecular details of HPV-positive and HPV-negative HNSCC are fascinating, we refer the reader to a number of recent papers and reviews that comprehensively cover these facets of the biology of HNSCC tumors.[7-10]

The picture that eventually emerged was one of very different cancers, with HPV-positive patients being far less likely to have the traditional risk factors of smoking and drinking while having substantially better cure rates than their HPV-

negative counterparts.[11] Underlying these differences in clinical phenotypes are distinct molecular characteristics of HPV-positive and HPV-negative tumors.[12] Gene expression studies have pointed to subtypes of the disease with different clinical and molecular characteristics. A recent analysis based on four discovery cohorts and two independent validation datasets classified HNSCC into three super groups called inflamed/mesenchymal (IMS), basal (BA), and classical (CL) based on previously used nomenclature.[12] Interestingly, HPV-positive tumors fell into only two of these groups (IMS and CL), whereas the BA group consisted exclusively of HPV-negative cancers. Furthermore, the classification appears to be prognostic for overall survival even within the HPV-positive tumors where the IMS HPV-positive group, enriched for immune-related genes, had the best outcome.

TP53 mutations were shown to be exclusive to HPV-negative tumors, presumably as a result of the phenocopying effect of E6 viral protein-mediated TP53 degradation. Similarly, whereas CDKN2A has been shown to be affected by copy number losses or mutations to the coding sequences of the gene, this was not seen in HPV-positive tumors as a result of its inactivation by the E7 viral protein. Other notable differences are seen in kinases that could be potential targets for therapy including more frequent mutation of *PIK3CA* and *FGFR 2/3* in HPV-positive tumors contrasted with amplification of *EGFR, FGFR1,* and *CCDN1* seen exclusively in HPV-negative tumors.[12-13]

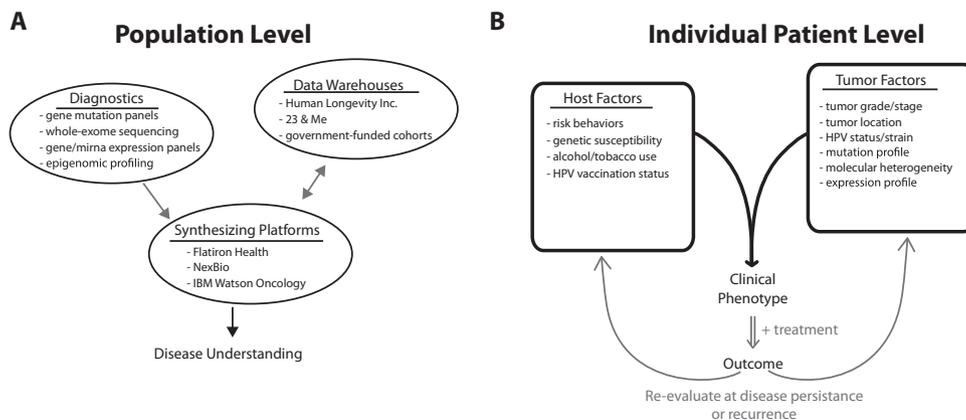
In tumors lacking HPV infection, long-term studies of *TP53* mutation have shown that its presence is associated with poor outcomes, an effect that seems to be accentuated by the functional effect of the mutation. Recent work by Gross et al looking across multiple data-layers has refined the interpretation of *TP53* mutations by showing that they usually co-occur with loss of the 3p chromosomal region and that the adverse prognostic effect coincides with the combinations of the two events.[14] The putative gene(s) on 3p have yet to be fully elucidated but one candidate is *FHIT*, which functions as a tumor suppressor and has been linked with radiosensitivity, perhaps explaining its key role in HNSCC.[15]

Larger cohorts such as The Cancer Genome Atlas (TCGA) have facilitated attention to increasingly rare genomic drivers of the disease. One example is Caspase 8 mutation, which only compromises approximately 8% of the TCGA patient cohort. Despite its relatively low frequency, this event has proven interesting as it occurs in mutual exclusion of the *TP53* mutation/3p deletion event, and has been shown to accelerate tumor growth through inhibition of death receptor mediated apoptosis pathways.[14,16] These tumors seem to have developed from a very different mechanism of oncogenesis than either their *TP53* mutated, or HPV-positive counterparts, and patients with the alteration would likely benefit from different treatment strategies.

Even as we begin to understand the drivers of HNSCC progression, new unsolved problems arise such as understanding the heterogeneity of the disease and the interplay of clonal populations within a single tumor. Current studies rely on molecular measurements taken from a single tumor sample at a single time-point, usually before intervention. The observation that patients with a high degree of intratumoral heterogeneity tend to have worse outcomes proposes new research directions to quantify the tumor not as a single unit but as a collection of diverse cellular populations.[17] Profiling at multiple sites within a tumor as well as multiple time-points along the treatment and progression of the tumor will add a new dimension to our understanding of HNSCC. However, to understand this more complex data, bigger and more phenotypically rich cohorts will be required.

THE RISE OF BIG DATA IN CANCER

In the age of the $1,000 genome, a new market for consumer genomics has emerged that promises both immediately actionable results to the patient as well as a treasure trove of data for the institutions overseeing its collection and maintenance. At its current state, clinical sequencing remains an optimistic enterprise with few truly actionable events detected by such assays. Although current prospects for such personalized

FIGURE 1. Schematic of the Precision Medicine Paradigm on the (A) Population and (B) Individual Patient Levels


treatments are poor, such large numbers of patients will facilitate better development and deployment of the next generation of cancer drugs, and provide patients and their physicians with a much more precise diagnosis of their disease.

TEACHING AN OLD DRUG NEW TRICKS

With consortia such as TCGA and the International Cancer Genome Consortium leading the way, the utility of large collections of molecularly profiled patients has become very clear. The amount of data available translates into improved power to explore the increasingly large list of molecular events that play a role in tumor initiation and progression.[18] These discoveries in turn provide opportunities for promising leads for drug development and even enable repurposing of drugs traditionally used for other diseases. For example, metformin, a biguanide hypoglycemic drug used to treat diabetes, is being explored in multiple cancers including HNSCC because of its metabolic effects and ability to activate AMPK.[19] Those properties open the door to targeting a variety of cancers where analysis of multiomics data reveals relevant functional alterations.

Moreover, reanalysis of clinical trials with new information on patients' genetic backgrounds will potentially facilitate repurposing of old drugs for patients with specific tumor characteristics. Such analysis has already shown success in a study of extraordinary responders that analyzed patients with exceptional responses in otherwise failed clinical trials.[19] These patients' response to targeted drugs can often then be analytically attributed to molecular alterations within their tumor, providing new leads for prospective study of the drug in a specific molecular context. Although promising, the large number of potential biomarkers gleaned from such post hoc analyses makes over-testing a real possibility and generated hypotheses will still need to be subjected to prospective studies. To combat approval of indications resulting from spurious correlations, regulators will have to ensure strict adherence and definition of design protocols. Furthermore, new clinical trial designs that randomize with specific knowledge of patients' genomics will be needed to allow for approval of targeted drugs for targeted uses.

THE INCOMING DATA DELUGE AND WHY IT MATTERS

With direct and indirect sources of revenue becoming increasingly certain, numerous private entities have emerged alongside research institutions (Fig. 1). Diagnostics have emerged from new (Foundation Medicine) and established (Sequenom, Illumina) companies offering targeted sequencing panels searching for actionable mutations in patient tumors. Data warehouses (Human Longevity, Inc., 23 and Me) are now offering cheap sequencing in exchange for control of market share and patient data. Middle layers (Flatiron Health, NextBio) are beginning to emerge to link such information directly to physicians as well as research entities along the spectrum of the drug development pipeline. Alongside

these efforts, personalized and precision-medicine initiatives are being declared across the world, which promise to compile genomic and phenotypic data in public efforts to provide rich datasets to the research community.[21-23]

Although it is clear how massive databases of molecular tumor profiles will improve our understanding of the disease on a population level, more work is needed to understand a single patient's tumor well enough to offer truly personalized treatments (Fig. 1). Much as our current understanding of HNSCC facilitates broad divisions of the patient population by factors such as smoking status, HPV infection, expression subtypes, or *TP53* mutation, the increased availability of data will allow for finer dissection of the population. Data aggregators will enable anonymized access to tumor profiles and access to treatment courses and outcomes of patients with similar tumors. New methods will be required to determine the key aspects driving the similarity of two tumors, be they anatomic, genetic, and/or histologic. Standardization of reporting protocols and data exchange will create a larger pool of potential matches to a given patient and allow for more informed treatment decisions to be made. Regulatory protocols and data security measures will need to be implemented to ensure the privacy of all parties involved.[24]

SMARTER OUTCOMES

It remains unclear whether a tumor's molecular characteristics will remain static throughout treatment or alter throughout therapy. The relative accessibility of HNSCC tumors should allow for exquisite tracking of the characteristics of a patients tumor but has been underutilized thus far. Small studies have been able to demonstrate target inhibition or pharmacodynamic effects of a drug, but exploration of new models and protocols for adaptive treatment regimens has yet to be assessed.

The incorporation of targeted therapy will change how we approach initial therapy and assess drug resistance. Combinations of drugs may be developed to preemptively silence resistance pathways.[25] Although the use of single targeted drugs may attack a key feature or vulnerability of the tumor, it is likely that a more detailed understanding of a patient's tumor and the specific pathways being altered will be necessary for effective combinatorial targeting. Even if a patient is likely to develop resistance, if it is predictable and its manifestation has its own treatment strategy, multistage treatment plans with careful planning and monitoring may be in order. Making these alternative treatment paradigms a reality will require a wide range of advancements such as better tissue biopsies or noninvasive measurements of tumor DNA from blood to track the molecular makeup of the tumor, as well as faster experimental and analytic pipelines for ensure timely treatment.

Alongside genomic advancements, the digitization of medical records will also allow for rich recording of patient outcomes past the standard metrics of progression-free interval and overall survival. Alternative metrics such as patient heart rate, activity levels, and sleep quality will be measured by specialized and/or consumer sensors, bands, and watches. Such rich measurements will be aggregated and used to inform

treatment by allowing for unbiased understanding of the effects of a treatment on quality of life.[26]

THE FUTURE OF PERSONALIZED MEDICINE

Genomic data is flowing at unprecedented rates. The biology of HNSCC is being dissected in increasingly remarkable detail. Smarter drugs are in the pipeline to cater treatment to the specific genetic makeup of a patient's tumor. Private enterprise has embraced the genome era and begun construction of giant silos of patient data. Precision medicine has reached the mainstream and is being heralded as the next great step in

the "war on cancer." However, significant hurdles remain before big data can be translated into better outcomes for patients with cancer. Determining which elements of big data are biologically and clinically relevant will require the development of new analysis methods, changes in clinical trial design, new infrastructure for data sharing, and, perhaps most importantly, close collaboration between bioinformaticists, oncologists, and the pharmaceutical industry.

Medical Education: Perils and Progress in Educating and Assessing a New Generation of Learners

Jill Gilbert, MD, Helen Chew, MD, Charlene Dewey, MD, MED, and Leora Horn, MD, MSC

Tinsley Harrison is well recognized as one of the premier medical educators in history.[1] However, the social, political, and cultural forces that shaped the health care landscape have changed since Harrison's time. In the mid-20th century, teaching was an endpoint in and of itself. Patients were largely indigent, and health care financial pressures were different, allowing teacher and trainee to spend ample time discussing and dissecting individual patient cases. Bedside teaching was paramount, and the trainee's most valuable learning occurred in the hospital through real-time patient-based cases. Duty hour restrictions did not exist. Moreover, students were expected to adapt to the methods of the teacher, a one-size-fits-all policy.[2]

In the late 20th century, the financial landscape of medicine changed, and with this change an altered view of medical education evolved.[2] Managed care had substantial effects on health care delivery and created new financial pressures for academic institutions now emphasizing patient volumes and rapid turnover to capture clinical revenues. Unfortunately, medical education, which required substantial amounts of faculty time and resources, took a back seat. Educators noted substantial pressure to increase volume and efficiency, eroding time for educational activities. Although the social contract of the Harrison-era emphasized patient care, the new social contract in the managed-care era emphasized cost containment and efficiency.[2] This ran counter to traditional medical education that emphasized the slow, methodical development of compassionate and intellectually thoughtful providers who could learn in a medical "utopia" regardless of cost to the patient or institution.[3] These new financial pressures served to drain key resources for medical education and further eroded the learning environment. Faculty development in medical education also suffered. Why develop a medical educator when medical education does not pay and, in fact, slows down potentially profitable providers?[3,4]

The 21st century has continued to emphasize fiscal responsibility in medicine with attendant pressures on academic institutions. Although these issues once stalled medical education, the new social contract demands medical cost containment and an emphasis on personalized care. This has created new opportunities for the medical educator. The public now demands caring, competent physicians who participate in quality and performance improvement activities as well as medical training that is mindful of global medical fiscal responsibility.[2] In fact, one could argue that the present day social contract, a melding of Harrison-era and managed-care era, forces to produce a new physician phenotype. Most importantly, medical educators will play a key role in the development of this knowledgeable, compassionate, and fiscally responsible provider. Thus, professional development of the medical educator in the 21st century is critical and represents "the personal and professional development of teachers, clinicians, researchers, and administrators to meet the goals, vision and mission of the institution in terms of its social and moral responsibility to the communities it serves."[5]

WHAT IS PROFESSIONAL DEVELOPMENT? WHY IT IS IMPORTANT?

Professional development is a planned program to encourage individuals and institutions to improve practice and manage change, which in turn can lead to improvements in learning outcomes for students and physicians and, ultimately, improved patient and community outcomes.[5,6] Professional development includes any individual involved in undergraduate or postgraduate medical education[5] and aims to promote the establishment of communities within academic institutions that value teaching, learning, leadership, and research in medical education.[5,7] A successful professional development program can be central to the growth and prosperity of an academic institution, but can also attend to the growth of the individual. This promotes a culture that values both institutional and personal growth.[5] McLean et al have suggested that an institution that values both the professional and personal development of its staff will nurture faculty members who are interested in becoming educa-

tional scholars, leaders, researchers, and/or service providers.[5] The establishment of a successful faculty development program can facilitate educational change and improvements in the academic medical environment.[8] Within the United States and abroad, many institutions established professional development programs decades ago to improve their educational missions with demonstrated success.[6-19] Nationally, professional organizations such as the Accreditation Council for Graduate Medical Education (ACGME) have modified how we evaluate and promote trainees to best support the evolving societal expectations of the modern physician.[20] Thus, change has brought new opportunity to medical education and laid the foundation for a utopia of sorts within this arena. Although this seems like a tall order, this goal can be achieved through innovative medical education programing, and we now enter a renaissance period in medical education to support this end product. We are already seeing the early influence of this new movement on both a national and an institutional level.[5,21,22] Educators have a responsibility to train the present and next generation to carry the torch, not only to service a new generation of learners, but also to create an innovative army of educators to maintain and, ultimately, build on the momentum of educator creativity and productivity.

Let's return to the original question, what would Tinsley Harrison do? In his book, *Tinsley Harrison, MD: Teacher of Medicine*, James Pittman notes: "He (Harrison) died a bitter critic of the mindless overuse of the medical technology he himself had helped develop and of what he considered the disoriented nature of universities and their even more disoriented medical schools."[1] Although Harrison might have been skeptical about some aspects of the modern health care landscape, one would suspect he would stand behind a movement that upholds medical education as a platform to enact monumental change in health care delivery with the ultimate goal of optimizing patient care.

PRINCIPLES OF LEADERSHIP EDUCATION AND DEVELOPMENT FOR MEDICAL EDUCATORS

George E. Thibault of Harvard Medical School noted, "curricula were developed first, and then students were taught and assessed. Now, curricula should be designed last, after public health needs are assessed, and they should include innovations such as interprofessional and interdisciplinary training, new models of clinical education, new content to complement the biologic sciences, competency-based and individualized education tracks to speed the training process, and incorporation of new educational technologies."[23] A changing health care landscape supports reform in medical education. To meet the learner "right where they are" regarding today's health care system needs, teachers must modify how they teach.

New challenges within health care systems and population health imply a need for faculty development of the medical educator to meet these new challenges. Additionally, professional organizations such as the ACGME have adopted new accreditation and evaluation systems to ensure graduating physicians can support and promote the new demands of our nation's health care needs. Specifically, physicians are no longer expected to function as independent actors but to function as leaders and participants in team-oriented care.[4,20] Patients, payers, and the public demand their providers are technologically adept, practice proactive evidence-based medicine with cost containment, include the patient in their decisions, and utilize health information technology to improve care for individuals and populations.[4,20] To meet these demands, the ACGME has produced the Next Accreditation System (NAS), which educators now need to develop mastery over and to develop novel programming to support others.

Developing such programs is not without potential challenges, but the potential rewards remain substantial on a personal, institutional, and national medical landscape perspective.[24] Table 1 demonstrates potential challenges and wins in terms of medical educator development and community outcomes. In truth, the challenge becomes not how we can afford to invest in such programming but rather how can we afford not to? Educational standards cannot afford to lag behind delivery-system change. Investments in innovative programming and development of the new medical educator are required to meet this challenge.

THE EVOLUTION OF TEACHING AND ASSESSMENT STRATEGIES

External forces affecting change in medical education include the social contract that requires a better assessment method to judge the competence of physicians before entering practice in the modern health care environment. The ACGME has developed the NAS to begin to meet this need. The NAS now requires all medical training programs to use competency-based milestone assessments. Previously, trainees were evaluated on broader core competencies that included patient care, medical knowledge, interpersonal and communication skills, professionalism, practice-based learning, and improvement and systems-based practice.[25] Faculty did not always receive training and may not have understood these terms; making honest, concrete evaluations of observable trainee progress and competence difficult, often resulting in inflation of skills and knowledge levels. In contrast, the NAS focuses on outcomes-based milestones for trainee performance within these aforementioned six domains of clinical competence. An example of such a milestone that fulfills the new social contract is: "Responds to each patient's unique characteristics and needs." The clinical competencies that this milestone speaks to are professionalism and interpersonal communication skills. Although this might seem like another esoteric description, the milestone itself is broken down into key observable behaviors "as determined by individual programs." For example, observable behaviors that may inform this milestone include: the trainee discussing end-of-life issues with a patient of a different cul-

TABLE 1. Potential Outcomes of a Successful Medical Education Program

Outputs	Activities to Support Outputs	Resources Required for Outputs	Potential Outcomes Related to Successful Outputs
Educationally sound curriculum or curricular intervention to meet the needs of changing health care landscape	Curricular development training including project-based experiential learning in curriculum development and implementation, and skills development in curricular evaluation	Faculty experts in curricular development Funding to support program Faculty time	Compassionate and knowledgeable providers who deliver efficient and cost effective care
Scholarship in medical education	Training in research design and methodology, data analysis, manuscript writing, grant writing, and statistics	Funding for research Faculty trained in medical education research methodology Possible medical education cooperative groups Faculty time	Innovative educational practices Dissemination of new knowledge
Leaders trained specifically to address, effectively navigate, and develop programing in an increasingly complex medical education and health care landscape	Training in leadership skills development, maintaining and developing organizational efficiency, development of personal leadership style, and how to develop people	Mentorship Faculty time Networking community Educators in leadership development Funding	Changes in organizational contexts and leadership roles Institutional and professional society support and promotion of faculty as medical educator

tural/ethnic background, trainee discussing informed consent with a patient with low literacy level, etc. The trainee is then judged based on an entrustment scale that describes the level of trust that the trainee can carry out the given activity competently and independently. For example, the trainee can perform the skill with distant supervision, the trainee can perform the skill with direct supervision, the trainee is aspirational and can teach this skill to others. This gives the faculty a more grounded view of how to evaluate trainees to ascertain clinical competence in an area of emphasis in modern-day medicine/health care. However, activities need to be prescribed that allow observable behaviors to ensue. Trainees will be evaluated on a trajectory of competence and should demonstrate progress, not perfection, as they advance toward independent practice. However, the question remains how is the behavior measured or observed to accurately place the trainee on a milestone trajectory? Additionally, what activities meet the millennial learner "right where they are" and, thus, provide a meaningful educational experience? To meet these challenges, educators need to cultivate and employ new assessment strategies. Some of these new processes are described below and placed in context of the aforementioned milestone.

In order to ground milestones in observable behavior, programs are encouraged to develop entrustable professional activities (EPAs) for each rotation. EPAs are units of professional practice that can be performed (and observed by faculty) with increasing autonomy and decreasing supervision over time.[26,27] Think of EPAs as essential goals to achieve over training. For instance, on the ward service, a trainee should know how to manage febrile neutropenia and conduct a family meeting; on the hematology consult rotation, a trainee should accurately interpret a peripheral blood smear; in their continuity clinic, a trainee should recognize and manage the toxicities associated with chemotherapy. EPAs can inform multiple competencies as noted in Table 2. The

training programs, under NAS, have the independence to create the types and numbers of EPAs for each rotation.

ASSESSMENT STRATEGIES
Direct Observation

Direct observation provides the most accurate assessment of a learner and provides the opportunity for immediate feedback. Direct observation removes the biases of hearsay, selective recall, or forgetting details that are common in global end-of-rotation ratings. One of the limitations of direct observation is that the rater may observe the learner in only a fraction of their working hours. Direct observation should be made by multiple observers on many occasions, and these should be reviewed by the training program's competency committee.

The 360-Degree Evaluation

Multisource or 360-degree evaluations are another assessment strategy that is valuable in providing evaluation of a learner from multiple raters or sources. Such evaluations are common in industry and gaining acceptance in the assess-

TABLE 2. Linking EPAs to ACGME Competencies

EPA Examples	ACGME Competencies					
	PC	MK	PBL	SBP	ICS	P
Manage neutropenic fevers	X					
Conduct a family meeting	X				X	X
Interpret a peripheral blood smear	X	X				
Manage chemotherapy toxicities	X	X		X		

Abbreviations: EPA, entrustable professional activities; ACGME, Accreditation Council for Graduate Medical Education; PC, patient care; MK, medical knowledge; PBL, practice-based learning and improvement; SBP, systems-based practice; ICS, interpersonal and communication skills; P, professionalism.

ment of physician competencies. A systematic review found that use of such evaluations by an adequate number of colleagues, coworkers, and patients were highly reliable, valid, and feasible.[28] Many competencies can be evaluated using multisource evaluations. For example, trainees can be assessed on their milestones, inpatient care, and communication skills by a wide array of members of the health care team, including peers, ward and clinic nurses, pharmacists, social workers, administrative workers, and by their patients. In addition, these evaluations may also reflect the competencies of professionalism and systems-based practice. Program coordinators can assess professionalism and communication skills.

Unprofessional behavior may be identified by 360-degree evaluations as trainees are unlikely to exhibit this behavior in the presence of a supervising physician. Interestingly, in a study of multisource evaluation of physicians' professionalism, ratings by peers, coworkers, and patients were highly correlated, but did not correlate with self-evaluations.[29] One example of a 360-degree assessment based on the ACGME core competencies is the B-29. It is a validated instrument for identifying unprofessional behaviors and can be used as a feedback tool for physicians to improve behaviors.[30] Like the previously cited study, reliability of multisource ratings depended on an adequate number and type of evaluations.

TEACHING STRATEGIES
Simulation/Standardized Patient Experience

The standardized patient (SP) or patient simulation is an individual trained to act as a real patient in order to simulate a set of symptoms or problems. Standardized patients present a high-fidelity simulation of a real clinical situation.[31] They also provide a standardized presentation of the same patient problem from examinee to examinee in assessment settings.[31] Prior studies of medical students have demonstrated that although real patients are the preferred method for medical students to learn communication skills, experiential techniques such as simulated patients, videotaped interviews, and instructor feedback are more effective than didactic sessions for teaching communication skills.[32] Simulation allows participants to experience the patient in a variety of roles and as often as required in a nonthreatening environment.[33] Despite prior studies indicating anxiety and skepticism associated with performing in front of peers, the feedback on performance skills provided by facilitators, peers, and patient actors broadens the experience for participants and, thus, could increase the learning experience. Back et al have shown that using patient actors does not require that the learners are skilled at acting, but rather enables trainees to learn in their usual role as physicians and introduces them to the value of simulated patients for refining communication skills.[34] Moreover, the use of SPs compared with real patients avoids the ethical conundrums of using real patients and ensures each trainee has the same experience.[35]

Let's return to the milestone mentioned previously: Responds to each patient's unique characteristics and needs.

Although the faculty member might globally note that a trainee is professional, has the evaluator actually witnessed the trainee communicating with the patient in a culturally competent manner and is the trainee able to involve the patient in his or her own care? Although this may occur in the course of clinic or ward duties, it is recognized that such opportunity may not regularly occur. Educators could use simulation/standardization training to inform this milestone in a structured encounter where the trainee discusses end-of-life issues with a patient from a different ethnic or socioeconomic backgrounds. Although this may occur in the course of training, this structured activity allows trained evaluators to observe these behaviors, and provide direct feedback (from both patient and evaluator) immediately at the point of interaction. Examples of such SP/simulation examples to teach this skill can be seen in Table 3.

Trainees would rotate through each example in a half-day session devoted to development of these communication skills. On a resource level, several items will be required including space, funding, faculty who are trained and willing to develop scripts for SP, training for the SP, faculty trained in communication skills and observation to observe and provide direct feedback (ideally several faculty members), and faculty and trainee time to perform these activities. The ACGME now mandates all programs to participate in training using simulation. Thus, the onus remains on the medical educator to plan and perform activities that meet the needs of the learners at each institution.

TABLE 3. Proposed Standardized Patient Simulations to Evaluate Cultural Competencies

Each trainee would rotate through each scenario below:

Standardized Patient 1:	The patient is an African American woman age 85. She is computer illiterate and very involved with her church. She is able to read at an 8th-grade level. She always comes to clinic with a daughter and granddaughter. She has been unable to tolerate previous chemotherapy for her metastatic breast cancer and has already had three regimens for metastatic disease. Discuss best treatment options.
Standardized Patient 2:	The patient is a Latino man, age 48, who is a recent immigrant. He does not speak or read English. He works in the construction industry. He is a smoker. He is now diagnosed with metastatic pancreatic cancer. He does not have family in this country. He does not have insurance. He has lost 30 lbs in the past 6 months and his performance status is 3. Discuss best treatment options.
Standardized Patient 3:	The patient is a Caucasian woman, age 32, from a rural community that is 60 miles from your medical center. She reads on a 4th-grade level. She can play games on the computer. She has three small children. She is married. She is unable to work. The annual household income is less than $15,000. She now has recurrent and refractory acute myeloid leukemia, but is eligible for a clinical trial. Discuss her options.

E-Learning

E-learning is a unique pedagogy in which Internet technology is used to enhance learner knowledge and performance.[36] Educational content delivered via e-learning is rapidly revolutionizing medical education and health care delivery. Educational websites, virtual patient simulations, online problem-based learning, podcasts, and interactive multimedia tutorials are all forms of e-learning.[36,37] Alur et al describe a blueprint for educating health professionals through e-learning that necessitates the development of an educational website that acts as a medium for sharing information while encouraging active learning, critical thinking, and independent and evidence-based learning by the learner.[38] A study evaluating 112 teaching websites in North America, the United Kingdom, and Australia found only 17% of websites ascribed to these principles.[38]

When used appropriately e-learning applications can enhance the efficiency and efficacy of educational interventions,[39] and basic science and clinical educators have begun using e-learning as adjuncts or replacements to traditional in-person courses. E-learning has the capability to result in effective learning, but also offers benefits that a traditional classroom may not offer. These benefits include efficiency,[40,41] flexible scheduling,[40,41] and customized feedback.[42] In addition, e-learning programs can be designed with hyperlinks that allow learners to independently research information and broaden their search to related topics. These attributes are particularly useful in the self-directed, problem-based learning environment, which is valued by practicing physicians. In addition, e-learning is able to overcome barriers of physical distance, allows unlimited viewers and viewing, is easily updated, and allows retention and transfer to new settings.[40-42] Barriers to the use of e-learning include lack of time for the user, dissatisfaction with speed of the medium, technology problems, student support issues, and instructional design.[43,44]

A prior meta-analysis demonstrated that e-learning leads to greater learning than no learning.[45] E-learning also has similar levels of participant satisfaction and equal or greater improvement in knowledge and skills acquisition compared with traditional in-person learning methods.[45,46] Prior studies regarding learning have shown that integration of new material into the learners' previous subject knowledge may be advantageous and result in effective learning.[47,48] Cook and Dupras[49] identified key elements required to develop an effective educational website including performing a needs analysis and specifying goals and objectives, determining technical resources and needs, evaluating and using preexisting software, securing commitment from participants to identify potential barriers to implementation, developing content in close coordination with Web design, encouraging active learning, self-reflection and use by the learner, evaluating the learner and the course, piloting the site, and monitoring the site. Harden and Laidlaw describe the CRISIS model for developing effective continuing medical education. In their model they describe convenience, relevance, individualization, self-assessment, independent learning, and systematic.[50] These frameworks are being used in the development of e-learning modules to ensure best practice.[50]

The Flipped Classroom

Traditionally, medicine has been taught by didactic lectures, from medical school through graduate training. However, the volume of medical knowledge has exploded, and the adaption of technology-based learning has increased in the last decades. In this learning environment, educators have to be more efficient and innovative. The concept of a flipped classroom refers to learners viewing information digitally on their own and using class time for more engaged, case-based learning or simulation, discussion, and/or clarification of concepts. Rather than the teacher delivering the same lecture to all students, students learn the material on their own, at their own pace, and the classroom time is used for actual hands-on teaching.[51] Flipped classrooms and related concepts, including blended learning, a combination of online modules and in-class instructions, have been used successfully in a variety of student rotations (third-year radiology clerkships,[52] fourth-year clerkships,[53] and emergency medicine residency).[54]

Training programs can incorporate flipped classrooms by building a library of digital recordings, PowerPoint presentations, papers, and other online resources that trainees can access before time set aside for interactive in-person discussions. The flipped classroom model allows educators to maximize their in-person learning time to convey critical information to the learner who has achieved some basic understanding before coming to their session. How can this be used in the era of NAS and the milestones? Consider the competency of medical knowledge. Most programs use the in-training exam and their gestalt of a fellow's medical intelligence to evaluate them. Under the milestones, a subcompetency for medical knowledge includes "knowledge of diagnostic teaching and procedures" (MK2). A flipped classroom would allow students to learn online about a specific disease, where risk factors, diagnostic tools, and treatment are reviewed, including the latest clinical trials. In person, they can have a focused case review, discuss appropriate testing, the limitations and indications for tests, and provide time for correct interpretation of tests and possible treatment strategies. Learners are not expected to pass a one-time grade, but rather to be on the appropriate continuum of learning for their level of training. Institutions, through their graduate medical education office, should provide coordinated resources for digital information.

Social Media

Social media has changed the way information is communicated and disseminated. Examples include podcasts, Twitter, and networking communities such as LinkedIn. Podcasting is a form of asynchronous learning where the learner can tune in at their own convenience and listen to talks or discussions. The American Society of Clinical Oncology (ASCO), as an example, uses podcasts where key *Journal of Clinical Oncology* articles are discussed, allowing the reader not only a

greater understanding of the study results, but how these results can be applied in their daily practice. Training programs can incorporate podcasts into their curriculum in a similar fashion. Twitter allows subscribers to send brief updates on topics they believe are important to their followers. An example of a recent tweet is "What are the treatment paradigms for prostate cancer?" that serves as a notice for an upcoming tumor board on ASCO University. ASCO members can tweet on interesting findings that are published or presented at meetings. Networking communities such as LinkedIn or Doximity allow health care professionals to connect with one another and industry partners, view new job postings or promotions, or connect with communities of liked-minded individuals online.

CONCLUSION

With all these changes, this is an exciting time in medical education. With new teaching and assessment strategies and all the technology available to the educator, we can now only ask "How could Tinsley Harrison do it differently?" We are teaching a new generation of students who have the Internet at their fingertips and an application for every indication. In our changing health care environment, with limited duty hours, busy clinics, and overflowing hospitals, adaptation of new assessment strategies and novel teaching strategies will allow for a generation of physicians who may not think like Harrison, but will continue to deliver outstanding patient care.

Perspectives on Clinical Trials for Gastrointestinal Malignancies

Cathy Eng, MD, FACP, Nancy Roach, Michele Longabaugh, RN, and George Fisher, MD, PhD

W e all accept the premise that clinical trials are essential to improving the care and outcomes of those afflicted with cancer. Indeed, without successful enrollment into clinical trials, there would be no new diagnostics or treatments for cancer. Yet, it is often quoted that fewer than 5% of adult patients with cancer participate in clinical trials. The dismal accrual rates have been the subject of many learned reviews. In this article, two academic oncologists, a patient advocate and a cancer survivor/author contribute our perspectives on the problem and have chosen to focus on gastrointestinal cancers in the United States as our example.

THE PROBLEM: THE PHYSCIAN PERSPECTIVE

First, we must ask if the approximately 5% participation rate in clinical trials is accurate, and of whom this 5% comprises. Murthy et al[1] calculated an enrollment fraction of 1.7% in National Cancer Institute (NCI)–sponsored clinical trials divided by the total estimated cancer cases in the United States. Whereas 3.0% of patients age 30 to 64 enrolled in a clinical trial, but only 1.3% of those age 65 to 74 participated. Given that the median age of diagnosis of a gastrointestinal (GI) malignancy is 71[2], it is clear that the majority of patients with GI cancer (i.e., those 65 and older) are underrepresented. In another snapshot of recent accrual, Al-Refaie et al[3] noted that of the 244,528 patients (with melanoma, breast, lung, esophagus, gastric, liver, pancreas, colon, rectum, or anal cancers) in the California Cancer Registry between 2001 and 2008, a meager 0.64% enrolled in a clinical trial. The enrollment rate was even further reduced among blacks compared with whites (0.48% vs. 0.67%, p < 0.05). Of those who did enroll, 97% had some form of health insurance and 3% listed insurance as either none or unknown. During this same period of time, it was estimated that 29.5% of California adults were uninsured.[4] Clearly, lack of insurance has been a major barrier to accrual. In sharp contrast, in 2007, the United Kingdom reported 32,000 patients (14% of the annual U.K. cancer incidence) were enrolled in clinical trials.[5] In 2014, the number of patients enrolled has increased dramatically to more than 60,000.[6]

Even among those who are eligible and insured, access to a trial is not a certainty. Of the 4,617 patients enrolled in a clinical trial[7] at John Hopkins Medicine (2003 to 2008), 628 patients (13.6%) were denied trial enrollment because of refusal of insurance coverage. To date, these challenges remain, and they appear to be mounting given the arduous amount of additional work that is sometimes required of health care providers. With the approval of the Affordable Care Act (ACA), it is expected that there will be increased patient enrollment since insurance providers are required by law to provide for routine patient costs associated with clinical trials.[7]

Recognizing the inefficiencies inherent to NCI-sponsored cooperative group research, the Institute of Medicine prompted a reduction/merger of cooperative groups with the intention of reducing redundancy and expediting the design and conduct of clinical trials.[8] As per the NCI's Operational Efficiency Working Group (OEWG) report, this has made some initial effect in regards to reinforcing investigators to follow a tight timeline.[9] Yet, the reimbursement rate per patient enrolled (approximately $2,000 per patient) has not changed for over a decade. This results in a financial loss to the institution and is an additional disincentive to open and accrue to NCI cooperative group trials. Furthermore, the effect of U.S. government budge sequestration adversely affected all aspects of research development from bench to bedside.[10] With increasing costs of research, largely due to the limitations of drug accessibility, even pharmaceutical-sponsored studies are being referred overseas because of the reduced costs and rapid enrollment compared with the United States. For example, when surveying 20 of the largest U.S. pharmaceutical companies, it is reported that up to one-third of phase III clinical trials are being conducted overseas.[11-13]

Personalized (or precision) medicine adds complexity to clinical trial enrollment. Patients and oncologists are more frequently ordering molecular profiling of tumor samples, with the hope of finding an actionable target. Patients are

seeking treatment that is tailored to their cancer, and they may choose off-label agents as a result of such tests instead of enrollment in a clinical trial. Furthermore, numerous clinical trials are now selecting patients with specific, and often rare, mutations. Accrual to these studies can be very slow and expensive when an investigator has to screen 100 patients to enroll 3 in a disease where the actionable mutation occurs in only 3%.

THE PERSONAL TOLL: THE PATIENT PERSPECTIVE

Access to and the availability of clinical trials are paramount to patients with cancer. To what lengths would you go to save your own life? What would it mean to be told all approved medical treatment options have been exhausted for your type of cancer? From the patient perspective, as much as one would desire to labor under the assumption that "plan A" treatment will cure your cancer, discussing "plan B" could prove beneficial before completion of primary treatment. Initial treatment plans should include long-term strategies for cancer management, regardless of stage at diagnosis. Indeed, initial conversations with an oncologist should include clinical trials, even if no trial is available for that patient at that time. Concern about whether the prescribed treatments will work easily overshadows any quoted statistics. Additionally, efficacy of current treatment regimens is a moot point to the newly diagnosed unless it is 100%. (For example: if a treatment has an 80% efficacy rate, the patient will undoubtedly ask what happens if he or she has a disease that is part of the 20% failure rate.)

Knowledge about available clinical trials offers a sense of preparedness that helps to fulfill a basic human need: safety. Physicians should not assume that patients will know what clinical trial options exist for their disease and thus proactively ask physicians about them if they are interested in enrollment. Even if that was the case, discovering and proficiently navigating clinical trial search engines proves difficult under the best of circumstances. Discussing clinical trial options with patients serves a dual purpose. First, it displays the physician's confidence in clinical trials as a viable treatment option, which serves to nourish the patient's precarious safety needs. Second, rapid and educated decision making is often critical for patients diagnosed with aggressive and/or rare cancers, and this requires proficiency in deciphering the current active clinical trial library. Cross referencing data for trial drugs also would be helpful to patients who want to explore every treatment avenue. Access to clinical trials for patients with any type of cancer— common or rare, primary or recurrent—is vital. The words "you have cancer" are life altering. Coupled with advanced staging or rarity, those words are life threatening. Improved access to and availability of clinical trials with promising drugs or treatment regimens do more than just satisfy enrollment numbers, they offer hope. And hope is essential for patients with cancer.

PROPOSALS FOR IMPROVEMENT: THE PATIENT ADVOCATE PERSPECTIVE

Most patients with cancer are diagnosed in a community setting. It is imperative to create a culture of research in which an oncologist is expected to discuss trials with patients, enroll or refer them when appropriate, and do so with minimum disruption to their practice while taking pride (and perhaps even a marketing advantage) in participating in a larger research effort.[14] Establishing an infrastructure that support trials conducted in the community is essential.

Clinical researchers need to design trials for real-world patients; trials that match the demographics of the disease and trials that can be conducted in a community setting. Eligibility criteria designed for phase I trials of cytotoxic chemotherapy should be simplified and loosened for phase II and III trials, especially for treatments that do not include cytotoxic chemotherapy. Published literature of rare cancers is largely based on retrospective single institution studies or database reviews. Allowing enrollment of patients with select rare diseases into common cancer trials would allow otherwise ineligible patients to have access to treatment and would provide additional prospective data for rare diseases. This methodology has already been accepted by the Gynecologic Oncology Group (GOG); patients with primary peritoneal cancers are allowed to enroll in ovarian cancer trials. GI oncologists have agreed to include gall bladder cancers in trials for cholangiocarcinomas. Therefore, why not include appendiceal and small intestinal adenocarcinomas in metastatic colorectal trials or ampullary tumors in pancreatic cancer trials? Studies can be powered for the primary endpoint of the more common tumor (if necessary). We do not pretend that appendiceal adenocarcinoma is the same as colon adenocarcinoma, yet, in the absence of data, we tend the treat them the same off protocol. Therefore why not gather some data on protocol?

Dramatic improvements in small subsets of molecularly defined lung cancers using targeted therapies have demonstrated the feasibility of this approach. However, will we ever be able to conduct a randomized trial in the 10% to 15% of gall bladder cancers that are HER2/*neu*-positive?[15] The proliferation of gene sequencing and other assays intended to detect specific molecular vulnerabilities in cancer have resulted in too many "one-off" experiments. That is, a nonprotocol patient who gets a test result suggesting that a drug might be useful, based on either preclinical experiments or clinical experience in another disease, might then respond or not respond to that drug, but that data is never (or seldom ever) added to a database. The pharmaceutical industry and the NCI have created basket trials that are agnostic of tumor site of origin and accrue to treatment arms based on molecularly defined targets. These basket studies are methods of discovery and not likely paths to U.S. Food and Drug Administration approval of a drug for a specific target.

Disease-specific, molecularly targeted therapies can only occur in more common cancers. BATTLE and ISPY trials for lung and breast cancer, respectively, offer disease-specific options in targeted therapy design that could be adopted in

colorectal cancer. Indeed there are plans to open an NCI-sponsored ASSIGN trial to test targeted agents in molecular subsets as second-line therapy of metastatic colon cancer. Although critically important to finding and validating new targeted agents for colorectal cancer, the difficulty in getting such a trial activated is daunting and would still leave the many other GI sites lacking this level of trial access.

Although studies have shown that the cost of care for patients in cancer clinical trials is not substantially greater than the costs of routine care, insurance[16] companies have not universally embraced clinical trials as a component of standard care for patients with cancer. Legislative efforts such as SB37 in California have mandated that insurers pay for the routine care costs for patients to participate in a clinical trial and cannot deny access to a trial. However, loopholes exist. Nearly 30% of California adults are uninsured, which makes us hopeful that ACA will provide coverage for and access to clinical trials for those who were previously uninsured.

In the 2014 *ASCO Educational Book*, the use of social media to improve clinical trial accrual was discussed.[17] Another creative use of the Internet is crowd sourcing for feedback on how to improve the design and accrual of a particular clinical trial. Leiter et al[18] used a Web-based platform that allowed participants to comment on the design of a clinical trial using metformin in prostate cancer. Hyperlinks were posted to social networking sites. The platform was available for 6 weeks, and this crowd-sourcing exercise resulted in 9 changes to the protocol, 4 of which were major changes. Certainly the potential of the Internet and social media to improve awareness of and accrual to trials remains relatively untapped.

Patient advocacy groups may positively influence clinical trial accrual. The Pancreatic Cancer Action Network (PANCAN) has reported that although only 3% of patients with pancreatic cancer in the United States enroll in trials, 16% of those patients have called a help line to participate in clinical trials. Although an obvious selection bias favors patients and families who want more information, we would contend that the effect is real and that PANCAN's advocacy for trials has an effect, even if not five-fold in magnitude. Sadly there are relatively few support groups for other GI sites and none of the size and financial power of those for breast and prostate cancer. However, if there could be a coalition of GI-minded advocacy groups to make clinical trial accrual a priority, we might hope that a similar improvement in accrual might occur.

Trials such as BATTLE, ISPY, and, hopefully, ASSIGN should be encouraged and supported. Novel design methodologies might make such trials easier to complete with fewer patients needed to achieve clinically relevant endpoints. The PANGEA trial[19] for gastroesophageal cancers is one such novel design that merits further attention.

In GI malignancies, the only molecular tests that have been validated to affect patient outcomes would be *RAS* testing for metastatic colorectal cancer, HER2/*neu* for metastatic gastric cancer, and microsatellite-instability (MSI) for stage II colon cancer. All other molecular tests should be the subject of further study. The plethora of molecular testing for cancer approved under the Clinical Laboratory Improvement Amendments of 1988 regulations is not linked to any accountability. Patients and oncologists alike, in good faith, may order such tests to be told that a drug seems like a good match for the genetic alteration "y" in the patient's tumor, but rarely are there data to support a clinical benefit of receiving that drug in that particular setting. We should find a way to encourage/mandate that any physician who orders a molecular profile (outside the confines of the examples listed above) should also obtain consent from the patient to review and discuss the results of the profile, and if a treatment is administered purely on the basis of the molecular testing, that the response to that therapy is registered anonymously in a database available to all researchers. The establishment of such a database could be a source of discovery and aid in the design of clinical trials to validate promising results. Currently, the patient may or may not respond, but that information is lost to a future generation of patients with cancer who might have benefited from that knowledge.

CONCLUSION

As academic oncologists, we know how rigorous the scientific methodology must be to prove a treatment is beneficial. As a community of providers, patients and families, we know all too well the emotional and physical toll a cancer diagnosis takes. The price of neglect is too high. Together we must find ways to increase access, improve design, and speed completion of clinical trials—for the good of all.

I Will Recommend a Clinical Trial—If I Can

William M. Sikov, MD, FACP

You have completed your examination and have left the patient's room to let her get dressed while preparing to sit down with her and her partner to discuss her diagnosis, stage, prognosis, and treatment recommendations. With the patient's permission, a second-year medical resident will sit in on this discussion. As you wait, you run through what you are planning to say, especially about her standard treatment options and about a clinical trial for which she appears to be eligible—a randomized study that could answer important questions about the treatment of her disease. You tell the resident that the doctor's role in suggesting and explaining a study to a patient is vital, even though the research staff will do much of the work if the patient agrees to consider the study. But you can only succeed if you try. Albrecht et al, studying interactions between oncologists and patients and their families at two comprehensive cancer centers, found that clinical trials were offered to patients only 20% of the time, but, when offered, 75% of patients agreed to participate.[1] In a telephone survey of 1,000 adults, 32% of responders said they would be very willing to participate in a cancer clinical trial if asked and another 38% indicated that they would be inclined to do so.[2]

Unfortunately, scenes like this could well become much less common for many medical oncologists, especially those who work at smaller academic cancer centers, community hospitals, and private practices, where the vast majority of Americans receive their oncologic care. Many sites that have been involved in clinical research for decades are finding it increasingly difficult to gain access to clinical trials that they can offer to more than a minute fraction of their patients. Why is this? Certainly there is no dearth of important questions to address regarding the management of many common cancers. In the past, many of the larger trials in which patients participated originated with the site's cooperative group; the creation of the Clinical Trials Study Unit (CTSU) offered the opportunity to enroll patients on phase II and III studies conducted by other groups. Many institutions and practices have supported their staff's participation in the groups, covering the costs of membership and travel to attend group meetings and accepting a reduction in "productivity" so that the site can contribute to the research effort.

You know that this part of the conversation can be disconcerting for the patient; she was referred to you because of your knowledge and experience, not to have such an important decision made by a computer, by a flip of a virtual coin. Why open this can of worms? You are already 40 minutes behind schedule, and the study discussion is bound to add at least 30 minutes to this visit. It is certainly not for the money; with the exception of a few well-funded pharmaceutical company–sponsored trials, your protocol office actually loses money on a per-accrual basis. It is not for the "glory"—there is no way your site will enroll enough patients on this large study to be given authorship credit, and, in the academic scheme of things, clinical research is a poor relation. You know the statistics, which you share with the resident—how few patients are candidates for available trials despite efforts to liberalize eligibility criteria, how few are offered the chance to be part of a trial, how few agree to participate (less than 5% of adult patients with cancer enroll in clinical trials, in comparison to more than 60% of children with cancer), and how many studies fail to meet accrual goals or take years longer than planned to answer the important questions they address. How many axillae were unnecessarily dissected because it took so long to complete ACOSOG Z0011?

The accomplishments of the U.S. cooperative groups in advancing the understanding of and improving outcomes for many different types of cancer should not be underestimated (see summary by Schilsky[3]); if you scan the lists of plenary and oral abstract presentations at the American Society of Clinical Oncology's Annual Meetings, or any other major national meeting over the past 2 decades, you will see ample evidence of their effect, despite being level-funded since 2003 (which has the effect of reducing available funding by a few percent every year, given inflation), and over the past few years, many presenters have reminded us of this origin for their practice-changing trials. Still, there is no doubt that they could have been more productive and efficient and that there were costs associated with their conduct that could be re-

duced, and thus it was no surprise when the Institute of Medicine report "A National Cancer Clinical Trials System for the 21st Century: Reinvigorating the NCI Cooperative Group Program" produced at the request of the National Cancer Institute (NCI), recommended major changes designed to improve the cooperative group system.[4] Many in the cooperative groups applauded the recommendations, which included providing additional funds to help the groups modernize systems and increase patient and physician incentives.

You know that the patient and those closest to her simply want to know what is best for her, not for some faceless stranger in the future, and admitting that we do not know what is best is difficult. You know that random selection, fear of receiving a placebo, and fear of developing any of the long list of potential side effects listed in the consent form (even if the list of side effects for the standard treatment is just as long) are among the greatest barriers to clinical trial participation.[5] As you explain to the resident, it is a delicate balance. If you come across as too enthusiastic about the experimental approach, it may seem that you are trying to "sell" the study and could lead the patient to believe that she would be getting inferior treatment if she is randomized to the control arm, so why do not you just give her the "better" treatment? You remind yourself of how often what some experts were sure was a major advance—such as bone marrow transplants for breast cancer and MACOP-B instead of CHOP for diffuse large cell B-cell lymphomas—proved to be no better and only more toxic when the randomized trials were finally completed.

Instead of using the Institute of Medicine report to support their efforts to lobby Congress for additional funds for the clinical trials program, the NCI leadership chose a different direction. While announcing plans to support upgrades in information technology, centralized laboratories, and biospecimen tracking, they compelled the existing cooperative groups to consolidate and announced reductions in overall accrual, achieved in part by eliminating sponsorship of studies with an accrual goal over 1,000. The NCI's decision essentially leaves the field of larger, randomized clinical trials to the pharmaceutical companies, which suggests that the only studies done will be those designed to support the approval of costly new therapies. The NCI's stated intent is to use its limited funds to sponsor early phase trials designed to test biomarker-driven hypotheses,[6] which by definition will be limited to the small subset of patients whose tumors test positive for a potentially targetable mutation. This strategy is designed to look for large differences in outcomes instead of incremental improvements rendered statistically significant by sheer size. While not questioning the value of this approach for hypothesis-testing in biologically defined patient subsets, it leaves scant resources to answer clinical questions that will not benefit a pharmaceutical sponsor, such as comparing two regimens comprised of generic drugs or determining if a biologically defined patient subgroup might do better without or with briefer exposure to a costly and/or toxic treatment that is the current standard of care.

You dread hearing "I do not want to be a guinea pig," because it makes you want to scream that none of your patients are guinea pigs and that giving a patient an investigational treatment—no matter how promising—before it has been proven to be more effective and/or less toxic in with a well-designed and well-conducted clinical trial would be inappropriate. Instead, you calmly tell them that it is only because patients like her agreed to participate in past studies that we have been able to define our current, yet admittedly imperfect, standard treatment. And when they ask you, "What would you do if she were your wife or partner?" you can honestly answer that you would support participating in the study. You can also say, to patients who are members of an ethnic minority, that it is important that a variety of ethnic groups take part in the study, to make sure that its results are broadly applicable and to identify any differences in disease biology and treatment effect; close to 90% of patients who enroll in NCI-sponsored clinical trials are white, of whom less than 6% are Hispanics/Latinos.[7] There may be the added challenge of overcoming suspicions as to the beneficence of the clinical trials process based on a few infamous historic precedents, such as the Tuskegee syphilis study.

In addition, except for the 30 Lead Academic Participating Sites (LAPS), which under the new system receive additional funding to support their clinical trials program, financial support for participating in NCI-sponsored studies remains inadequate. After spending the last 20 to 30 years training the next generation of medical oncologists, radiation oncologists, surgeons, etc., to revere the randomized clinical trial and encouraging cancer programs to hire research staff, the rug is being pulled out from under their feet. To maintain these research programs will require even greater dependence on pharmaceutical company–sponsored studies. To expand and diversify their study portfolios, cooperative groups have established or expanded affiliated "foundations," which hope to compete with contract research organizations with the promise of improving the science associated with these trials; it is too early to know how successful these efforts will be. And although many of the pharmaceutical companies have been generous in supporting investigator-initiated studies that may never lead to drug approval or label expansion, to what extent this will continue is unclear.

You will have to explain that participating in a study may require additional office visits, blood tests, scans, questionnaires, blood and/or tissue samples, in some cases even additional biopsies, for correlative research studies. New ways of analyzing patients and their cancers promise to revolutionize our understanding of and, hopefully, treatment for her cancer, offering the hope of truly personalized oncology, but only if studies are completed that demonstrate a correlation between these findings and patient outcomes. You comment to the resident that maybe we should make it easier to enroll in studies, or harder to refuse them. In some countries the only way to get a standard treatment is to participate in a study, but fortunately that is not often the case in the United States. Of course it is easier to accrue if the only way to get a promising investi-

gational treatment is on trial, such as in the adjuvant trastu-
zumab studies. Would it not be easier if consent forms were not
20 or more pages long, with interminable lists of potential (if
rare) side effects? Do we really expect our patients to read and
comprehend such a lengthy document, even if (supposedly)
written at an eighth-grade level?

So what can or should we do about the direction of the U.S. clinical trials system? I agree with those who have spoken in favor of a publicly funded clinical trials system,[3,8] and I do not expect or want the NCI leadership to reverse direction on the value of precision medicine trials. Although that initiative is important, I would like to believe that we can walk and chew gum at the same time; that is, conduct those smaller-focused studies without relinquishing the ability to pose pertinent questions that require much larger trials to answer. So we should lobby our congresspeople and senators to increase funding to the National Institutes of Health that is earmarked to the cancer clinical trials program, perhaps even specified to go toward larger trials, some of which may be designed to determine if we can reduce the toxicity and cost of treatment without reducing its efficacy. We could make the argument that a relatively small investment in such studies could potentially save the system a great deal more. As an alternative to government spending, we should encourage philanthropies like the Conquer Cancer Foundation to consider trying to enlarge their donor base by offering individuals and foundations the opportunity to step into this gap and help fund large, simple trials that address important questions. Such trials could be run on, relatively speaking, a shoestring budget, with sites making up for low per-case funding with higher accrual, and reducing costs by collecting only key outcomes and toxicity data and minimizing costs by holding study group meetings via the Web.

We could even explore creating a virtual tissue bank, where samples are held at the treating institutions and sent to a designated research facility only when requested.

It boils down to understanding the importance of your role
as the patient's physician and advocate, even if it is the first
time you have met. If you truly believe that participating in the
study could be her best option, you can also acknowledge that
an important reason why you take the time to do this is so that
when you, or another physician, perhaps even that resident, sit
down with a patient like her in 5, 10, or 20 years you will be
able to say whether treatment A is better, equivalent to, infe-
rior to, or less or more toxic, than treatment B. In the end,
when the results of this study have been presented and pub-
lished, you can both be proud to have been part of the process.

That is, assuming you still have sufficient access to trials to offer to her and your other patients.

OVERVIEW

Genomic studies have shown that large numbers of candidate targets are observed in breast cancer. Nevertheless, only a few of them are validated as relevant targets in clinical studies. Estrogen receptor (ER) and HER2 expressions could be associated with a level I evidence. Beyond ER and HER2, *BRCA* and *PIK3CA* mutations (when targeted with alpha-specific PI3K inhibitors) could be considered as promising targets in breast cancer since they have been associated with objective responses in phase I/II trials. In addition to these four molecular alterations, several others have shown promising results in preclinical studies and are being investigated in clinical trials. These genomic alterations include *AKT1*, *ERBB2*, and *ESR1* mutations. These considerations highlight the lack of evidence for using multiplex technologies to individualize therapy in metastatic breast cancer. Sequencing multiple genes to treat metastatic breast cancer is very promising but should be done in the context of clinical trials, either to enrich phase I/II trials in patients with genomic alterations or to show medical usefulness of new biotechnologies like next-generation sequencing (NGS). Although most current approaches of precision medicine are aiming at targeting drivers, additional applications could be developed in the future. This includes the identification of DNA repair deficiencies, mechanisms of immune suppression, and identification of minority lethal subclones. Finally, one of the very promising applications of genomics for metastatic breast cancer is the identification of pathway activation or defects at the individual level. For example, gene expression and single nucleotide polymorphisms (SNP) signatures are being developed to detect kinase (such as mammalian target of rapamycin [mTOR]/CDK4) activations or DNA repair deficiencies.

Molecular studies have shown that breast cancer includes a large number of subgroups defined by the presence of a specific genomic or protein alteration. ER expression was the first validated target in breast cancer, leading to the optimal development of endocrine therapy.[1] In the late 1990s, HER2 overexpression was validated as a target and was shown to be a predictive biomarker for the efficacy of trastuzumab.[2] During the 2000s, genomic analyses based on gene expression arrays suggested that breast cancer could be divided into four different subgroups: luminal A, luminal B, HER2-enriched, and basal-like.[3-5] Further studies have suggested that basal-like cancers can be subdivided into six subgroups.[6] More recently, studies on NGS have suggested that approximately 40 genomic alterations can be found in primary breast cancers.[7,8] Overall, this introduction emphasizes that each single breast cancer presents a specific molecular profile and specific molecular mechanisms of cancer progression. Parallel to the advances in the understanding of disease biology, several advances in technology could dramatically change patient care. Indeed, it has been shown that high-throughput DNA sequencing together with comparative genomic hybridization (CGH; copy number analyses) can be performed robustly in the clinical practice.[9,10] This has led to the development of precision medicine that involves multiplex molecular analyses to identify molecular mechanisms of cancer progression in each individual in order to improve treatment. In the following review, we present the current state of this approach in metastatic breast cancers (mBC). Several technologies are available to identify genomic alterations in individuals. First, sequencing allows for the detection of mutations. Sanger sequencing, the original method of sequencing, is an approach that allows analysis of only a few genes at the same time. NGS allows sequencing large number of DNA bases in a single run. This latter technology allows multigene sequencing for precision medicine purposes. In some specific platforms and conditions, NGS can also allow quantifying gene copy numbers, although CGH array or fluorescence in situ hybridization analyses are usually better for this purpose. Finally, gene expression array and reverse transcription polymerase chain reaction quantify gene expression. More recently, RNA sequencing is being developed to assess gene expression, translocations, and mutations.

LEVEL OF EVIDENCE SCALE FOR DRUG TARGETS

NGS and other high-throughput technologies analyze several hundred or thousands of genes in the same assay. These technologies can identify many genomic alterations in each patient. Nevertheless, only a few of them are truly implicated in the disease progression. A level of evidence scale that ranks

targets according to their relevance has been developed to facilitate interpretation of these high-throughput assays, better communicate results to patients, and prioritize research needs.[11] Level I evidence includes molecular alterations that have been shown to be validated targets, either based on phase III trials or several large phase I/II trials. Level II evidence includes molecular alterations associated with response to treatment in small or unique phase I/II trials. Level III molecular alterations include those that have been considered as promising targets based on preclinical studies. Finally, level IV evidence includes genomic alterations that are selected based on bioinformatics analyses only, without biologic studies to support them. This level of evidence scale also makes a difference according to whether the molecular alteration has been investigated in the same disease and whether studies included negative controls (evidence that patients without the alteration do not derive benefit from the targeted therapies). This level of evidence scale does not evaluate the medical usefulness of targeting the molecular alteration (benefit as compared with standard of care), but the antitumor activity obtained by targeting it. In the next sections of this article, we will use this level of evidence scale to classify molecular alterations in breast cancer. From this analysis, we will further discuss the current positioning of multiplex assay to treat patients with breast cancer.

MOLECULAR TARGETS AND THEIR RESPECTIVE LEVEL OF EVIDENCE IN BREAST CANCERS

Molecular alterations can be divided between drivers, mechanisms of resistance, mutational process and DNA-repair defects, immune alterations, cell death, angiogenesis, and metabolism. These latter three systems will not be discussed in the present article. The list of the most investigated molecular alterations and their level of evidence are reported in Table 1.

Oncogenic drivers can be defined as molecular alterations involved in malignant transformation and cancer progression. Targeting a driver is expected to lead to tumor shrinkage (known as oncogene deaddiction). As mentioned in the introduction, the two historic drivers include ER expression

KEY POINTS

- Only a few molecular alterations are validated as targets in breast cancer (specifically ER and HER2 expression).
- Driver identification in breast cancers includes DNA-based analyses but also detection of pathway activation and dependency (e.g., ER, mTOR, and CDK4).
- Driver identification is not the sole application of genomics to personalize therapy for metastatic breast cancer.
- There is no evidence that using multiplex genomic testing for metastatic breast cancer improves outcomes.
- Ongoing trials are evaluating the medical usefulness of next-generation sequencing in metastatic breast cancers.

TABLE 1. Potential Applications of Genomics for Metastatic Breast Cancers

Application of Genomics	Optimal Technology	Targets	Level of Evidence Associated with the Target[11]
Drivers (DNA)	Next-generation sequencing if multiple genes validated	ERBB2 amplification	I
		PIK3CA mutations	II
		AKT1 mutations	III
		ERBB2 mutations	III
Drivers (RNA/ proteins)	Gene expression Phosphoprotein assays	ER expression	I
		mTOR activation	ND
		CDK4/6 activation	ND
Lethal subclone	Ultra-deep sequencing Circulating DNA	ESR1 mutations	III
DNA repair	Targeted sequencing Whole-exome sequencing SNP arrays	BRCA1/2 mutations	I/II
Immune system	Whole-exome sequencing RNA sequencing	PD-L1 overexpression	ND
		Neoantigen	

Abbreviations: ER, estrogen receptor; mTOR, mammalian target of rapamycin; ND, not determined; PD-L1, programmed death ligand 1.

and *ERBB2*-amplification. These two targets are associated with level I evidence. Additional candidate molecular alterations are being investigated in breast cancer. These alterations should be divided between DNA-based assays and pathway-based assays. At the DNA level, there are between 10 to 20 genomic alterations that are currently the targets of drug development.

PIK3CA mutations are observed in approximately 25% of breast cancers, mainly those with ER or HER2 expression.[12] PI3K activates AKT1 that subsequently activates mTOR. AKT1 also interact with pathways that do not relate with mTOR, including FOXO, BAD, and GSK3. Several drug families target PI3K/AKT/mTOR pathways, including mTOR inhibitors, AKT inhibitors, nonselective PI3K inhibitors, and alpha-selective PI3K inhibitors. In an ancillary study of the BOLERO2 trial, *PIK3CA* mutations were not predictive for the efficacy of mTOR separate inhibitors in ER-positive/ HER2-negative breast cancer.[13] Nonselective PI3K inhibitors target most of the PI3K subunits and thus present a narrow therapeutic index. These drugs can therefore achieve modest PI3K inhibition. This could explain why nonselective PI3K inhibitors have shown mitigated results in phase II randomized trials.[14] Conversely, alpha-selective inhibitors are very potent inhibitors of alpha subunit, a major player of PI3K activity in cancer. Interestingly, phase I studies using alpha-selective PI3K inhibitors have shown extremely encouraging results in patients who with *PIK3CA* mutations, suggesting that PIK3CA mutation could be a relevant target in mBC.[15,16] This genomic alteration should be ranked level IIa. Activating *AKT1* mutation is the other genomic alteration located in

the pathway. First, *AKT1* mutations occur in approximately 3% of breast cancers. These alterations are oncogenic in preclinical models and have been associated with objective response to mTOR inhibitors in molecular screening programs.[10] Ongoing studies are investigating the efficacy of AKT inhibitors in patients with this genomic alteration. Although some retrospective analyses suggest oncogene deaddiction in patients with *AKT1* mutations, this target is still considered to be a level III target.

FGFR1 amplifications occur in approximately 10% of breast cancers, mainly those with ER expression. This alteration has been associated with very promising results in preclinical studies.[17] Nevertheless, treatment with highly specific and bioactive FGFR inhibitors failed to demonstrate antitumor activity in phase I trials.[18] Interestingly, multikinase inhibitors like lucitanib were associated with promising antitumor activity in patients presenting *FGFR1* amplifications,[19] but whether this antitumor activity relates to FGFR inhibition is unclear. *FGFR1* amplification could be associated with level III evidence as a target. *CCND1* is amplified in approximately 15% of breast cancers. This amplification is not clearly associated with CCND1 expression, and clinical studies have failed to validate that CCND1 amplification are relevant targets in breast cancer.[20] Finally, the last interesting target located on tyrosine kinase is *ERBB2* mutations. These mutations have been shown to be activating mutations and to be associated with antitumor activity of neratinib, a HER2 inhibitor.[21] Phase II trials are ongoing. This target is currently considered as level III evidence but could jump to level I if consistent studies report high levels of antitumor activity for neratinib in this genomic segment.

Besides alterations at the DNA levels, assessing pathway activation and dependency could provide relevant information about driving forces of cancer progression. To illustrate, ER expression drives cancer progression in ER-positive breast cancer, although no alteration is usually detected at the DNA level. This emphasizes the relevance of assessing pathway activation in breast cancer. The Cancer Genome Atlas data have suggested that PI3K/AKT/mTOR and CDK4/Rb pathways are the two most relevant targetable pathways in breast cancer. Gene expression signatures could provide information about activation status of these pathways, together with assessment of phosphoproteins. For example, in the BO-LERO3 trial, biomarker studies showed that activation of mTOR (specifically PS6K) is associated with high sensitivity to everolimus.

Emergence of lethal subclone is a well-described mechanism of resistance to targeted therapies. In patients with lung cancer, it has been well documented that T790M mutations, although the minority at the time of diagnosis, become predominant after resistance to EGFR inhibitors.[22] In breast cancer, a similar phenomenon is being observed with *ESR1*. *ESR1* is the gene that encodes for ER. Although less than 1% of early breast cancers present mutations, it is considered that between 10% to 30% of breast cancers resistant to aromatase inhibitors will have a hotspot mutation thus leading to ligand-independent activation of the receptor.[23,24] It has been suggested from preclinical works that high-dose fulvestrant could present some antitumor activity in this subset of patients. Several new ER degraders like GDC-0810 are being developed in this setting (NCT01823835). Until now, this target is classified level III. There are several questions surrounding this genomic alteration that could have some clinical influence. First, as opposed to T790M, this mutation has not yet been reported in a minority subclone in a primary tumor. Finding the *ESR1* mutation in a minority clone in a primary tumor would open the path for the development of ultra-deep sequencing to detect them and potentially treating them very early during the disease course. Second, the use of circulating DNA could help detect these mutations during the disease course and treat them early. Finally, one study has suggested that *ESR1* mutations could be associated with very poor outcome. If validated, this finding would suggest that this genomic segment would deserve some fast-track approvals based on phase II data.

The third application for genomic tests is the identification of DNA repair defects and mutational processes at the individual level. Identifying DNA repair defects could lead to administration of personalized synthetic lethality strategies or specific genotoxic agents. The best example in breast cancer is provided by *BRCA1* and *BRCA2* mutations. When biallelic, *BRCA1* and *BRCA2* mutations and/or loss lead to homologous recombination deficiency and genomic instability. *BRCA1/2* mutations have been associated with sensitivity to PARP1 inhibitors (synthetic lethality) and DNA alkylating agents (genotoxic).[25] Interestingly in these trials, patients without *BRCA1/2* alterations did not present a similar degree of antitumor activity as compared with patients with mutations. Based on these consistent data from phase III and large phase II programs, *BRCA1/2* mutations as drug targets have a level I evidence.[11] The controversy in this area is more about how to position each therapeutic strategy (PARP1 inhibition and DNA alkylating agents) and to show medical usefulness over standard of care, rather than whether *BRCA1/2* mutations constitute a target per se. The second controversy is about whether some functional tests evaluating homologous recombination deficiency (HRD) could have better performance than detecting *BRCA1/2* mutations. HRD tests could have better performance either by selecting the right patient with the *BRCA1/2* mutation or by identifying patients with BRCA1/2 wild-type who present with HRD. When assessed retrospectively, the HRD test developed by Myriad was not associated with a differential sensitivity between platinum and docetaxel. The HRD test developed by Clovis has been associated with sensitivity to the PARP inhibitor rucaparib, even in the absence of *BRCA* mutation.[26] An ongoing phase II trial (RUBY) is testing whether rucaparib could present antitumor activity in patients with BRCA1/2 wild-type who present a high HRD. Beyond HRD and BRCA, assessing other DNA repair genes or pathways could allow expanding the array of patients who could be eligible for synthetic lethality strategies. ATM and ATR mutations are observed in approximately 2% of breast cancers and could define a subset of patients eligible for synthetic lethality approaches. In terms of pathways, several studies have suggested that the mutational pattern detected by whole-exome sequencing could allow for defining which DNA repair pathway is

altered in each individual.[27] This could potentially lead to the use of whole-exome sequencing to individualize synthetic lethality approaches for patient treatment.

Finally, the fourth potential application field of genomics to individualize therapy is immunology. Genomics could allow detecting neoantigens and expression of ligands for immune checkpoints,[28] but also test the competence of the cancer cell to present antigens and to be killed. Recent data obtained in metastatic triple-negative breast cancer suggest that anti-PD-1 antibody could present some antitumor activity.[29] Finally, genomic tests could evaluate whether the host could generate an antitumor immune response following immunogenic cell death.[30] For example, *TLR4* polymorphisms confer lack of immunogenicity and have been associated with resistance to anthracyclines in patients with breast cancer.[30]

CLINICAL DEVELOPMENT OF PRECISION MEDICINE IN METASTATIC BREAST CANCER: WHICH TECHNOLOGY? WHICH SAMPLES? WHICH TRIALS?

As discussed in the previous section, there are large numbers of applications for genomics to better treat patients in the metastatic setting. Each application deserves a specific technology and it is important to define which technology will be developed for which purpose. Current approaches of precision medicine aims at identifying drivers at the DNA level. For this purpose, sequencing is the best technology. Whether sequencing should be based on Sanger technology or should consist in NGS depends on the number of genes to be tested. An important aspect of breast cancer is the high number of copy number alterations that could potentially drive cancer progression. Assessing gene copy numbers requires fluorescence in situ hybridization technology for a single or a few genes, or CGH/SNP arrays for a large number of genes. Interestingly, some centers can now robustly assess copy number using NGS technology.[9] This therefore makes this technology a preferred choice for clinical research programs that aim to identify drivers in mBC. Alternatively, circulating DNA could be useful when biopsies are not feasible. As mentioned previously, assessment of pathways activation could be done by gene expression arrays, reverse transcription polymerase chain reaction, or phosphoprotein assays. Other technologies could be dedicated to specific purposes of clinical research. First, ultra-deep sequencing could be an interesting approach to detect minority clones, and circulating DNA could be an interesting approach to detect the appearance of resistance. SNP array could be interesting to quantify HRD. On a long-term perspective, one could argue that the best approach to personalize therapy will be to apply whole-exome sequencing to hard-to-treat mBC. Whole-exome sequencing offers the advantage of detecting both drivers, DNA repair defects and neoantigens.[28] Finally, RNA sequencing could offer the advantage of detecting pathway activation and target expression.

One field for controversy is which sample should be used for target identification in patients. Primary tumors offer the advantage of being accessible and not requiring additional biopsies. Nevertheless, several studies have shown that targets can be lost or gained during the disease evolution.[31] More recently, evidence has been reported that targets acquired during the disease course—although not trunk alterations— could drive cancer progression.[32] This emphasizes the need to assess genomic and molecular targets at the time of treatment decision and start. Assessing cancer biology at the time of treatment decision would need to perform biopsies of metastatic sites. Whenever this is feasible, biopsy of metastatic sites should be the priority since it allows assessing genomic alterations but also RNA and protein expression together with immune markers. Nevertheless, if the tumor site is difficult to biopsy or in case of bone disease, circulating DNA could be a possible alternative.

Until now, there has been no data to support the use of DNA- or RNA-based technologies in daily practice for patients with mBC. Several nonrandomized trials have been performed but they did not provide a clear picture about the potential medical usefulness of precision medicine for breast cancer. In the SAFIR01 trial,[10] approximately 28% of the patients presented evidence of antitumor activity but only 10% had an objective response. These numbers align with phase I/II trials that tested drugs without molecular selection. In a clinical trial testing gene expression, Von Hoff et al reported that a group of patients had their progressive-free survival prolonged under genomic-based therapy.[33] Nevertheless, this trial did not have a control group with patients treated with the same treatments but not driven by genomics. Outside of these two trials, there is no large study reporting efficacy of genomics in mBC, and therefore, with the exception of prospective clinical trials, multiplex approaches cannot be recommended for routine practice.

The next question is how to provide evidence that the use of genomics improves outcomes in patients with mBC. There are two possible strategies to address this question. The first strategy consists of prospectively validating each target in large clinical trials. This strategy is currently being used in most of the clinical programs in breast cancer. For example, HER2 inhibitors are being developed in patients with ERBB2 mutations, PI3K inhibitors are being developed in patients with PIK3CA mutations, AKT inhibitors in patients with AKT1 mutations, and so on. This approach will lead to the clinical validation of several genomic alterations. Once the number of such genomic alterations is large enough, companion diagnosis will very likely switch from Sanger single-gene sequencing to NGS. The second approach will consist of the clinical validation of a multiplex approach. In this design, the trial does not aim to validate each genomic alteration, but to test the hypothesis that using a multiplex technology improves outcomes. For example, the SAFIR02 trial (NCT02299999) is testing the hypothesis that use of NGS and CGH arrays improves outcomes compared with standard of care.

MOVING TO RATIONALE COMBINATIONS

As previously mentioned, breast cancer is a complex disease in which each patient could present several altered genomic alterations and pathways. Therefore, there is a strong rationale to

combine drugs in the era of molecular medicine. There are three possible ways of combining drugs. First, drugs can be combined based on the presence of multiple genomic alterations. It has been suggested that multiple genomic alterations on drivers could be associated with resistance to therapy.[34] Combining drugs that target different genomic alterations could therefore lead to antitumor activity. This is the rationale to combine HER2 and PI3K inhibitors in patients with *ERBB2*-amplified, PIK3CA-mutated BC. The second rationale to combine therapies would be to target molecular processes in different systems. For example, *ERBB2*-amplified BC is associated with a high level of PD-L1 expression and PD-L1-induced immune suppression. There is therefore a rationale to combine HER2-inhibitors and anti-PD-1 in patients presenting *ERBB2*-amplified and PD-L1-induced immune suppression (PANACEA; NCT02129556). Finally, other combinations will aim at avoiding cancer cell adaptation. For example, cancer cells presenting a *PIK3CA* mutation can further adapt to PI3K inhibitors through CDK4 or mTOR activation. This provided a rationale to evaluate triple combinations therapy.

CONCLUSIONS AND PERSPECTIVES

A high number of gene or molecular alterations could be considered as actionable in breast cancer. Nevertheless, only a few of them (ER, HER2 expressions, and—to a lesser extent—BRCA and PIK3CA mutations) are currently validated as relevant targets. There is therefore no robust evidence that using a multiplex technology in mBC improves patient outcomes. Nevertheless, this approach could allow for accelerated drug development by detecting patients with genomic alterations and driving them to phase I/II trials. The current approach to validating genomics for mBC consists of testing drug efficacy in each genomic segment by validating each molecular alteration one by one. Since most of these genomic alterations are rare, there is a need to develop very large molecular screening programs. Several international screening programs have been set up recently including the AURORA program, developed by Breast International Group. Alternative development of precision medicine could consist of evaluating the overall effect of sequencing technologies in the whole population of patients with breast cancer, independently of each single alteration. This approach is being used in the SAFIR02 trial. Finally, one of the major challenges in the future will be optimally to implement these new technologies to secure access to innovations for all patients. To achieve this goal, the Institut National du Cancer has set up 28 public genomic centers in France that have a goal to offer access to genomic tests for free to all patients with cancer. This model, initially based on Sanger sequencing, is currently moving to NGS.

Surgery or Ablative Radiotherapy for Breast Cancer Oligometastases

Joseph K. Salama, MD, and Steven J. Chmura, MD, PhD

OVERVIEW

Precisely focused radiation or surgical resection of limited metastases resulted in long-term disease control and survival in multiple studies of patients with oligometastatic breast cancer. The integration of these ablative techniques into standard systemic therapy regimens has the potential to be paradigm shifting, leaving many patients without evidence of disease. Although an attractive treatment option, the utility of these therapies have not been proven in controlled studies, and improved outcomes may be because of patient selection or favorable biology alone. Ongoing studies continue to refine radiation techniques and determine the role for ablative therapies in the management of patients with metastatic breast cancer (MBC). Additionally, patient selection for metastasis-directed therapies is based on clinical criteria, with many not benefiting from therapies that may have substantial toxicities. Recent reports are beginning to uncover the biology of oligometastatic cancer, but much work is needed. Current and developing trials that integrate both clinical and translational endpoints have the potential to transform management strategies in women with limited MBC.

The use of novel surgical and radiotherapeutic techniques for the treatment of few breast cancer metastases has been gaining considerable interest.[1,2] For both patients and physicians, the treatment of limited metastases, rendering a patient without evidence of cancer and, potentially cured, is an exciting concept. However, despite single-institution studies demonstrating improved outcomes compared with historic series of patients treated with systemic therapy alone, there is a lack of evidence proving that this treatment approach will extend progression-free survival (PFS) or overall survival (OS) for some patients with breast cancer with limited metastatic disease. Herein, we will review the evidence supporting the treatment of patients with oligometastatic breast cancer with ablative (surgery or radiation techniques). We will review what has been described for selection of these patients and their follow-up. We will also comment on ongoing clinical trials that may help to elucidate some of these questions. Finally, we will review what little is known about the biology driving the oligometastatic state.

Breast cancer has long served as a model to understand the mechanisms underlying the biology of metastatic cancer. Based on clinical observations in the late 19th and early 20th century, Halstead described an orderly and direct spread of malignancy from the primary tumor to regional lymph nodes and then to directly connected metastases.[3] The increase in radical and ultra-radical en-bloc operations resulted from this philosophy, attempting to remove all evidence of cancer. The continued evidence of distant cancer dissemination despite aggressive sur-

geries suggested a need for alternative hypotheses. The systemic hypothesis of metastasis was first described by Keynes and perhaps articulated most clearly by Fisher.[4] It suggested that widespread dissemination of disease occurred before clinical detection of the primary tumor. Therefore, cancers were dichotomized into either those that were localized to the primary site or those that were widespread. If widespread, increasing aggressive surgeries to the primary tumor and regional lymphatics, would not improve patient outcomes. Rather, systemic therapies delivered adjuvantly or neoadjuvantly could reduce distant metastases and, ultimately, have been integrated into standard treatment regimens. However, based on the clinical observations that not all breast cancers were widely metastatic at initial presentation, and that some patients with metastases had long disease-free intervals after metastasectomy and without systemic therapy, an alternative hypothesis was called for.

Hellman advanced our understanding of the natural history of metastasis by elucidating the spectrum hypothesis[5] in which some breast cancers remain locoregionally confined, others metastatic at presentation, and the remaining subset progressing from locoregional confinement to widespread metastases. Soon thereafter, Hellman and Weichselbaum described the clinically meaningful oligometastatic state, arising as a corollary of the spectrum hypothesis, where metastases limited in number and destination organ are unlikely to progress rapidly.[6] This was based on successful surgical removal of metastases, reported by Weinlechner as early as 1882,[7] and long-term survival (1939) and cure (1947) after metastasectomy.[8] Whether arising de

novo at the time of diagnosis, or induced because of the effects of systemic therapy, patients with limited metastases present a potential opportunity to affect the natural history of MBC. In these patients, long-term disease control may be achieved with ablation of all known metastases. Identification of patients who could achieve long-term disease-free intervals after metastasis-directed therapy has the potential to shift treatment paradigms, in a similar way to curative intent treatment of women with breast cancer supraclavicular metastases.

It is not surprising that during the course of a century, different mechanisms underlying metastatic disease have been proposed. The disease that Hallstead saw on a regular basis, clinically detected locoregionally advanced breast masses, is now an uncommon presentation. More often than not, because of extensive education and screening efforts, patients present with relatively small breast cancers, often nonpalpable, with no adenopathy or involvement of lymph nodes and microscopic cells detected only with the aid of immunohistochemistry. Biologically, locoregionally advanced breast cancers and screen-detected breast cancers are different diseases. As the primary disease has changed, so might the behavior of the resulting metastatic disease. Similarly, with advanced imaging techniques such as high-resolution whole-body CT with or without PET and/or MRI, our ability to detect metastases is far greater than when investigations were limited to radiographic imaging at the time of clinically substantial symptoms. Just as we have developed different techniques to treat locoregional disease, so must we consider adapting the strategies that have been historically used for the treatment of metastatic disease.

INCIDENCE OF OLIGOMETASTASIS IN BREAST CANCER

Perhaps the first question that needs to be addressed is "how common are oligometastases in patients with breast cancer?"

KEY POINTS

- Oligometastases are a common presentation in many cancer types and are frequently represented in patients with breast cancer who are enrolled in clinical trials.
- Patients with oligometastases have a favorable prognosis compared to patients with more widespread metastases.
- Surgical complete resection of breast cancer metastases to the lung and liver in patients with oligometastases and long disease-free intervals have been associated with favorable survival compared with historical controls. Recent improvements in radiotherapy planning and delivery have allowed for the precise targeting of breast cancer metastases to any organ in the body with tumor control approaching that of surgical series.
- Data supporting use of surgery and/or ablative radiation are limited and primarily retrospective.
- Enrollment into ongoing prospective controlled studies is critical to determine if there is truly a benefit to either ablative radiation or surgical resection of all known metastases.

The true answer is that we do not know. The reason is that, up until recently, a diagnosis of metastatic disease was considered a dichotomous terminal event, with the number of metastases not considered to influence the eventual outcome or immediate treatment. Therefore, few studies have prospectively collected and reported the number of metastases at time of enrollment or metastatic diagnosis. More often, secondary analyses of prospectively (or retrospectively) collected data have sufficed to give us a hint at how often patients present with limited metastatic cancer.

From the available data, it appears that many, if not the majority of patients with MBC present with limited metastatic disease. Data from recently published first-line MBC trials, suggest that a large proportion of patients present with oligometastases, and those with fewer metastases have improved outcomes, as summarized in Table 1. Approximately 50% of patients enrolled in recent first-line MBC trials with differing estrogen receptor (ER) and HER2 status had less than two metastatic sites, and as many as 75% of patients with first-line MBC had less than four metastatic sites. The challenge of using these data is the definition of metastatic sites can be variable and may be interpreted by some to refer to individual metastases, individual organs, or organ systems (skeletal system). Despite this limitation, the data suggest that metastases are likely limited at presentation and not widespread, at least in patients who are considered candidates for prospective clinical trials. This is supported by analyses of large carefully followed breast cancer cohorts, where 17% of patients with early-stage breast cancer who progressed to metastatic disease presented with one to five metastases.[9] Interestingly, those who presented symptomatically with metastases were less likely to have oligometastases compared with those that were screen detected (14.5% vs. 26.7%; p = 0.22). These data are consistent with what has been described for other commonly occurring cancers, such as colorectal, prostate, and non-small cell lung cancer, which is reassuring if one assumes that there is some common underlying biology governing metastases.

WHAT IS THE BEHAVIOR OF PATIENTS WITH LIMITED METASTATIC DISEASE?

For the routine use of ablative therapies for patients with breast cancer with limited metastatic disease to be clinically meaningful, the rate of disease progression must be different in these patients than that of more widespread rapidly progressing cancer. Certainly, if the few detected metastases were the sentinels of an impending rapid spread of to come, then ablative therapy could not be a meaningful component of breast cancer management. What data that exist are limited and are often the same studies that describe the incidence of limited metastases. Therefore, to date, the level of evidence is not rigorous. However, the evidence that exists suggests that those who present with fewer metastases have a more protracted clinical course than those who present with more widespread metastases. Therefore, not all patients with lim-

ited metastases should be considered to be showing the tip of the iceberg of their disease.

It is, therefore, instructive that in a large group of women treated with anthracycline-based systemic therapy, those with one to five metastases (number of metastases not metastatic organs) had significantly improved survival outcomes compared with those with more metastases.[10] Specifically, the median survival for women with five or more metastases was 146 weeks compared with 96 weeks in those with six to 12 metastases, compared with 80 weeks in those with 13 to 20 metastases (p < 0.01). Interestingly, a long-term analysis of patients with stage I to stage III breast cancer followed after initial locoregional therapy, found no difference in the time of presentation of metastases between those who presented with one to five metastases and those with more widespread disease, both being about 29.9 months. However, patients with one to five metastases had significantly longer OS after progression than patients with more widespread disease (median survival of 107.7 vs. 22 months; p = 0.001). Furthermore, the 5-year actuarial survival for patients with limited metastatic disease was 59.6% compared with 11.6% for those patients with widespread metastases.[9] These limited data suggest that an oligometastatic population of patients with breast cancer exists, these patients are well represented in the populations of recent clinical trials, and have a unique biology with longer survival than patients with more widespread metastases. However, these data are usually limited to single-institutional series, and it is clear that more robust analyses are needed in larger datasets.

THE EVOLUTION OF TREATMENT
Long-Term Disease Control with Systemic Therapies Alone

Currently, the standard of care (SOC) for MBC, similar to many other cancers, is delivery of systemic agents in the form of cytotoxics, biologics, and/or hormonal therapies, when appropriate, with radiation and/or surgery reserved for the management of symptomatic, nonresponsive, or potentially catastrophic metastases. However, chemotherapy is curative in a remarkably small number or patients with MBC. An analysis of more than 1,500 women with MBC treated with doxorubicin and alkylating agent-based chemotherapy reported only 1.9% remained in complete remission and free of relapse at 15 years.[11] These women were more likely to be younger, have a good performance status, be premenopausal, and have fewer metastatic sites. Furthermore, of the 1.9% (30 patients) of women who were disease-free after chemotherapy, one-third had metastasis-directed therapy in the form of tumor debulking or adjuvant therapy including hepatic artery infusion, radiation, or surgery. Similar studies have confirmed the rarity and existence of long-term control of MBC when treated with systemic therapies alone.[12,13]

For selected patients with limited metastatic disease from multiple histologies, elimination of all clinically detected metastases in addition to standard systemic therapies, either surgically or via ablative radiotherapy, has been shown to result in long-term disease control with greater percentages of patients without evidence of disease compared with those treated with systemic therapy alone. Resection or radiation of pulmonary,[14,15] hepatic,[16,17] central nervous system,[18,19] adrenal,[20,21] and multiple organ metastases[22-24] has been associated with 20% to 25% long-term disease control in these selected patients.

SURGICAL REMOVAL OF PULMONARY AND HEPATIC BREAST CANCER METASTASES

When these data are restricted specifically to patients with MBC, surgical resection of liver metastases has been shown to result in promising median PFS (14 to 34 months) and OS (24 to 63 months), whereas, after removal of pulmonary metastases, median survivals have ranged between 32 and 97

months, and 5-year survivals have ranged from 27% to 80%.[2,25] To date, all of the reported studies have been retrospective, and, therefore, although hypothesis generating, they are not conclusive of the benefits of these therapies. In one of the largest retrospective analyses of patients with breast cancer undergoing pulmonary metastasectomy pooling data from more than 460 women from multiple international institutions with specialty in pulmonary resection for metastases, approximately 60% of the patients had a single pulmonary metastasis and approximately 10% had three or more metastases. The median survival for this cohort was 35 months. The cumulative 5-year survival rate was 35%, the 10-year survival rate was 20%, and the 15-year survival rate was 18%. Patients with longer disease-free intervals, complete resections, and fewer metastases had improved OS. In women with a single metastasis completely resected and a disease-free interval longer than 36 months, the 5-year OS was 50% compared with 13% in those with multiple metastases and a disease-free interval less than 36 months.[25]

Similar results are seen in large retrospective analyses of patients with MBC undergoing hepatic metastasectomy; although, in general, the number of patients reported in these series are smaller than those reported for pulmonary metastasectomy. In one of the largest series of 86 patients, with primarily solitary (62%) and small (85% less than 5 cm) metastases with a median follow-up of 62 months, the median OS was 57 months.[26] Although the complication rate was 21%, most (72%) required no intervention, and there were no postoperative deaths. Ninety percent were able to undergo complete resection (R0) and only one patient had macroscopically positive resection margins (R2). Patients with a partial response (PR) to chemotherapy before hepatic resection had a median survival of 79.4 months compared with 22.9 months in those progressing before hepatic surgery (p < 0.001). Additionally, patients with ER/progesterone receptor (PR)-positive primary tumors had a median survival of 76.8 months after hepatic resection compared with 28.3 months in ER/PR-negative primary tumors (p < 0.001). Similar to those undergoing a pulmonary metastasectomy, a longer disease-free interval, longer than 24 months, was associated with longer OS (100.7 vs. 47.5 months; p < 0.001).

The importance of surgical removal or radiotherapy to all radiographically or metabolically detected metastases is becoming ever more important as systemic therapies are increasingly effective. Although systemic therapies have improved control of subclinical breast cancer metastases and prolonged of progression-free intervals in patients with MBC,[27] most long-term survivors following systemic therapy had aggressive treatment to all known metastases.[11] This is likely because of the fact that in patients with oligometastatic disease, from breast[28,29] as well as other primary tumors,[30] sites of progression are most likely in known metastases, and not in new metastatic locations. Therefore, ablative therapy to all known metastases has the potential to maximize the therapeutic benefit for these patients.

The importance of achieving an R0, complete resection in patients undergoing metastasectomy is clear from both pulmonary and hepatic metastasectomy data. From the largest analysis of patients undergoing pulmonary metastasectomy, those undergoing a complete resection had 5-year survival of 38%, 10-year survival of 22% and 15-year survival of 20%, and a median survival of 37 months compared with a 5-year survival of 18% and a median survival of 25 months in those who underwent incomplete resection (p = 0.0009).[25] Additionally, in patients undergoing a hepatic metastasectomy, those undergoing a complete resection had a median OS of 57 months compared with 33.6 months in patients undergoing R1/R2 resections (p = 0.17).

From these data clinical characteristics of preferred patients for surgical resection begin to emerge. Patients selected for surgery should have longer disease-free intervals. The exact disease-free interval is not known, but for both patients undergoing both pulmonary and hepatic resection has been reported at longer than 2 years.[26] Patients should also be able to undergo a complete resection, have fewer metastases, and have ER/PR or HER2-positive tumors.[2]

RADIOTHERAPY FOR BREAST CANCER METASTASES

Advances in the planning, targeting, and delivery of radiotherapy have recently added a new tool against oligometastases. Many patients with MBC are not candidates for surgery because of medical comorbidity, personal preference to avoid surgery in the setting of metastasis, or invasion of metastases into unresectable organs. In these situations, radiotherapy is ideally suited for the treatment of limited metastases. Newer radiation techniques, commonly termed stereotactic body radiotherapy (SBRT) or stereotactic ablative radiotherapy (SABR), but perhaps most accurately described as hypofractionated image-guided radiotherapy (HIGRT), precisely deliver single or few radiation treatments at doses 2 to 10 times that of conventional radiation treatments.[31] Derived from intracranial stereotactic radiosurgery, these treatments deliver radiation doses wrapped tightly around targeted metastases, while sparing surrounding normal tissues. These higher radiation doses are thought to engage additional tumoricidal mechanisms beyond DNA damage, including endothelial-mediated[32,33] and immune-mediated.[34,35] Although doses of at least 54 Gy have been shown necessary when using three radiation doses to target tumors in the lung and liver,[36] other more protracted dosing schemes have been shown effective as well.[22] These techniques have been shown to be effective even when targeting larger metastases[37] with treated metastasis control ranging from 70% to 90%.[31]

Perhaps the best data for the treatment of MBC with ablative radiotherapy comes from the University of Rochester.[29] A pooled analysis of 40 women with limited breast cancer metastases treated on two sequential protocols using radiotherapy for limited metastatic disease reported promising outcomes. The median time to enrollment was 12 months after diagnosis of metastases and 56 months after initial breast cancer diagnosis, and 90% had been pretreated with systemic therapy. The 2-year and 4-year PFS was 44% and 38%, respectively. At 4 years, the treated metastasis control

per patient was 80%. Four-year actuarial OS was 59%, the median survival was not reached. Patients with a solitary metastasis had improved PFS and OS compared with those with more than one metastasis (p = 0.028). Additionally, those with bone-only metastases fared particularly well with seven out of eight without evidence of recurrence and alive at a median follow-up of 50 months. Those with stable or responding lesions fared better than those with progressing lesions (2-year PFS 13% vs. 53%, p = 0.026; 2-year OS 63% vs. 81%, p = 0.061).

Identifying patients with breast cancer who are most likely to benefit from metastasis-directed radiation therapy remains a substantial challenge. Currently, patients with oligometastatic disease are selected via easily assessed clinical criteria. Patients with intracranial metastases, synchronous oligometastases, male gender, and nonadenocarcinoma histology have been associated with worse outcomes for receiving ablative radiotherapy in general.[38] In patients with breast cancer receiving ablative radiotherapy, specifically, those with bone metastases, bone-only metastases, single metastases, and stable or responding metastases have improved outcomes.[29] Similar results have been seen in large data sets of patients undergoing radiation for limited metastatic disease. In particular, a pooled analysis of more than 200 patients showed that patients with breast cancer and those with bone metastases had improved survival.[39] However, these clinical criteria are imperfect surrogates for identifying those with the true underlying biology of oligometastases.

Although these advanced radiation techniques have been shown to be effective in targeting few metastases in limited organs,[15,16,23,40] the studies evaluating patients with multiple metastases have been small, and limited to a few institutions.[22,24,28] Therefore, data are scarce describing treatment and toxicity outcomes of patients with more than three or two close metastases. In particular, when targeted metastases are in close proximity, the target organ and surrounding normal tissues are exposed to higher integral radiation doses. When three to four metastases are targeted, the volume of low-dose radiation in the body can be substantial in both target and normal organs. In this situation, the potential toxic effects of radiation are not well characterized. The reported toxicities of ablative radiotherapy are increasingly reported in the literature, but they are limited.[23,41-44]

CLINICAL TRIALS OF ABLATIVE RADIOTHERAPY AND SURGERY FOR CURATIVE TREATMENT FOR PATIENTS WITH BREAST CANCER AND LIMITED METASTASIS

Although the reported radiation and surgical series have been primarily retrospective, taken together they suggest long-term survival after metastasis-directed therapy in patients with limited breast cancer metastases. The benefits these patients derive may come from delaying progression in known metastases, as well as preventing known metastases from seeding new metastases. Furthermore, ablative radiation has been shown to have an abscopal effect, which may

improve outcomes by inhibiting progression of untreated micrometastatic foci.[45,46]

It must be remembered when evaluating the data for ablative therapy for limited breast cancer, benefits must be weighed carefully against the risks. Typically, the patients considered for these interventions are highly selected with good performance status and limited burden of disease. Therefore, the numerically high rates of median and OS may be because of selection or indolent biology. Additionally, some have questioned if promising outcomes observed after surgery or radiation of all oligometastases may be because of the underlying biology and not necessarily the metastasis-directed therapy.[47] Furthermore, given that other promising therapies for MBC, such as stem cell transplant were not successful,[48] we owe it to our patients to prove this benefit. This is particularly important when considering the toxicity of treatment, which can only be evaluated in robust analyses. In addition to postoperative complications, SBRT has been associated with vertebral body fractures, hepatic dysfunction, respiratory failure, and bowel perforation.[23] These could greatly affect a patient's quality of life, for potentially no benefit. Additional considerations should be given to cost of treatment. More advanced radiotherapy techniques have a substantially higher cost than conventional radiotherapy.[49] However, despite this cost, these treatments may prevent future need for palliative-intent radiotherapy, and may delay the need for costly targeted pharmaceuticals. Only prospectively collected high-quality data will answer these questions reinforcing the need to accrue to open trials.

SBRT is being used increasingly as a technique to treat patients with limited MBC. An international survey of radiation oncologists found that 61% were using SBRT to treat patients with limited metastases. Furthermore, of those not currently offering this treatment, more than half were planning to start offering SBRT for limited metastases in the next 3 years.[49] Although there is increasing evidence that in selected patients administration of SBRT for oligometastatic disease appears beneficial and its use is becoming more common, this has not been proven in controlled studies. Therefore, the initiation of randomized trials to ultimately prove clinical benefit is essential. However, conducting these trials may be increasingly difficult because of SBRT becoming the de facto SOC[50] without Level I evidence. Hence, the initiation of systematic and randomized clinical trials is important not only because of the potential to change or keep the SOC, but also because of the timing. There is currently a streamlined randomized phase II trial (NRG BR002) to determine if the ablation of all known metastases in addition to SOC improves PFS in women with one to two breast cancer metastases. If a PFS signal is seen, this will roll directly into a phase III study to determine if ablation of all breast cancer metastases can improve OS. This study is critical to determine what benefits, if any, there are to treating women with limited MBC.

To improve the radiotherapy techniques used to treat patients with metastases in close proximity and those with three

or more metastases, there is also a phase I dose de-escalation study (NRG BR001: NCT02206334) being conducted in which patients with breast, lung, and prostate cancer with two metastases in close proximity (less than 5 cm) or those with three to four metastases will receive radiation to all known sites of disease. Each metastasis will be assigned to one of seven regions (neck and mediastinum, lung central, lung peripheral, spinal, osseous, abdominopelvic, and hepatic) based on the potential for normal tissue toxicity. Doses for each region were selected based on all available data and expert consensus. Doses will be de-escalated to each region should toxicity be seen. An alternative approach, currently used in the SABR COMET study (NCT01446744) is a dose-stratified method.[51] Careful analysis of adverse events combined will help to truly understand the tolerances of normal tissues to this type of ablative radiation.

Recent investigations have suggested potential biologic markers of the oligometastatic state. Analyses of resected pulmonary metastases, and the combination of primary and metastatic tumors have identified a microRNA signature that, when present, identifies patients whose disease is unlikely to progress rapidly or in a widespread manner. In particular, increased expression of microRNA 200c was found to be associated with a polymetastatic phenotype in vivo as well as in clinically selected patients with oligometastatic disease.[52] When restricted to patients with lung metastases only, microRNA signatures can classify patients as oligometastatic compared with polymetastatic, and also differentiate those patients with a low recurrence probability following surgical resection.[53] Further validation is needed in prospective series to validate this as a potential patient selection tool.

Currently, there are no validated biomarkers for response evaluation after ablative radiotherapy for patients with oligometastatic disease. PET scans utilizing fludeoxyglucose as an imaging biomarker have shown potential for response evaluation after ablative therapy. Only 10% of patients with a PR on first postradiotherapy PET, and 29% of those with a complete response progressed during follow-up.[54] Additionally, PET was able to detect responses in those with nonmeasureable lesions by standard RECIST, particularly useful in patients with breast cancer who often present with osseous-only metastases. Another potential biomarker to evaluate response to ablative therapy is via enumeration of circulating tumor cells (CTCs). Already established as a prognostic tool for patients with MBC as well as a predictive tool evaluating response to systemic therapy,[55] the presence of less than five CTCs per 7.5 mL whole blood at baseline may also serve as a way to identify those patients with truly oligometastatic disease from the cohort of patients with few clinically apparent metastases. Furthermore, the ability of surgery or ablative radiotherapy to reduce the number of CTCs to less than five may predict good responses to therapy. Furthermore, the eradication of previously detectable CTCs after metastasectomy or ablative radiation may indicate that the primary sources of CTCs were the known and treated metastases and not from the occult sites reseeding after ablative therapy preventing durable long-term control.

In conclusion, from available data many if not most patients with MBC present with a limited number of metastases, which portents improved outcomes. Ablation of imaging-detected metastases, with either surgery or radiation, has been associated with long disease-free intervals for patients with breast cancer. Although ablative therapies are gaining in popularity, only now are prospective trials open to identify the role of ablative therapy in oligometastatic breast cancer. Patients should be enrolled in these studies to identify the true effect of ablative therapy. Although early data are beginning to elucidate the biologic underpinnings of patients with oligometastatic disease, more work is needed, and biomarkers need to be validated in this patient population to better identify responses to treatment. All of this work is needed to truly determine if there is potentially a subset of patients with MBC that can achieve long-term survival. With better identification of which patients belong in this subset and what the utility is of the ablative therapy options, a new treatment paradigm may become the cure for a subset of patients with MBC.

Neoadjuvant Therapy for Breast Cancer: Controversies in Clinical Trial Design and Standard of Care

Julia White, MD, and Angela DeMichele, MD, MSCE

OVERVIEW

Neoadjuvant therapy for breast cancer has been increasingly used in recent years as first-line treatment for operable breast cancer—serving as both a management strategy and a research tool. In addition to the established clinical benefits of down-staging more locally advanced cancers and improving breast-conservation rates, investigators have recognized the potential advantages of this approach in developing new therapies. Preoperative systemic therapy provides the opportunity for in vivo assessment of pharmacodynamic markers to assess biologic effects and allows new compounds to be tested in a more responsive, treatment-naive population. In addition, early surrogates of response, such as pathologic complete response (pCR) and residual cancer burden, provide proximate measures that correlate with long-term outcomes, thus potentially shortening the time needed to identify effective adjuvant therapies. Despite the advantages of neoadjuvant therapy for research and clinical practice, its use is characterized by persistent controversy and healthy debate regarding how to optimally use research findings and when to integrate them into the standard of care for daily management. Among the controversies surrounding neoadjuvant therapy use are questions about defining the best endpoint for assessing treatment efficacy, deciding when results from research should be used in daily clinical practice, and how the growing use of neoadjuvant therapy affects locoregional treatments.

Neoadjuvant therapy for breast cancer has gained traction in recent years as both a management strategy and research tool. In addition to the established benefits of downstaging inoperable cancers and improving breast-conservation rates,[1,2] investigators have recognized this approach's potential advantages for developing new therapies. Preoperative therapy provides the opportunity for in vivo assessment of pharmacodynamics markers to assess biologic effects and allows new compounds to be tested in a more responsive, treatment-naive population. In addition, early surrogates of response, such as pCR and residual cancer burden, provide proximate measures that correlate with long-term outcomes, thus potentially shortening the time needed to identify effective adjuvant therapies. But with these advantages, come challenges, both in optimizing the research data that is obtained and integrating this approach into the standard of care. What are the appropriate endpoints for neoadjuvant clinical trials? When do we integrate findings from these clinical trials into standard systemic therapy approaches? And finally, what are the implications of neoadjuvant therapy and trials on locoregional surgical and radiation therapy outcomes and approaches? These controversies continue to evolve as our understanding of the biology and natural history of breast cancer subtypes and use of preoperative therapy grows.

APPROPRIATE ENDPOINTS FOR NEOADJUVANT CLINICAL TRIALS

There has been substantial enthusiasm for pCR as a surrogate marker in neoadjuvant trials. This arose out of observations in several randomized trials in which patients who experienced a pathologic response on the whole had lower rates of recurrence than those who did not—a prognostic benefit that was even greater when evaluated within breast cancer receptor subsets.[3,4] The subsequent U.S. Food and Drug Administration (FDA) meta-analysis defined the magnitude of the difference in event-free survival (EFS) for pCR compared with non-pCR prognostic groups as defined by the eradication of all invasive cancer in the breast and axillary lymph nodes.[5] This analysis showed that overall pCR rates and the magnitude of the differences in outcome were highest in the HR-negative/HER2-positive and triple-negative subsets.

But for pCR to be utilized as a surrogate marker in clinical trials of new therapies, it must also be a predictive marker. As such, one would hypothesize that an increase in pCR rate in a population of patients receiving investigational therapy would be associated with a subsequent improvement in event rates (EFS, overall survival [OS]) over patients in the control group. The FDA meta-analysis was not able to demonstrate such a relationship in the trials that were included in their analysis. The authors cautioned that this did not rule out the

possibility that such a relationship exists, but that, among the studies included in that analysis, no such association was seen. This could have been caused by the overall low rates of pCR in those studies and the fact that only one trial included targeted therapy. That trial was the NOAH trial,[6] which randomly selected patients to receive a preoperative anthracycline/taxane regimen with or without trastuzumab, and it showed that trastuzumab significantly improved pCR rates and subsequently improved EFS (hazard ratio [HR] 0.59, p = 0.013). This subsequently translated to a benefit of trastuzumab in the adjuvant setting that was demonstrated in the combined National Surgical Adjuvant Breast and Bowel Project (NSABP) B-31/North Central Cancer Treatment Group (NCCTG) 9831 trials with an absolute improvement in disease-free survival (DFS) of 12% (HR 0.48, p < 0.0001).[7]

Although these studies appear to support pCR as a good surrogate predictive marker in HER2-positive disease, concerns were raised again when the results of the NeoALTTO and ALTTO trials were reported.[8-10] These trials investigated whether the receptor tyrosine kinase inhibitor, lapatinib, would further improve outcomes for patients treated with chemotherapy and trastuzumab in the neoadjuvant and adjuvant settings, respectively. Patients in the NeoALTTO trial were randomly assigned to 12 weeks of paclitaxel with either trastuzumab alone, lapatinib alone, or the combination. Patients then went to surgery and received anthracycline postoperatively. Patients receiving the combination of trastuzumab and lapatinib had a significantly higher pCR rate than those receiving trastuzumab alone (pCR rates 51.3 vs. 29.5, p = 0.0001). In light of the encouraging pCR findings, the large, adjuvant ALTTO trial was launched, while follow-up on NeoALTTO continued. The treatment plan in the ALTTO trial differed in an important respect from NeoALTTO: all chemotherapy was given preoperatively, includ-

ing anthracycline. Interestingly, the trials matured, and the results were published within months of each other. Notably, EFS, OS, and the association between pCR and EFS or OS (analyzed by landmark analysis at 30 weeks after random selection) were secondary endpoints in the NeoALTTO trial, with far less power to detect a significant difference than the ALTTO trial. Despite the significant improvement in pCR rate for the combination of trastuzumab and lapatinib over trastuzumab alone, EFS in the NeoALTTO trial did not differ between the combination and trastuzumab groups (EFS 0.78 and 0.47–1.28, respectively, p = 0.33). pCR retained its prognostic significance in landmark analyses showing that 3-year EFS and OS were significantly improved for women who achieved pCR compared with those who did not (p = 0.0003 and p = 0.005, respectively). Similarly, the adjuvant ALTTO trial also failed to show a benefit in DFS for patients receiving the combination of trastuzumab and lapatinib compared to those receiving trastuzumab alone. The HR was 0.84 (97.5% CI, 0.70 to 1.02) on the basis of about 2,100 patients in each of the two groups. The two-sided p value of 0.048 was not significant because the investigators had added another comparison: the noninferiority of trastuzumab followed by lapatinib versus trastuzumab, both for a total of 1 year.

In light of these results, should pCR be abandoned as a surrogate predictive marker in neoadjuvant trials? Limitations in the design of these trials would potentially lead to that conclusion erroneously; therefore, several issues must be taken into account. First, because the anthracycline component of the chemotherapy regimen was given postoperatively in the NeoALTTO trial, the comparison of pCR rates hinged only on the differences between the taxane and targeted therapies. This may have exaggerated the effects of lapatinib, since anthracyclines are well known to be active in HER2-positive disease,[11] and dampened the ability of pCR to predict survival endpoints in NeoALTTO when such a critical component of therapy was given postoperatively. Differences in the design of NeoALTTO and ALTTO also may have played a role in the inability of ALTTO to demonstrate a DFS benefit. Patients in ALTTO were more likely to have node-negative or estrogen receptor (ER)-positive disease than those in the NeoALTTO trial, thus providing a lower overall event rate. Moreover, the HR achieved in the ALTTO trial would have been predicted by the FDA meta-analysis, as shown by a subsequent statistical analysis.[12] The meta-analysis showed that the EFS HR for patients with HER2-positive breast cancer achieving a pCR compared with those not achieving a pCR was 0.39 (95% CI, 0.31 to 0.50), a 61% reduction in the hazard of recurrence. A 20% improvement in pCR rate with the combination of trastuzumab and lapatinib over trastuzumab alone, as seen in the NeoALTTO trial, would result in one in five patients moving from the no pCR Kaplan-Meier curve to the pCR curve. This would predict an HR for the comparison to fall to 0.83—very similar to the 0.84 seen in both the NeoALTTO and ALTTO trials.

Moving forward, pCR may still be the appropriate endpoint for neoadjuvant trials but with study design requirements that will make it possible to accurately assess pCR to

KEY POINTS

- Neoadjuvant systemic therapy improves surgical outcomes and is a platform for translational research and clinical trials.
- New therapeutic approaches that result from neoadjuvant trials ideally demonstrate benefits in terms of pathologic complete response and event-free and overall survival.
- Downstaging with neoadjuvant therapy enables more women to undergo breast conservation with lumpectomy and breast radiotherapy.
- Locoregional cancer outcomes comparable to mastectomy are expected from breast conservation in appropriately selected patients after neoadjuvant therapy.
- Postmastectomy radiotherapy appears to be of most benefit after neoadjuvant therapy in those with extensive clinical stage III breast cancer (T3–4, N2–3).
- The extent of locoregional therapy necessary for those who downstage to pathologically node negative after neoadjuvant therapy is evolving and clinical trials are ongoing.

select the most promising agents to take forward to confirmatory trials. First, all chemotherapy should be given before surgery. Second, pathologic assessment of residual diseae at surgery must use the FDA-recommended definition of elimination of all invasive cancer in the breast and axillary lymph nodes. Third, the neoadjuvant trial and subsequent adjuvant trial must have identical chemotherapy treatment plans and minimal differences in variability in postoperative treatments such as radiation. Finally, the subsequent confirmatory phase III trial should be sufficiently powered for the EFS HR that would be predicted by the improvement in pCR. The FDA has proposed such a strategy in its guidance allowing pCR to be considered an endpoint for accelerated approval of drugs before completion of confirmatory trials.[13]

INTEGRATING FINDINGS FROM NEOADJUVANT CLINICAL TRIALS INTO STANDARD SYSTEMIC THERAPY

The neoadjuvant setting is used to test both new agents on the path to regulatory approval and previously approved agents that could provide benefit in this setting. In addition to improving EFS, such trials may show other important clinical benefits of new neoadjuvant approaches for patients. These include improving the likelihood of resectability or breast conservation or reducing the need for full axillary dissection. These are tangible benefits to patients that are demonstrable at the time of initial report of pCR findings, and they do not require waiting for reductions in locoregional/distant recurrence or survival.

When should the practicing physician implement new neoadjuvant strategies with existing drugs for these outcomes? In this situation, toxicity plays a key role in determining whether the potential benefit is worth the risk for the individual patient. An example of this conundrum is whether to add carboplatin or bevacizumab to anthracycline/taxane-based neoadjuvant chemotherapy in patients with triple-negative (ER-/PR-/HER2-) breast cancer. pCR rates in triple-negative disease with standard therapy are typically in the 35% to 40% range, and patients without a pCR have an abysmal prognosis, with a median survival of 3 years.[5] Platinum analogs have been demonstrated to be highly active in BRCA-mutated breast cancer, a group that significantly overlaps with sporadic triple-negative disease. Several small neoadjuvant trials showed higher than expected pCR rates (> 70%) with the addition of carboplatin to anthracycline/taxane-based regimens in BRCA-mutation carriers. Thus, a phase II randomized trial, Cancer and Leukemia Group B 40603, was undertaken to evaluate this strategy in unselected patients with locally advanced, triple-negative disease.[14] This trial randomly selected 443 patients to receive weekly paclitaxel with or without concurrent carboplatin (every 3 weeks at area under the curve = 6), followed by four cycles of doxorubicin and cyclophosphamide. A 2 × 2 factorial design was employed to simultaneously evaluate the effect of adding bevacizumab to this treatment strategy. The addition of carboplatin to the standard chemotherapy regimen significantly

increased the pCR rate (breast and axilla) from 41% to 54% (p = 0.0029). Several additional proximate outcomes showed improvement as well, with carboplatin increasing the proportion of patients who converted from clinical node-positive to pathologically node-negative status and the proportion who became eligible for breast-conserving therapy.

But these benefits did come with a price. The overall number of serious adverse events, defined as any unexpected grade 3 or higher toxicity or toxicity that required hospitalization or surgical intervention, was higher in the carboplatin arm, including higher rates of febrile neutropenia and severe nausea, vomiting, and dehydration. Patients assigned to carboplatin were more likely to miss two or more doses of paclitaxel and required more dose reductions of paclitaxel, and 20% were unable to complete all planned doses of doxorubicin/cyclophosphamide. Thus, the risk/benefit equation of adding carboplatin to standard neoadjuvant chemotherapy for triple-negative breast cancer is complicated. In the absence of EFS/OS data, the most appropriate candidates are those who would benefit most from surgical downstaging; those with conditions that increase intolerance to standard therapy could have that therapy compromised with the addition of carboplatin. The treatment decision requires individualization of therapy and extensive discussion with the patient about possible implications before embarking on this new treatment approach.

IMPLICATIONS OF NEOADJUVANT THERAPY ON LOCOREGIONAL TREATMENT WITH RADIOTHERAPY

The increasing use of neoadjuvant systemic therapy for breast cancer has had the dual effect of providing important benefits and causing significant controversy regarding the locoregional treatment of breast cancer with radiotherapy. One of the clearly established benefits of neoadjuvant therapy is that it enables more women to undergo breast conservation with lumpectomy and breast radiotherapy who otherwise would have been treated with mastectomy.[1,2] Despite results demonstrating in-breast recurrence after breast conservation was similar for those who received neoadjuvant compared with adjuvant chemotherapy,[1] there was some reluctance expressed for breast-conservation approaches after neoadjuvant therapy for those women whose extent of disease before neoadjuvant therapy made them initial mastectomy candidates.[15] This was based on findings from the NSABP B-18 clinical trial that reported the in-breast recurrence rate was higher in patients who were initially mastectomy candidates and were converted to breast conservation by neoadjuvant therapy, compared with those who were initially candidates for breast-conserving surgery (15.7% vs. 9.9%, respectively; p = 0.04).[16] More recent studies have found that this local recurrence pattern is related to more aggressive biologic behavior of larger, higher stage and grade breast cancers in the group of women who are initially mastectomy candidates and not because they underwent breast conservation as a result of downstaging following neoadjuvant therapy.[17] A

growing body of literature now supports that when appropriately selected by downstaging, breast conservation can yield comparable locoregional cancer outcomes in comparison to mastectomy after neoadjuvant therapy irrespective of age, subtype, and whether mastectomy was initially intended.[17-20] As newer neoadjuvant agents are utilized resulting in even higher rates of pathologic response in some breast cancers,[5] women with more locally advanced breast cancer are even better poised to feasibly and safely achieve breast conservation when desired. In contrast, the increasing use of neoadjuvant systemic therapy has created considerable controversy and debate regarding the optimal use of postmastectomy radiotherapy in this setting.

INDICATIONS FOR POSTMASTECTOMY RADIOTHERAPY WHEN NEOADJUVANT SYSTEMIC THERAPY IS DELIVERED

Clinical decision making regarding the use of postmastectomy radiotherapy has been established from numerous randomized clinical trials and meta-analyses where pathologic staging from mastectomy as the first line of breast cancer therapy was the determinant of receiving radiotherapy.[21,22] This data consistently demonstrates that for women with axillary node-positive breast cancer, the addition of chest wall and regional nodal radiotherapy after mastectomy and adjuvant chemotherapy can improve breast cancer survival by a few percent, in addition to providing large gains in locoregional cancer control.[21,22] This benefit in survival from postmastectomy radiotherapy is similarly seen for those patients with four or more involved axillary nodes, as well as many with one to three positive axillary nodes.[22] As a result, it is generally recommended that patients who have axillary nodal metastases receive radiotherapy to the chest wall and regional nodes after mastectomy, and conversely, radiotherapy is not typically recommended after mastectomy when negative axillary nodes are found. The absence of similar evidence when neoadjuvant chemotherapy is delivered as first line of breast cancer treatment has led to conflicting opinions regarding which factors are most important for determining postmastectomy radiotherapy benefit: the clinical stage before neoadjuvant chemotherapy or the pathologic stage at surgery after neoadjuvant chemotherapy. It is clear that both sides of the debate regarding postmastectomy radiotherapy use in the setting of neoadjuvant chemotherapy stems from a desire to minimize harm to patients with breast cancer. Those who endorse that postmastectomy radiotherapy should be recommended based on the presence of positive axillary nodal metastases before neoadjuvant therapy caution that omitting radiotherapy based on chemotherapy response places women at risk for worse breast cancer mortality.[23] On the other hand, some support the idea that pathologic node status after neoadjuvant chemotherapy is the important factor, and they argue that for patients who are downstaged to pathologically node-negative status, postmastectomy radiotherapy may not offer significant benefit and therefore adds excess toxicity.[24]

Most of the literature on the use of postmastectomy radiotherapy after neoadjuvant chemotherapy is from retrospective case studies from single institutions (Table 1). The largest single series that retrospectively examined outcomes after neoadjuvant chemotherapy by postmastectomy practice patterns is by Huang et al, in 676 women treated between 1974 and 2000 on six prospective clinical trials studying anthracycline based neoadjuvant chemotherapy at The University of Texas MD Anderson Cancer Center.[25] Roughly 80% (542) received radiotherapy, while approximately 20% (134) were observed postmastectomy. The majority of cases were clinical stage III (70%), and only 8% and 14%, respectively, experienced a pCR from neoadjuvant therapy in the observed and irradiated groups. The 10-year rate of locoregional recurrence (LRR) was significantly lower (p = 0.0001) and OS was better (p = 0.006) in the group that received postmastectomy radiotherapy (Table 1).[25] In a multivariate Cox regression analysis of factors associated with LRR, radiation use was the most significant variable, with an HR for no radiation of 4.7 (95% CI, 2.7 to 8.1; p < 0.0001). Other factors found to be important for developing LRR included 20% or more pathologically positive axillary nodes after neoadjuvant therapy and clinical stage IIIB to stage IV disease. A subsequent study from this institution reported cancer out-

TABLE 1. Retrospective Studies Evaluating Cancer Outcomes in Relationship to Postmastectomy Radiotherapy Use after Neoadjuvant Chemotherapy

comes relative to pattern of postmastectomy radiotherapy use in 106 women who experienced pCR from neoadjuvant chemotherapy.[26] The majority of cases were clinical stage III (70%). When the entire group was analyzed, there was no significant advantage in LRR in the 72 patients who were irradiated compared with those who received observed postmastectomy (p = 0.40; Table 1). However, when only the 74 patients with clinical stage III disease were analyzed, postmastectomy radiotherapy was associated with a significantly lower 10-year rate of LRR (7.3% in the patients who were irradiated vs. 33.3% in those who did not receive radiotherapy postmastectomy; p = 0.040) and better OS (77.3% for the patients who were irradiated and 33.3% for the patients who were not irradiated, p = 0.0016), leading the authors to recommend routine treatment for patients with clinical stage III disease, even when achieving a pCR.[26] Two other studies examined cancer outcomes retrospectively by postmastectomy use in those who were downstaged to pathologically node-negative (ypN0) following neoadjuvant chemotherapy. Le Scodan et al reviewed 1,054 patients with breast cancer treated with neoadjuvant chemotherapy at Institut Curie and René Huguenin Hospitals between 1990 and 2004 to find 134 that had ypN0 status after neoadjuvant chemotherapy and mastectomy.[27] Of the 134 eligible patients, 78 (58.2%) received postmastectomy radiotherapy and 56 (41.8%) did not. At a median follow-up time of 91.4 months, the 5-year LRR-free survival and OS rate was 96.2% and 88.3% with postmastectomy radiotherapy and 92.5% and 94.3% without postmastectomy radiotherapy, respectively (p = not significant), and no significant changes in cancer outcomes were found at 10 years. Another retrospective study conducted in nine Korean institutions, identified 417 patients with clinical stage II-III breast cancer who achieved a ypN0 at surgery after receiving neoadjuvant chemotherapy between 1998 and 2009. Of these, 151 patients underwent mastectomy, and 105 (69.5%) received postmastectomy radiotherapy. There was no significant benefit in reducing LRR or improving OS in the radiotherapy group (Table 1).[28] From these studies, it can be observed that postmastectomy radiotherapy appears to be of most benefit after neoadjuvant therapy in those with extensive clinical stage III disease (T3– 4, N2–3), even when a pCR is observed and when axillary nodes remain pathologically involved.

PATHOLOGIC RESPONSE TO NEOADJUVANT THERAPY AS A PREDICTOR OF LRR RISK AND NEED FOR POSTMASTECTOMY RADIOTHERAPY

Evidence supports that neoadjuvant chemotherapy response is linked to lower rates of subsequent LRR risk in the absence of postmastectomy radiotherapy. Mamounas et al[29] analyzed LRR rates in approximately 3,000 women enrolled onto two NSABP clinical trials evaluating neoadjuvant chemotherapy (NSABP B-18 and NSABP B-27). Both protocols specified that patients treated with mastectomy were not allowed to receive any radiotherapy. The combined analysis of these two trials provides important insight on the rates, patterns, and

independent predictors of LRR after neoadjuvant chemotherapy and mastectomy. The 10-year cumulative incidence of LRR was 12.3% for patients who underwent mastectomy (local, 8.9%; regional, 3.4%). Independent predictors of LRR postmastectomy, were clinical tumor size, clinical node status, and pathologic node status/pathologic breast response. In particular, those with clinically involved nodes before chemotherapy who had pathologically node-negative disease (ypN0) at surgery (with or without pCR in the breast) had a lower LRR than those who were found to have persistent nodal metastases pathologically. In a small subset of 102 patients undergoing mastectomy with clinically positive nodes before neoadjuvant chemotherapy who were downstaged to ypN0 afterwards, the risk of chest wall and regional nodal recurrence was between 0% and 10.8% at 10 years. These LRR rates fit into a low-risk category of patients who may not experience a significant benefit from postmastectomy radiotherapy, particularly in terms of improved survival, and could be spared the associated toxicity. It is important to emphasize that the results of the combined analysis of NSABP B-18 and B-27 are primarily applicable to patients with clinical stage I to II disease; 55% of the patients presented with cT1–2N0 disease, 20% with cT1–2N1 disease, and 6% with cT3N0 disease. Only 9% of the patients presented with cT3N1 disease.

The combined analysis of NSABP B-18 and B-27 supports that for patients who have positive nodes before neoadjuvant chemotherapy, the rate of LRR can be modified downward if the nodes become pathologically node-negative after neoadjuvant chemotherapy (particularly if there is also pCR in the breast). These findings are supported by the outcomes reported in the retrospective studies in those downstaged to ypN0 after neoadjuvant therapy as described above.[27,28] However, prospective data are needed to ensure omission of postmastectomy is safe given the extensive data supporting its benefit in improving survival for the treatment of node-positive breast cancer.[21,22] The NSABP B-51/Radiation Therapy Oncology Group (RTOG) 1304 phase III clinical trial (NCT01872975)[30] is designed to answer whether regional radiotherapy improves the invasive breast cancer recurrence-free interval rate (local, regional, and distant recurrences and deaths resulting from breast cancer) in women who present with clinical N1 axillary node disease (documented pathologically by needle biopsy) before neoadjuvant chemotherapy and then become pathologically node-negative at time of surgery. After mastectomy, patients are randomly assigned to no radiotherapy or chest wall and regional nodal radiotherapy, and after lumpectomy, random assignment is to breast radiotherapy alone or breast and regional lymph node radiotherapy.

CONCLUSION

In summary, the neoadjuvant setting provides a wealth of opportunities to identify better treatment strategies through clinical trials, evaluate new drugs for efficacy, and improve locoregional outcomes for individual patients. However, to fully realize these opportunities, clinical trials must be de-

signed with appropriate endpoints, sample size, and patient populations. pCR may be a proximate surrogate endpoint that can speed the process of identifying promising new therapies, but its ability to accurately predict meaningful, long-term outcomes has not yet been established. More work is necessary to determine the magnitude of increase in pCR within specific breast cancer populations that will lead to im-

provement in EFS, so that only the most promising agents move forward to confirmatory trials. In the interim, increases in pCR may lead to accelerated approval of new drugs or new therapeutic strategies with existing agents that can benefit patients. But these proximate benefits must be weighed against toxicity and treatment effect of these agents that could potentially undermine later outcomes.

Management of Older Women with Early-Stage Breast Cancer

OVERVIEW

Breast cancer is a disease of aging. The average age at diagnosis is 61, and the majority of deaths occur after age 65. Caring for older women with breast cancer is a major challenge, as many have coexisting illness that can preclude optimal breast cancer treatment and which frequently have greater effect than the breast cancer itself. Older patients with cancer should be screened or have a brief geriatric assessment to detect potentially remediable problems not usually assessed by oncologists (e.g., self-care, falls, social support, nutrition). Older women with early-stage breast cancer should be treated initially with surgery unless they have an exceedingly short life expectancy. Primary endocrine therapy should be considered for patients who have hormone receptor–positive tumors and a very short life expectancy, an acute illness that delays surgery, or tumors that need to be downstaged to be resectable. Sentinel node biopsy should be considered for patients in whom it might affect treatment decisions. Breast irradiation after breast-conserving surgery may be omitted for selected older women, especially for those with hormone receptor–positive early-stage breast cancer that are compliant with adjuvant endocrine therapy. The majority of older women with stage I and II breast cancer have hormone receptor–positive, HER2-negative tumors, and endocrine therapy provides them with optimal systemic treatment. If these patients have life expectancies exceeding at least 5 years, they should be considered for genetic assays to determine the potential value of chemotherapy. Partnering care with geriatricians or primary care physicians trained in geriatrics should be considered for all vulnerable and frail older patients.

Breast cancer is a disease of aging. Currently, the average age at onset of diagnosis in the United States is 61—similar to other developed nations—and the majority of deaths occur in women age 65 and older. The challenges of caring for these patients will continue to increase as the numbers of older women surge in our aging population. Despite the large numbers of older patients with breast cancer, little clinical trial data exist to guide decision making. This is of concern since many older patients with breast cancer have comorbidities that result in loss of function that may compromise their breast cancer care. Of note, and perhaps somewhat because of these limitations, breast cancer–specific survival when adjusted for age is less for older patients, suggesting that these patients are not being given optimal state-of-the-art care.[1] This article addresses issues related to surgery, radiation therapy, and adjuvant therapy for older women with early-stage breast cancer. Outstanding references related to these issues are available.[2-4]

SURGICAL MANAGEMENT

In the 1980s, the question regarding surgery in older patients was, "Can we?" Herbman et al showed that older women could tolerate mastectomy and had a substantial long-term survival and concluded the standard treatment—mastec-

tomy at that time—should not be withheld from these patients.[5] Today the question is different: "Should we?" In many ways, early-stage breast cancer in older, healthy women should be considered more of an inconvenience than a threat to their lives. The treatment should minimize not only the inconvenience but also the morbidity produced. Although radiation to the breast is well tolerated, it does increase breast pain, fibrosis, and retraction for at least a limited amount of time, as shown in Cancer and Leukemia Group B (CALGB) 9343.[6] In many older women with comorbidities, the effect of breast cancer on their quality of life is less than in younger patients because of their limited life expectancy. In these older women especially, the major goal should be limiting treatment to the minimum amount necessary to prevent locoregional recurrence during the patient's remaining lifetime.

When the older woman presents with early-stage breast cancer, the surgeon must evaluate the size and location of the cancer by physical exam and imaging and then determine the patient's general health status and life expectancy. For those with severe comorbidities and limited life expectancy, it may be best to avoid surgery all together. If the cancer is hormone-receptor positive, the use of an aromatase inhibitor (AI) or tamoxifen can often control the cancer for the duration of the patient's life.[7] For healthier older women, the decision is be-

tween lumpectomy and mastectomy and between sentinel node biopsy, axillary dissection, or no axillary surgery.

If the surgeon's assessment suggests that lumpectomy is likely to be successful, this is almost always the best approach, as it limits surgical morbidity and likely provides the best quality of life. In many cases, this is the only surgery required and radiation may not be needed. If lumpectomy does not initially appear possible, and the patient's disease is hormone receptor positive, the surgeon must decide if preoperative hormone therapy could potentially convert the patient to conservation.[8] If so, this should be offered to the patient, setting the expectation that it may be 6 months or longer before surgery is undertaken. For those who do not have hormone receptor–positive disease or who will not be able to be converted to conservation, immediate mastectomy is appropriate. For these patients, reconstruction should be considered, being mindful of their underlying health. Older women should not be excluded from having reconstruction, and it should not be assumed that all older women want reconstruction. Reconstruction is very much an individual decision based on the patient's health, lifestyle, and expectations.

The next issue is axillary surgery, a decision that should be based on whether the patient has clinically node-positive or node-negative disease. For those older women with clinically positive axillary nodes who are surgical candidates, axillary dissection is appropriate. Axillary radiation instead of dissection can be considered for those felt not to be surgical candidates. For those who have clinically node-negative disease and who require mastectomy, sentinel node biopsy is appropriate with conversion to axillary dissection if node positive. Older women with low volume axillary disease can likely avoid postmastectomy radiation; hence, dissection may often be the least morbid and most convenient management approach. For those undergoing lumpectomy, sentinel node biopsy is often not needed. It has been shown that for clinical stage I hormone receptor–positive cancers in patients who do not undergo any axillary surgery and do not have radiation, only 3% recur in the axilla at 10 years.[9] For those radiated, almost none will recur in the axilla. For women who

have hormone receptor–negative disease or larger tumors or for whom the decision regarding chemotherapy will be determined by the node status, sentinel node biopsy is appropriate, in accordance with the Z11 trial[10,11] and AMAROS trial findings.[12] Otherwise, sentinel node biopsy can be avoided.

Much hinges on what we consider to be an acceptable level of locoregional recurrence. A current recommendation is that an acceptable locoregional recurrence rate should be 1% or less per year or within 10% at 10 years.[13] This is in line with our acceptance of local recurrence for lumpectomy plus radiation in women younger than age 50, for whom the in-breast recurrence rate at 10 years is approximately 10%.[14] If this rate is acceptable, then lumpectomy without radiation—with an approximately 9% risk of in-breast recurrence at 10 years—for clinically stage I, hormone receptor–positive breast cancer should be acceptable.[6]

In summary, surgery in the older patients should be the minimum necessary to keep the risk of locoregional recurrence to an acceptable level and within the life expectancy of the patient. In many women with early-stage breast cancer, lumpectomy plus hormone therapy is all that is needed.

RADIATION THERAPY

After lumpectomy, the decision to add radiation therapy for older women needs to be carefully considered. The Early Breast Cancer Trialists' Collaborative Group (EBCTCG) published an updated analysis using individual patient data from 10,801 patients included in 17 randomized trials of radiation after breast-conserving surgery.[15] This publication revealed that the addition of radiation therapy was associated with a highly significant absolute benefit of 15.7% in any first recurrence (local, regional, or distant recurrence) at 10 years ($2p < 0.00001$). The benefits of radiation therapy varied when adjusted for estrogen receptor status, grade, and age.

The potential benefits of radiation among age groups in the EBCTCG analysis revealed that the absolute benefit of radiation therapy depended on the baseline risk of recurrence: a function of age. With increasing age, the baseline risk of recurrence was lower, leading to a smaller but still significant absolute benefit of radiation overall. In women older than age 70, the baseline risk of recurrence and therefore the benefit derived from radiation was about half—an 8.9% absolute reduction in a 10-year risk of a locoregional or distant recurrence. This analysis was based on chronologic age and included healthy older women as well as those with comorbidities.

This concept of proportional benefits—that the absolute benefit of radiation therapy varies with the underlying risk of recurrence—raises the question of whether radiation therapy following breast-conserving surgery can be safely omitted if the absolute risk is low. This question was directly addressed by four randomized trials of endocrine therapy with radiation therapy or endocrine therapy alone in older women with estrogen receptor–positive breast cancer (Table 1). Each of these trials showed that the addition of radiation therapy to

KEY POINTS

- The goals of treatment of older patients are typically different than for younger patients and should be clearly defined when making treatment recommendations.
- Life expectancy and comorbidities are key factors in treatment decisions.
- Surgical and radiation oncology decisions should focus on optimizing local control while minimizing a negative effect on quality of life.
- Adjuvant chemotherapy should only be considered if it will improve survival more than several percentage points.
- We believe that caring for older patients is best done by a team of experts including oncologists, geriatricians, and other support staff.

TABLE 1. Randomized Trials of Hormonal Therapy and Breast-Conserving Surgery with or without Radiation Therapy in Older Women

Trial (No. of Patients)	Inclusion Criteria	Locoregional Recurrence without RT	Locoregional Recurrence with RT	p Value	Overall Survival Difference
CALGB[9] (636)	Age 70 and older	10% at 10 yr	2% at 10 yr	< 0.001	Not significant
	T1, HR+/unknown				
	Negative nodes				
Princess Margaret[59] (749)	Age 50 and older, T1/2, N0 (cN0 if older than 65, pN0 if younger than 65), no chemotherapy	17.6% at 8 yr	3.5% at 8 yr	< 0.001	Not significant
PRIME II[60] (1,326)	Age 65 and older, T size up to 3 cm, N0	2.7% at 5 yr	0.6% at 5 yr	0.004	Not significant
ABCSG[61] (869)	Postmenopausal, T size up to 3 cm, HR+, N0, grade 1/2	5.1% at 5 yr	0.4% at 5 yr	< 0.001	Not significant

Abbreviations: RT, radiation therapy; CALGB, Cancer and Leukemia Group B; HR, hormone receptor.

endocrine therapy in older women was associated with a small but statistically significant benefit in local control, but that radiation therapy did not improve overall survival or distant disease-free survival. The lack of survival benefit is not a result of less healthy patients being preferentially enrolled in the studies. Of note, a comparison of expected all-cause mortality between the general population and that seen in the CALGB 9343 trial showed that the women enrolled in this trial had better than average life expectancy, even with early-stage breast cancer.[9]

The National Surgical Adjuvant Breast and Bowel Project B-21 study analyzed the effect of radiation therapy alone, endocrine therapy with tamoxifen, and both treatments in women of all ages with cancers 1 cm or smaller in size; the trial did not include an arm in which patients received neither endocrine nor radiation therapy.[16] In this study, 5% of women discontinued tamoxifen or placebo because of side effects, and 11% withdrew for other reasons. Endocrine therapy alone is associated with side effects, and one large study showed that discontinuation of endocrine therapy was more likely for women older than age 65 than for those ages 55 to 65.[17]

Without a survival or distant disease-free benefit associated with radiation therapy in randomized trials among older women with early-stage breast cancer, the key question is whether a patient is willing to trade the improved local control afforded by radiation with its inconvenience, potential side effects, and cost. Radiation therapy is generally well tolerated in older women[18] but can be associated with rare but serious side effects such as secondary malignancies and cardiac toxicity. The risk of radiation-induced malignancy decreases with increasing patient age and is associated with a latency period of usually at least 5 to 20 years.[19] Likewise, although the risk of radiation-induced cardiac toxicity is higher among women with pre-existing cardiac risk factors, a majority of cardiac events (i.e., myocardial infarction, coronary revascularization, or death from ischemic heart disease) occur 10 years or more after radiation exposure.[20] Moreover, both the risks of secondary malignancies and cardiac toxicity appear to be decreasing with modern breast radiation techniques.[19,21] The assessment of life expectancy is critical in de-

termining the potential magnitude of benefit associated with radiation therapy versus the potential for toxicity, a measure not used in randomized trials.

The inconvenience associated with receipt of radiation therapy can be lessened in the older patient with omission of a boost and hypofractionation, which can reduce the daily treatment span by almost one-half. The European Organisation for Research and Treatment of Cancer conducted a randomized trial of 5,318 patients to study the benefit of adding a 16-Gy boost to the lumpectomy site after 50 Gy of whole breast radiation therapy.[22] The use of a boost reduced local recurrence at 10 years by 41% at the expense of increased breast fibrosis. However, similar to the pattern revealed in the EBCTCG meta-analysis, when the degree of reduction in local recurrence afforded by the boost was examined within age groups, the absolute magnitude of benefit diminished with increasing age because of a lower baseline risk of recurrence in older women. Women older than age 60 had a 7.3% and 3.8% risk of local recurrence at 10 years without and with the boost, respectively—a difference of 3.5%. This is in contrast to women age 40 and younger in whom the boost reduced the risk of local recurrence from 23.9% to 13.5%, a difference of 10.4%.

In addition to omission of a boost, hypofractionation, which reduces the total number of treatments can decrease the burden associated with receiving radiation therapy. Recently, mature data have revealed that the use of hypofractionation is as effective as conventional treatment schedules. Whelan et al randomly selected 1,234 women with early-stage breast cancer treated with breast-conserving surgery to receive whole breast radiation using a 5-week schedule (200 cGy per fraction for 25 treatments) versus a hypofractionated 3-week schedule (266 cGy per fraction for 16 treatments).[23] No difference was seen in the risk of local recurrence at 10 years or in cosmetic outcome. Subset analyses revealed that the efficacy of hypofractionation was similar in both younger and older women. Likewise, the United Kingdom Standardization of breast radiotherapy (START)-B trial randomly assigned 2,215 women to a 5-week schedule (200 cGy per fraction for 25 treatments) versus a hypofractionated 3-week schedule (266 cGy per fraction for 15 treatments).[24] At a me-

dian follow-up of 9.9 years, there was no significant difference in the likelihood of local recurrence between the two treatment arms. Indeed, the absolute rate of local recurrence was slightly lower (by 1%, p = 0.21) and freedom from marked or moderate cosmetic change improved (hazard ratio [HR] 0.77; 95% CI, 0.66 to 0.89) in the hypofractionated arm. Unlike partial breast radiation and intraoperative radiation, which also reduce treatment length, boost omission and hypofractionation do not require additional equipment or training, potentially enabling patients to have fewer radiation visits in all radiation treatment centers.

A question that remains unanswered is whether tumor biology may be more relevant than patient age in determining the risk of local recurrence. A retrospective study of 1,434 patients treated with breast-conserving surgery and radiation therapy at three hospitals used immunohistochemistry and grade to divide the cancers into five tumor subtypes: Luminal A, Luminal B, Luminal-HER2, HER2, and triple negative.[25] The overall risk of local recurrence at 5 years was only 1.6%. However, in addition to patient age, tumor subtype was a highly significant predictor for local recurrence. Among patients older than age 64, the crude risk of local recurrence was under 0.5% for all subtypes, except those with triple-negative cancers where it jumped to 6.9%. An initial report of a randomized study of 769 women older than age 50 with early-stage breast cancer treated with endocrine therapy with or without radiation therapy reported a reduction in the risk of local recurrence with radiation therapy from 13.8% to 5% at a median follow-up of 10 years (p < 0.0001).[26] However, interestingly, among a subset of 304 patients in whom molecular subtyping was performed, those with Luminal A cancers did not derive benefit from radiation therapy as the risk of local recurrence was low even without radiation therapy. In these patients with Luminal A disease, there was a 5.5% risk without and 4.9% risk with radiation (p = 0.9). In contrast, those patients with Luminal B cancers had a higher baseline risk of local recurrence and a striking improvement in this risk with the addition of radiation therapy: 16.1% with tamoxifen alone and 3.9% with both tamoxifen and radiation (p = 0.05). It is likely that the lower likelihood of local recurrence in older patients is not because of age itself but that older patients are more likely to have cancers with more favorable subtypes.[27] Prospective trials that omit radiation in women with low-risk tumor subtypes are currently underway.

Estimation of the individual's risk of recurrence will improve with further molecular characterization of cancers and life expectancy, and functional age calculations can be used to put this risk into context for an individual patient. In addition, a careful assessment of comorbidity and other potential impediments to receiving radiation therapy, such as being a great distance from a radiation treatment facility, is necessary to balance these burdens associated with treatment with its potential benefits. Although radiation therapy is associated with increased treatment time, it may reduce the likelihood of mastectomy at a later date, when an older patient's functional status may become further compromised.[28] Therefore, the choice regarding radiation therapy needs to be made by

assessing a patient's preference for treatment outcomes—recurrence-free versus mastectomy-free survival relative to the treatment burden and potential risk of side effects. Future research aimed at enhancing patient comprehension about these tradeoffs will help facilitate informed decision making. In the interim, given the lack of survival benefit seen in randomized trials and small differences in local control, the decision to prescribe routine use of radiation therapy for older patients with low-risk biology or with significant comorbidity should be made on a case-by-case basis

ADJUVANT SYSTEMIC THERAPY

The decision to recommend chemotherapy to an older patient with early-stage breast cancer is complicated and requires knowledge of life expectancy, the risks and benefits of the proposed treatment, and the patient's and family's goals for treatment.[29] In general, for healthy older patients with estimated survivals of 10 years or more, state-of-the-art treatments similar to those used for younger patients should be recommended. Although older women have a higher frequency of less aggressive tumors such as hormone receptor–positive, HER2-negative tumors, as many as 25% to 30% of older patients have HER2-positive and triple-negative breast cancers, as well as more aggressive, genetically defined subtypes.[27] We suggest that before making any treatment decisions, whether for endocrine therapy or chemotherapy, the patient's life expectancy be calculated using readily available online calculators. The ePrognosis calculators are based on patient setting (e.g., community, nursing home, hospital) and estimate survivals from 6 months to up to 10 years; accurate estimates of life expectancy are crucial and take only a minimal amount of time, but it does require asking several questions related to function not usually obtained in the routine history and physical examination. For patients with an average life expectancy of less than 5 years, the value of adjuvant endocrine therapy and certainly chemotherapy is likely to be minimal except in the case of patients with extremely high-risk disease.

For clinical care, breast cancers in older patients can be divided into three subtypes: (1) hormone receptor positive and HER2 negative, the most common subtype accounting for approximately 70% of patients, 2) HER2-positive tumors, and 3) triple-negative tumors—the latter two each accounting for approximately 15% of tumors. In older patients with small hormone receptor–positive tumors, including those with hormone receptor–positive, HER2-positive tumors, endocrine therapy with either AIs or tamoxifen is the mainstay of treatment. Survival benefits are similar for both AIs and tamoxifen but overall risk of relapse is a few percent lower with AIs.[30] The toxicities of both tamoxifen and AIs are both well defined, with arthralgia, myalgia, and bone loss being the major toxicities for AI therapy, and endometrial cancer and venous thromboembolism the major side effects for tamoxifen. In general, AIs may be preferable as initial treatment in most older patients, because unlike tamoxifen, they are not associated with endometrial carcinoma and do not increase

TABLE 2. Recommendations for Adjuvant Systemic Therapy for Patients with Life Expectancies Longer Than 5 Years

Tumor Phenotype	Extent of Disease	Recommendation
Hormone receptor–positive and HER2 negative	All	Tamoxifen or aromatase inhibitor for most
	Node-negative	Consider genetic-based assay (recurrence score and others) when chemotherapy is a consideration
	1-3 nodes positive	Tamoxifen or aromatase inhibitor
	Four or more nodes	Consider chemotherapy and discuss if greater than 3% survival benefit at 10 years using online calculators
Triple negative		Consider chemotherapy if 3% of greater survival at 10 years
		Consider anthracycline and taxane regimens if survival benefit at 10 years is 3% greater than anthracycline or taxane regimens alone
HER2 positive	Small node-negative tumors	Consider paclitaxel and trastuzumab for most
	Larger node negative of node-positive tumors	Consider docetaxel, carboplatin, and trastuzumab because of more favorable toxicity profile compared to anthracycline, taxane, and trastuzumab combinations
	All	Tamoxifen or aromatase inhibitor for hormone receptor positive
		Calculate added value of chemotherapy and trastuzumab for patients with low-risk tumors and consider not recommending if survival benefit at 10 years less than 3%

the need for yearly gynecologic examinations in older women who have not had a hysterectomy. Although arthralgia and myalgia are less likely to be seen in older patients treated with AI therapy,[31] they can result in pain and functional loss and create a cause for discontinuing therapy. It is important to query older patients on either tamoxifen or AIs about their adherence and persistence with endocrine therapy. Numerous studies have shown that lack of compliance with the use of these medications is substantial, with approximately 50% of patients not completing 5 years of therapy.[17,32]

The absolute added value in improving survival with the addition of chemotherapy to endocrine therapy in older patients with hormone receptor–positive, HER2-negative tumors is highly dependent on the risk of tumor recurrence. In general, the majority of patients with node-negative hormone receptor–positive, HER2-negative tumors will derive little benefit from chemotherapy. The decision to consider chemotherapy in these patients is best made using multigene molecular assays such as the recurrence score or other assays, which can provide prognostic or predictive information.[33-35] For patients with positive nodes, chemotherapy is likely to be of small value for those with low recurrence scores and with one to three positive lymph nodes.[36,37] Those patients with four or more nodes should be considered for chemotherapy if their life expectancy exceeds 5 years. The majority of recurrences for patients with this phenotype are seen after 5 years, even though the hazard rate for recurrence is highest in the first 5 years. Patients with a life expectancy of less than 5 years, irrespective of nodal involvement, are not likely to derive any benefit from chemotherapy if they have hormone receptor–positive, HER2-negative tumors.

For older patients with triple-negative breast cancer and a life expectancy exceeding 5 years (the timeframe in which most of these tumors recur), the major systemic treatment consideration is chemotherapy. Several chemotherapy regimens are appropriate in these patients and can be roughly divided into anthracycline and nonanthracycline treatments.[38] We suggest using online calculators including Adjuvant! Online and Predict to help guide treatment decisions. Similar to our colleagues in the United Kingdom, we believe that chemotherapy should only be considered if there is at least a 3% to 5% improvement in 10-year overall survival and recommended only if survival benefit exceeds 5% at 10 years. Survival benefits of less than 3% are questionable, as the calculators have been verified mostly in younger patients and lack large samples of older patients, especially those treated with more aggressive anthracycline and taxane regimens. A recent study suggested that Adjuvant! Online overestimated the benefits of chemotherapy in older patients.[39] In general, regimens such as doxorubicin and cyclophosphamide[40] or docetaxel and cyclophosphamide[41] are preferred, unless the calculated benefit for anthracycline and taxane regimens are at least several percentage points higher. It has been previously shown that older patients with node-positive breast cancer treated with more aggressive chemotherapy regimens derive similar benefits as younger patients but with greater toxicity.[42,43] Anthracycline regimens are associated with increased risks of cardiac toxicity and, more importantly, the development of acute myelogenous leukemia (AML) and myelodysplasia (MDS).[43] Taxane regimens have substantial risks of peripheral neuropathy, a potential toxicity that can dramatically impede function and impair the quality of life of older patients.[44] The risks of cardiac toxicity and AML/MDS for anthracycline compared to nonanthracycline regimens detract from their potential benefits as calculated in online models. It is essential to get the patient's perspective when offering chemotherapy and to carefully inform patients and families of the potential for major toxicities. Acute and severe grade 3 and 4 toxicities can be reasonably estimated before starting chemotherapy,[45-47] and presenting these risks may be helpful in the treatment discussions with older patients.

For a few percent gain in survival, it is our experience that many older patients will decline chemotherapy if it is likely to affect their physical function.

Older patients with HER2-positive tumors can benefit greatly from chemotherapy and trastuzumab. Both patients with hormone receptor–positive and hormone receptor–negative tumors benefit, but the greatest absolute benefit is seen in those with a hormone receptor–negative, HER2-positive phenotype—the most aggressive phenotype for patients who do receive adjuvant systemic therapy. Recent data have suggested that a combination of weekly paclitaxel and trastuzumab for patients with stage I, node-negative disease provides outstanding disease control with an estimated relapse-free survival of 98% at 3 years.[48] More aggressive regimens should be considered for older patients with higher-risk node-negative (i.e., tumors greater than 2 cm) or node-positive HER2-positive breast cancer, including docetaxel, carboplatin, and trastuzumab, or anthracycline and taxane regimens with trastuzumab— because their overall survival benefits are similar.[49] A major concern when offering chemotherapy and trastuzumab to older patients is the risk for cardiac toxicity,[50] which is enhanced in anthracycline regimens. Before initiation of chemotherapy, patients should have estimation of left ventricular ejection fractions (LVEF) using either echocardiographic or nuclear medicine methods. Those patients with below-normal LVEF or those with normal cardiac function but other risk factors for heart disease should be referred to a cardiologist for consideration of prophylactic use of beta-blockers and/or angiotensin-converting enzyme inhibitors.[51] The use of anti-HER2 directed therapy alone or in addition to endocrine therapy in the adjuvant setting has not been adequately studied. Ongoing trials utilizing ado-trastuzumab emtansine as a single agent are in progress and focused on further minimizing cardiotoxicity while maintaining similar efficacy to current chemotherapy and trastuzumab regimens.[52]

For patients who present with large primary lesions or extensive locoregional disease but without distant metastases, neoadjuvant therapy can improve chances for breast conservation. For patients with hormone receptor–positive, HER2-negative tumors, neoadjuvant endocrine therapy can be extremely effective, possibly as effective as chemotherapy.[53] For those with triple-negative breast cancer and good life expectancy, anthracycline and taxane regimens can be used. For patients with HER2-positive disease, neoadjuvant therapy that includes pertuzumab in addition to trastuzumab provides the best chances for tumor reduction.[54,55] A summary of our recommendations for adjuvant systemic therapy is shown in Table 2.

CONCLUSION

Caring for older patients with cancer takes time and in our opinion is best done using a team of interested and informed specialists including surgical radiation and medical oncologists. In addition, other support staff such as counseling, palliative care, nutritional, and physical and occupational therapy are frequently integral to optimizing outcomes. Geriatric assessment can be learned and performed in a short period of time and can identify problems that, if addressed, may improve a patient's tolerance for treatment, quality of life, and perhaps survival.[56,57] The goals of therapy for seriously ill patients age 60 and older suggests that loss of physical or cognitive function is a major treatment-related concern.[58] This would likely be of even greater concern for 70- and 80-year-old patients. We believe that estimating life expectancy, performing the geriatric assessment to separate vulnerable from healthy older patients, and then using this information to optimize treatment based on the evidence of randomized trials will result in the best outcomes.

Triple-Negative Breast Cancer: Immune Modulation as the New Treatment Paradigm

Mary L. Disis, MD, and Sasha E. Stanton, MD, PhD

OVERVIEW

Recent studies of tumor lymphocytic immune infiltrates in breast cancer have suggested an improved prognosis associated with increasing levels of tumor-infiltrating lymphocytes (TIL). Triple-negative breast cancer (TNBC) is the breast cancer subtype that has the greatest incidence of patients with a robust tumor immune infiltrate, although it is still a minority of patients. Elevated levels of either intratumoral or stromal T cells are associated with an improved overall survival (OS) and disease-free survival (DFS) in TNBC as compared with other breast cancer subtypes. TNBC may be immunogenic for several reasons. Subtypes of TNBC have a significant number of genetic mutations, and the immune system may see the aberrant proteins encoded by these mutations as foreign. Moreover, TNBC is associated with a prognostic gene signature that also includes B cells. Antibodies secreted by B cells may bind to tumor antigens and amplify the adaptive immune response that has already been initiated in the tumor. New immune modulatory agents, including immune checkpoint inhibitors, have shown activity in immunogenic tumors such as melanoma and bladder cancer and have recently been tested in TNBC. The clinical response rates observed, patterns of response, and adverse event profiles are similar to what has been described in melanoma where this class of agents has already been approved for clinical use in some cases. Lessons learned in assessing the immunogenicity of TNBC, potential mechanisms of immune stimulation, and response to immune modulatory drugs lay the foundation for the development of immune-based therapies in all subtypes of the disease.

The immune system is controlled by a balance of cellular signals that both initiate immune responses and actively inhibit inflammation induced by immunity. The ability to suppress immunity is critical to protect normal tissues from collateral damage during pathogen-destructive immune responses. The cells of both the innate (neutrophils, monocytes, macrophages, and a host of antigen-presenting cells [APC]) and the adaptive (T and B lymphocytes) immune system are called on to respond to pathogens or other threats. Working in concert, innate immune cells are required for T cells and B cells to be able to identify immunogenic proteins (i.e., antigens in the environment). Further, innate immune cells produce cytokines that optimize lymphocytic function. The lymphocytes can then recognize cells expressing foreign proteins and kill those cells. The generation of adaptive immunity in the appropriate cytokine milieu allows for the development of memory cells: long-lived lymphocytes that remain in lymph nodes and readily respond to the specific threat if further exposure occurs.

Proinflammatory type I immunity is the immune response needed to eliminate cancer. In a type I immune response, CD4 T-helper (Th) lymphocytes, called Th1, secrete cytokines such as interferon-gamma (IFN-gamma) and TNF-alpha that activate and enhance the lytic function of CD8 T-lymphocytes. Cytokines produced by type I T cells induce the upregulation of costimulatory molecules on APC, of the innate immune system allowing those cells to more effectively present immunogenic proteins to the T cells. CD8 T cells are cytolytic, and once they dock on a target through interaction with antigenic peptide containing major histocompatibility complex (MHC) molecules on the surface of that target, they either induce cell senescence or directly lyse target cells via a series of enzymatic reactions.

Breast cancer is capable of stimulating the immune system. It is well defined that some breast tumors have substantial lymphocytic infiltration, and the more T cells found in the cancer, the more favorable the prognosis.[1] Most breast cancers, however, have been infiltrated with few or even no T cells.[2,3] Breast cancers have modest levels of lymphocytic infiltrates for many reasons. One is that the immune cells found in the tumor microenvironment of breast cancer are type II cells. The CD4 Th2 cells express cytokines such as interleukin (IL)-10 and IL-6, which dampen destructive immunity. Innate immune cells and high levels of regulatory T cells (Treg) in the type II environment secrete substances that both inhibit the function of CD8 T cells and prevent their migration to the tumor, producing only a limited number of less active CD8 T cells available to induce tumor regression. Breast cancer can secrete substances that influence APC to educate T

cells to become type II rather than type I cells.[4] Most antigens present in breast cancer are self proteins, and the portions of the proteins that are most likely to stimulate T cells induce a regulatory immune response.[5] Furthermore, 30% to 50% of all breast cancers have upregulated programmed death ligand 1 receptor (PD-L1) on the cell surface.[6] When PD-L1 binds with programmed cell death protein 1 (PD-1) on the surface of T cells, the lymphocytes become inactivated. These are just a few of the mechanisms by which robust type I immunity is prevented from developing in breast cancer.

Breast cancer subtypes differ in the level of immune infiltration observed in the tumor. More patients with TNBC fall into the category of having a robust tumor T-cell infiltrate than any other subtype. Hormone receptor–positive disease is the subtype associated with the least robust number of TIL. HER2-positive disease has also been shown to have a number of patients with significant TIL in their tumor. In HER2-positive breast cancer, the numbers of TIL can be further increased by treatment with trastuzumab.[7] However, the prognostic significance of a robust TIL response is most pronounced for the TNBC subtype.

TUMOR LYMPHOCYTIC INFILTRATES IN TRIPLE-NEGATIVE BREAST CANCER

The clinical importance of tumor immune infiltrates has been an emerging area of research in breast cancer, particularly in TNBC where increased immune infiltrate predicts both response to chemotherapy and improved survival.[8,9] Tumors that have greater than 50% lymphocytic infiltrate are called lymphocyte-predominant breast cancer (LPBC) and

have the best prognosis. Interestingly, TNBC is most likely to have LPBC.[2,10] The presence of LPBC has been shown to predict improved pathologic complete response (pCR) to neoadjuvant chemotherapy. LPBC is associated with a pCR of approximately 40%, whereas tumors with no lymphocytic infiltrate have a 4% pCR rate (OR 1.39; 95% CI, 1.08 to 1.78; p = 0.012).[1] Specifically, in TNBC, LPBC was an independent predictor for improved pCR in multivariate analysis (OR 2.17; 95% CI, 1.27 to 3.72; p = 0.005).[1] A meta-analysis of studies examining TIL and pCR in all breast cancers with TIL present in the pretreatment biopsy predicted a 2.5-times increased pCR rate in TNBC (OR 3.30; 95% CI, 2.31 to 4.73; p < 0.0001).[11] The presence of TIL has also been shown to predict an improved clinical outcome in TNBC. In a study of 256 triple-negative tumors, LPBC was associated with both an improved DFS (p = 0.018; hazard ratio [HR] 0.30; 95% CI, 0.11 to 0.81) and OS (p = 0.036; HR 0.29; 95% CI, 0.091 to 0.92), and when TIL were evaluated as a continuous variable, every 10% increase in TIL correlated with a 17% decrease in the risk of recurrence (p = 0.023; HR 0.83; 95% CI, 0.71 to 0.98) and a 27% decreased risk of death (p = 0.035; HR 0.73; 95% CI, 0.54 to 0.98).[2] Similar results from a study of 278 patients showed that 5-year OS of patients with TNBC with LBPC compared to those without TIL was 91% and 55%, respectively, (HR 0.19; 95% CI, 0.06 to 0.61; p = 0.0017) further emphasizing that high TIL predict a portion of patients with TNBC who do well in this otherwise poor outcome subtype.[8] When a meta-analysis of TIL was performed in almost 3,000 patients with TNBC with a median 113-month follow-up, increased TILs were associated with 30% reduction in risk of recurrence (HR 0.70; 95% CI, 0.56 to 0.87; p = 0.001), 22% decreased risk of distant recurrence (HR 0.78; 95% CI, 0.68 to 0.90; p = 0.0008), and a 35% decreased risk of death (HR 0.66; 95% CI, 0.53 to 0.83; p = 0.0003).[10] Although LPBC has been shown to predict benefit in TNBC, it has not been shown to predict improved OS or DFS in HR-positive or HER2-positive breast cancer.[2]

Although evaluation of TIL gives a global measure of lymphocytic immune infiltrate, it does not define the specific phenotype of populations of immune cells infiltrating the tumor, and these immune subsets may further define clinical outcome and guide further immune therapy. Triple-negative tumors have been evaluated for cytotoxic CD8 T-cell infiltrate, which has been shown to predict improved OS in breast cancers in general.[12] Intratumoral CD8 T-cell infiltration above the mean per high-powered field predicted a pCR of 46% compared with a low CD8 T-cell infiltration (15%; p = 0.002), with an increased intratumoral CD8/FOXP3 ratio independently predicting improved pCR (OR 5.32; 95% CI, 1.62 to 19.98; p = 0.005) in a study of 110 patients with TNBC after receiving neoadjuvant chemotherapy.[13] Furthermore, in multiple studies, the presence of CD8 T-cell infiltrate has been associated with improved survival in TNBC, although response with increasing levels of CD8 T-cell infiltrate has not been quantified as it has with LPBC. Improved relapse-free survival was found in a study of 448 triple-negative tumors either with intratumoral (p = 0.016) or stromal (p = 0.001) CD8[+] T

cells. Improved disease-specific survival (p = 0.031; response rate [RR] 0.70; 95% CI, 0.5 to 1.0) was observed as well.[14] Similarly, CD8 T cells increased above the mean predicted improved disease-specific survival in 927 triple-negative breast tumors (p = 0.001; HR 0.35; 95% CI, 0.23 to 0.54).[15] Although TNBC is the subtype most associated with TIL, only a minority of patients' tumors demonstrate LPBC, suggesting immune modulatory therapy is needed to increase the adaptive immune infiltrate to levels necessary for survival benefit in the majority of patients with this breast cancer subtype.

POTENTIAL MECHANISMS OF IMMUNE STIMULATION IN TRIPLE-NEGATIVE BREAST CANCER

What makes TNBC more likely to be infiltrated with lymphocytes than other breast cancer subtypes? One potential mechanism is that TNBC is immunogenic because of genetic instability and increased mutations. Mutated genes may encode proteins that appear slightly different to the immune system. Peptide epitopes that contain a mutation and are presented to T cells in the MHC may be recognized as more foreign than nonmutated sequences. A recent study evaluating patients with metastatic melanoma treated with the CTLA-4 blocking monoclonal antibodies ipilimumab or tremelimumab demonstrated that the level of tumor mutational load was associated with the degree of clinical benefit from these immune modulators (p = 0.01).[16] The authors further evaluated a mutational signature consisting of specific peptide sequences that were shared across patients' tumors and predicted to bind with higher affinity to MHC. The neo-epitope signature demonstrated a stronger association between response and OS than mutational load alone.[16]

Tumors from patients with TNBC are more likely than other subtypes to demonstrate chromosomal instability and, potentially, mutations.[17] In a survey of over 300 breast tumors, although chromosomal instability predicted worse prognosis for most subtypes, there was no clinical effect observed for patients with TNBC. Recent investigations have performed deep sequencing on 104 cases of TNBC and demonstrated that tumor gene mutations were highly variable with the median number of somatic mutations about 50, but only one-third of the mutations identified were expressed—a requirement for immune recognition.[18] These data suggest that although tumor-specific mutations may play a role for the enhanced immunogenicity of TNBC, there must be other contributing factors.

Compared with other breast cancer subtypes, TNBC has also been associated with a positive prognostic signature that is B cell–specific. B cells are mediated by Th2 T cells and, when present in breast cancer, have been associated with increased cell growth.[19] Evidence suggests, however, that tumor-targeting B cells may enhance antitumor immunity by stimulating antibody-dependent cell-mediated cytotoxicity, a mechanism of tumor cell death initiated by IFN-gamma secreting natural killer (NK) cells.[20] Several investigators have identified a meta-gene signature that includes a B-cell/plasma cell component associated with improved survival, particularly in the basal cell phenotype of TNBC.[21] A ratio of

high B cell and low IL-8 identified one-third of TNBC with good prognosis (HR 0.37; 95% CI, 0.22 to 0.61; p < 0.001). The B-cell signature was shown to increase the predictive value of other prognostic signatures for TNBC when used in combination.[22] Finally, recent studies have used mRNA sequencing to assess the degree of somatic hypermutations in B cells thus evaluating B-cell population diversity in breast tumors. The presence of clonal B-cell populations in TNBC—indicating an evolving adaptive immune response—was associated with an improved metastasis-free and progression-free survival.[23] Antibodies of multiple different specificities binding to proteins expressed in TNBC could draw increased numbers of innate immune cells capable of processing and presenting tumor antigens to T cells to the tumor bed. Moreover, the type I cytokines produced by the NK cells recruited via antibody Fc receptors could further activate an adaptive immune response.

Although the majority of TNBC requires immune modulatory therapies that would increase TIL, those patients with high levels of TIL might benefit from the use of immune checkpoint inhibitor agents to further augment the lymphocytic response to beneficial therapeutic effect.

IMMUNE CHECKPOINT INHIBITORS IN TRIPLE-NEGATIVE BREAST CANCER

As TNBC seems to be the subtype most associated with the presence of TIL, clinical studies have attempted to assess the utility of immune checkpoint inhibitor therapy as a potential effective treatment for the disease. Immune checkpoint proteins are present on normal tissues, cells of the innate immune system, and lymphocytes. When a T cell interacts through its immune checkpoint receptor protein (e.g., PD-1), with the companion receptor on an APC or tumor cell (e.g., PD-L1), that T cell will be inactivated. Immune checkpoint proteins become upregulated in the presence of inflammation and, as stated above, are a part of the host's natural defenses limiting immune-mediated destruction of normal tissues.

Monoclonal antibodies have been developed that will block specific immune checkpoint proteins. Three of these antibodies are approved by the U.S. Food and Drug Administration for the treatment of metastatic melanoma and are used as a standard of care for some patients. Ipilimumab blocks CTLA-4 and does not allow the T cell to interact with the receptor via CD28 on its cell surface. Nivolumab and pembrolizumab are antibodies that will block PD-1 on the surface of T cells and prevents those T cells from interacting with PD-L1. Monoclonal antibodies that will block PD-L1 are also being studied in clinical trials.

Investigations evaluating the presence of PD-1 on TIL and PD-L1 on tumor cells in breast cancer have found that immune checkpoint proteins are upregulated in many breast cancers, particularly the triple-negative subtype. The reported incidence of expression is highly variable and may depend on methods used to assess immune checkpoint proteins as well as the quality of reagents available to interrogate tissues for protein expression. One study of 116 breast cancers

TABLE 1. Unique Characteristics of Immune Checkpoint Inhibitor Therapy

Clinical Observation	Rational
Slower time to response than observed with standard cytotoxic agents	T cells proliferate and divide in response to antigen and immunomodulation. T cells need time to expand to the numbers required for an influence on tumor growth.
Initial increase in tumor size followed by regression	Trafficking T cells can infiltrate the tumor in high enough numbers to cause inflammation and swelling—known as pseudoprogression.
Immune-related adverse events	General immune stimulators, such as checkpoint inhibitors, can induce immunity reactive to normal tissues that are immunologically active (e.g., skin, gut).
Prolonged periods of disease stabilization	T cells and tumor cells can exist in an immunologic equilibrium in which T cells control tumor growth but do not eradicate cancer.
Mixed responses with some lesions responding while other metastatic sites progress	This represents the development of immunologic remodeling where some metastatic deposits have developed mechanisms of immune resistance.

found that PD-1 was expressed on the surface of 50% of TIL, PD-L1 was present in 45% of breast cancers, and concurrent expression of both occurred in 29%.[24] TILs expressing PD-1 were more commonly found in the triple-negative subtype (70%) than in the rest of the subtypes (25% to 44%, p < 0.001). PD-L1 was also more commonly expressed in triple-negative disease than the other subtypes (59 vs. 33%, p = 0.017). In this study, PD-1-positive TILs were associated specifically with the presence of p53 mutations in TNBC potentially representing a neoepitope signature, whereas there was no correlation of the expression of PD-L1 and mutational load. An additional study analyzing PD-L1 gene expression and using data from the Cancer Genome Atlas found that TNBC showed significant upregulation of PD-L1 as compared to other subtypes (p < 0.001). Evaluation by tissue microarray demonstrated 19% of 105 patients with TNBC expressed PD-L1.[25] Data such as these has supported the study of immune checkpoint inhibitors in TNBC.

One of the first completed clinical trials of a PD-1 monoclonal antibody (pembrolizumab) in TNBC was reported at the 2014 San Antonio Breast Cancer meeting by Nanda et al.[26] The phase Ib study enrolled 32 patients with TNBC who had recurrent or metastatic disease (47% of which had more than three lines of previous chemotherapy) with PD-L1 expression in their tumor (58% of all patients screened had PD-L1-positive tumors). Pembrolizumab was administered 10 mg/kg intravenously every 2 weeks, and treatment could continue indefinitely as long as patients were stable and their disease was not clearly progressing as assessed by RECIST v1.1 every 8 weeks. Treatment with PD-1 blockade was tolerable, with 56% of patients reporting an adverse event, but only 16% with grade 3–5 toxicity. There was one treatment-related death caused by disseminated intravascular coagulation. The overall RR was 19% (27 patients were evaluable for response) with one (4%) complete response, four (15%) partial responses, and seven patients (26%) with stable disease. Of note, the median time to response was 18 weeks (range, 7 to 32) underscoring the unique kinetics of response seen with immune modulation as compared with conventional cytotoxic agents. Other unique characteristics of immune checkpoint inhibitor therapy are shown in Table 1.

Initial data from a phase I study of an anti-PD-L1 mono-

clonal antibody, MPDL3280A, in metastatic TNBC was also reported.[27] To date, Emens et al have treated 12 patients with PD-L1-positive disease. Grade 3– 4 toxicities occurred in 8% of patients (one renal insufficiency). Although immune-related adverse events have been reported with the use of immune checkpoint inhibitor agents (Table 2), only one patient in this study demonstrated grade 2 pyrexia that was potentially attributable to immune activation. In general, immune-related adverse events occur in a minority of patients. There were no toxicity related deaths. Despite the fact that over 90% of patients had been previously treated with more than two prior regimens and one-third of those enrolled had visceral metastases, the overall RR was 33% in the nine patients evaluable for efficacy (one complete response and two partial responses). All responses were seen within the first 6 weeks of treatment.

CONCLUSION

Population-based studies of TIL in breast cancer have underscored that the disease is immunologically active, with TNBC showing the greatest benefit from an endogenous immune response. Initial studies of immune modulation clearly indicate that TNBC is responsive to newly developed immuno-oncology agents that have been clinically effective in classic immunologic tumors such as melanoma. This observation furthermore may allow immune-based therapies to move rapidly from clinical development to standard of care in TNBC. Rational combinations to further enhance immunity should be tested in all subtypes of breast cancer. Identifying the components of the tumor immune environment that improve prognosis in breast cancer may also identify methods

TABLE 2. Immune-Related Adverse Events

Site	Adverse Event
Skin	Rash, pruritus, hives, sun sensitivity
Liver	Elevated liver function tests, hepatitis
Endocrine	Headache, visual field changes, adrenal insufficiency, hypopituitarism, hypothyroid, hypophysitis
Gut	Diarrhea, colitis

to modify the tumor immune environment to improve prognosis for tumors that do not contain TIL. For TNBC, controlling tumor growth with immunologically active conventional chemotherapies in combination with immune checkpoint inhibitors could increase response rates. For patients with limited T-cell infiltration vaccine priming before or concurrent with immune checkpoint inhibitors may result in clinical benefit. A better understanding of the immune microenvironment and why certain subtypes of breast cancer are more, or less, immunogenic will speed the clinical application of immune modulatory therapies to the benefit of all patients with breast cancer. Lessons learned in triple-negative disease is a great start to improved outcomes for all.

Triple-Negative Breast Cancer: Molecular Subtypes and New Targets for Therapy

Brian D. Lehmann, PhD, Jennifer A. Pietenpol, PhD, and Antoinette R. Tan, MD, MHSc

OVERVIEW

Triple-negative breast cancer (TNBC) is a molecularly diverse disease. This heterogeneity has limited the success of targeted therapy in unselected patients to date. Recent transcriptional analysis has divided TNBC into transcriptionally similar subtypes that may have different sensitivity to neoadjuvant chemotherapy and targeted therapy. At present, chemotherapy is the mainstay of treatment for early-stage and advanced TNBC; however, several actionable targets show promise in preclinical studies. Novel therapeutic strategies are currently being tested in phase II and phase III trials and will likely require patient stratification before therapy. Examples of these tailored approaches include poly(ADP-ribose) polymerase inhibitors for *BRCA*-mutated TNBC, antiandrogens for androgen receptor (AR)–positive TNBC, fibroblast growth factor receptor (FGFR) inhibitors for TNBC harboring FGFR amplifications, and gamma-secretase inhibitors for TNBC with mutations in the PEST domain of NOTCH proteins. Treatment of TNBC based on molecular subsets represents a potential algorithm for the future. Well-designed clinical trials with incorporation of integrated biomarkers are necessary to advance the development of molecularly targeted therapy for different subgroups of TNBC.

TNBC is a heterogeneous collection of breast cancers lacking expression of estrogen receptor (ER), progesterone receptor (PR), and HER2 amplification. Together these tumors represent approximately 15% of all breast cancers, preferentially affect young women, and are more frequent in women of African and Hispanic descent.[1,2] Patients with TNBC have a higher risk of both local and distant recurrence, and metastasis is more likely to occur in the brain and lungs rather than bone compared to other subtypes. The overwhelming majority of metastases of TNBC occur within the first 3 years following diagnosis, and patients who have not recurred during this time have similar survival rates as do patients with ER-positive breast cancers.[3]

There is a well-established association between deleterious *BRCA1* mutations and the risk of developing TNBC, with lifetime risks reaching as high as 50% to 85%. BRCA1 encodes an E3 ubiquitin protein ligase essential for homologous recombination mediated-repair of DNA double-stand breaks. Retrospective analysis and previous trials have shown striking pathologic complete response (pCR) rates in *BRCA1* mutation carriers (72% to 90%) with single-agent neoadjuvant DNA-crosslinking platinum salts (e.g., cisplatin).[4,5] In the metastatic TNBC setting, a phase III study (Triple Negative Breast Cancer Trial, TNT) of carboplatin area under the curve (AUC) 6 every 3 weeks compared with docetaxel 100 mg/m^2 every 3 weeks as first-line treatment was conducted in 376 women with assessment of *BRCA* status.[6] In the overall population, at a median follow-up of 11 months, outcomes were similar in terms of response rate (31.4% vs. 35.6%; p = 0.44), progression-free survival (PFS, 4.5 vs. 3.1 months), and overall survival (OS, 12.3 vs. 12.4 months), between the docetaxel and carboplatin arm, respectively. However, *BRCA* mutant carriers who received carboplatin compared with docetaxel experienced a significantly greater response (68% vs. 33.3%; 95% CI, 6.3 to 63.1; p = 0.03). The median PFS for patients with *BRCA1/2* mutations in the carboplatin group was 6.8 months compared with 3.1 months for non-*BRCA* mutation carriers, and 4.8 months and 4.6 months, respectively, among patients with and without *BRCA1/2* mutations treated with docetaxel. These data strongly support the use of a platinum agent for metastatic TNBC with *BRCA* mutations.

Although germ-line *BRCA1* mutations are more frequently observed in TNBC,[7] only a few recurrently mutated genes across the heterogeneous group of tumors make up TNBC. Recent sequencing efforts have shown the most frequent somatic mutations occur in TP53 (62%) and PIK3CA (10%), the gene encoding the p110alpha catalytic subunit of phosphatidylinositol-3 kinase (PI3K).[8,9] In addition to diverse mutations, TNBC tumors also display heterogeneity at the copy number and expression level with several clusters containing basal-like tumors.[10] Unlike ER-positive and HER2-amplified breast cancers, the lack of high frequency oncogenic driver mutations in TNBC means limited molecularly targeted treatments for this disease.

Neoadjuvant chemotherapy has proven efficacy in the treatment of TNBC and the regimens include combinations of anthracyclines, alkylating agents, taxanes, and platinum salts. Patients treated with neoadjuvant chemotherapy who experience a pCR at the time of surgery have significant improvements in both disease-free survival (DFS) and OS compared to patients with residual invasive disease.[11] The latter patients have a much poorer prognosis and are six times more likely to have recurrence and 12 times more likely to die.[12,13] Currently, there are no clinically actionable biomarkers to predict which patients with TNBC will experience a pCR.

MOLECULAR HETEROGENEITY OF TNBC

TNBC show a remarkable diversity of histologic patterns and subtypes. Although majority are high-grade invasive ductal carcinomas, a small subset has distinct pathologic features and indolent clinical behavior. Rare cases of adenoid cystic carcinomas and secretory carcinomas share common recurrent chromosomal translocations, resulting in oncogenic chimeric fusions (MYB-NFIB and ETV6-NTRK3, respectively).[14,15] In addition, several TNBC have atypical medullary and metaplastic histologies. Medullary carcinomas are characterized by infiltrating carcinomas with circumscribed pushing borders, dense peripheral lymphoid infiltrate, and have favorable outcome, whereas metaplastic carcinomas display differentiation toward squamous epithelium with mesenchymal components and cells displaying spindle, chondroid, osseous, or rhabdoid morphologies.[16,17]

Given the diverse pathologic classifications, one would predict that TNBC have a diverse array of biologic subtypes that could be revealed by transcriptional profiling. Initial global transcriptional studies showed TNBC to largely display basal-like gene expression.[18] This observation led many

investigators to consider basal-like breast tumors and TNBC to be relatively synonymous. The uniform basal-like gene expression pattern in TNBC is largely a result of the significant transcriptional differences between hormonally driven cancers and TNBC.[19] However, when analyzed independent from ER- and HER2-positive cancers, TNBC have quite heterogeneous gene expression patterns that can be used to classify the tumors into distinct subtypes.[20,21]

SUBTYPES OF TNBC

Using gene expression analyses from 386 tumors, we recently identified six distinct TNBC subtypes, each displaying unique biologies.[20] The TNBC molecular subtypes include two basal-like (BL1 and BL2), an immunomodulatory (IM), a mesenchymal (M), a mesenchymal stem-like (MSL), and a luminal AR (LAR) subtype. The BL1 subtype is characterized by elevated cell cycle and DNA damage response gene expression, while the BL2 subtype is enriched in growth factor signaling and myoepithelial markers. Both M and MSL share elevated expression of genes involved in epithelial-mesenchymal-transition (EMT) and growth factor pathways, but the MSL subtype has decreased expression of genes involved in proliferation. Consistent with the dedifferentiated mesenchymal gene expression pattern is the recent analysis of metaplastic breast cancers showing the majority of chondroid and spindle cell carcinomas to be of the MSL subtype.[17] The IM subtype is composed of immune antigens and genes involved in cytokine and core immune signal transduction pathways. The LAR subtype is characterized by luminal gene expression and is driven by the AR. Comparison with the intrinsic subtypes demonstrated that BL1, BL2, IM, and M are largely composed of basal-like subtype, while MSL has a large fraction of normal-like and LAR mostly composed of luminal and HER2 subtypes.[19] In addition to the intrinsic subtypes, a claudin-low subtype has recently been described and is enriched for EMT markers, immune response, and cancer stem cell–like genes.[22] This claudin-low subtype is mostly composed of M and MSL TNBC subtypes.[19]

In addition, we identified representative cell lines and demonstrated differential sensitivity to chemotherapy and targeted agents. BL1 cell lines are sensitive to genotoxic agents, LAR cell lines have differential sensitivity to the LAR antagonist bicalutamide and PI3K inhibitors, mesenchymal cell lines are more sensitive to the multifamily tyrosine kinase inhibitor dasatinib, and M cell lines display some sensitivity to PI3K/mTOR inhibitors. Subtyping of breast tumors from The Cancer Genome Atlas (TCGA) resulted in identification of 163 tumors and analysis of the clinical data associated with TNBC tumors demonstrated that the median OS and DFS of patients with BL1, IM, and MSL subtype tumors were nearly double that of patients with BL2, LAR, and M tumors.[23] Further, patients with tumors of the IM subtype had the best outcome. Analysis of the gene expression data from the IM subtype and identification of transcripts associated with lymphocytes suggests that the IM tumor samples may contain

tumor-infiltrating lymphocytes (TILs). The favorable outcome of patients with TNBC with higher levels of TILs associated with their tumors has recently been demonstrated in two adjuvant phase III trials.[24]

A similar transcriptional analysis was recently performed on a smaller cohort of 84 patients, and investigators identified four stable TNBC subgroups associated with distinct clinical outcomes.[21] They defined these subtypes as "luminal/androgen receptor (LAR)," "mesenchymal (MES)," "basal-like/immune-suppressed (BLIS)," and "basal-like/immune activated (BLIA)" groups. Similar to the previous study, TNBC patients with tumors expressing immune component features had the best outcome. Between the two studies there is clearly evident overlap between MSL and MES, IM and BL1 with BLIA, M with BLIS, and the two LAR subtypes. In summary, these data show that reproducible and distinct transcriptional subtypes can be unmasked when TNBC samples are analyzed in the absence of ER- and HER2-expressing tumors and as sample size is increased there will likely be additional unique subtypes revealed.

Despite the rather aggressive clinical behavior of TNBC, approximately 30% of patients with TNBC benefit from chemotherapy. In a retrospective reanalysis of pretreatment biopsies, TNBC molecular subtypes were predictive of response to neoadjuvant anthracycline and cyclophosphamide followed by taxane.[25] This study showed BL1 had the highest pCR rate (50%) at time of surgery and BL2 and LAR had the lowest (0% and 10%, respectively). Similar to the initial classification, patients with LAR subtype were significantly older at diagnosis, and recent preclinical data suggest that these patients may benefit from antiandrogen or PI3K inhibitors.[26] We recently demonstrated that PIK3CA kinase domain mutations are a frequent event in AR-positive TNBC tumors relative to the other subtypes (40% vs. 4%), and targeting of AR in LAR cells increases sensitivity to PI3K inhibitors. These data suggest that although there are few genomic alterations shared by TNBC as a whole, individual subtypes may be enriched in select somatic alterations, several of which may afford opportunities for preclinical discovery and translation to clinical investigation.

NOVEL APPROACHES FOR TREATMENT OF TNBC

Chemotherapy at present is the main treatment for patients with TNBC. No specific targeted agent has U.S. Food and Drug Administration (FDA) or European Medicines Agency (EMA) approval to treat TNBC in the adjuvant, neoadjuvant, or metastatic settings. This article discusses the most recent data on promising and novel targeted, nonimmunotherapeutic approaches currently under evaluation for TNBC.

Poly(ADP-Ribose) Polymerase Inhibition

The PARP enzyme plays an important role in the repair of DNA single-strand breaks via the base-excision repair (BER) pathway. PARP protein binds directly to sites of DNA damage and recruits other DNA repair enzymes. In normal cells,

BER and homologous recombination (HR, repair of DNA double-strand breaks) are both available to repair damaged DNA. In cancer cells of *BRCA1* or *BRCA2* mutation carriers, where HR is nonfunctional, PARP inhibition leads to an accumulation of DNA single-strand breaks that degenerate into double-strand breaks and result in cell death, as the cells are unable to repair DNA damage by either BER or HR.[27] This "synthetic lethality" has been demonstrated in several preclinical studies where BRCA-deficient cells are markedly sensitive to PARP inhibitors.[28,29] The prevalence of *BRCA1* or *2* mutations in TNBC is estimated to be between 10.6% and 19.8%.[7,30] Since genomic instability is common to both *BRCA*-mutated cancers and TNBC, investigators have tried to expand BRCA-deficient tumors to include those TNBC with transcriptional profiles similar to BRCA-mutants, referred to as BRCAness.[31] These observations have led to multiple efforts in evaluating PARP inhibitors as monotherapy or in combination with cytotoxic agents in the treatment of both mutant and sporadic TNBC.

Olaparib was the first oral PARP inhibitor to be approved under accelerated approval by the FDA in December 2014 as single-agent treatment of patients with a deleterious or suspected deleterious germ-line *BRCA* mutated advanced ovarian cancer, treated with three or more prior lines of chemotherapy. Additionally, the EMA recommended approval of olaparib for use in the maintenance treatment of platinum-sensitive relapsed *BRCA*-mutated (germ line and/or somatic) high-grade serous epithelial ovarian, fallopian tube, or primary peritoneal cancer in complete response or partial response to platinum-based chemotherapy, and has been granted marketing authorization by the European Commission. The side effects of PARP inhibitors are mild and include fatigue, nausea, and vomiting.

In breast cancer, the antitumor activity of PARP inhibitors is evidenced in several metastatic trials, and the most compelling subset to benefit are the patients that harbor *BRCA*-mutations. Several phase II trials of PARP inhibitors as monotherapy have been conducted in patients with metastatic breast cancer (MBC). Tutt et al evaluated olaparib in 54 patients with MBC and germ-line *BRCA* mutations who were treated previously with a median of three prior chemotherapy regimens.[32] Two cohorts were enrolled. One group (50% triple negative) was treated with olaparib 400 mg twice daily and the second group (64% triple negative) with 100 mg twice daily. In patients with TNBC, the response rate was 54% (7/13) in the higher-dose group, and 25% (4/16) in the lower-dose group; all were partial responses. Disease stabilization was 31% and 44%, respectively. This proof of concept study confirmed activity in *BRCA*-mutated TNBC, as well as in patients who were ER positive and HER2 positive. In an international, multicenter phase II study by Kaufman et al, 298 patients with *BRCA1* and *BRCA2*-associated cancers, including breast, ovarian, pancreatic, and prostate, were treated with olaparib 400 mg twice daily.[33] In the MBC cohort of 62 patients, the overall response rate was 12.9% (95% CI, 5.7% to 23.9%; all partial responses). In the 30 patients with ER-negative tumors, the response rate was 13.3% (95% CI,

3.8% to 30.7%). The lower efficacy in this trial may be a result of a more pretreated population in which the median number of prior chemotherapies was 4.6 and a higher percentage of patients with prior platinum exposure. In another multi-center trial, no responses were observed in 15 patients with non-*BRCA* TNBC who received olaparib 400 mg twice a day, indicating that single-agent PARP inhibitor is not likely to be a treatment approach for sporadic TNBC.[34]

Veliparib, another oral PARP 1 and 2 inhibitor, has been extensively evaluated in combination with several chemo-therapeutic agents as a chemopotentiator. Isakoff et al con-ducted a study in 41 patients with MBC who had at least one prior cytotoxic regimen and were given veliparib 30 mg orally twice daily day 1 through 7 (originally started at 40 mg but reduced secondary to grade 4 thrombocytopenia) and te-mozolomide 100 mg/m^2 orally daily day 1 through 5 every 28 days.[35] The response rate in *BRCA*-mutation carriers was 37.5% (3/8), including one complete response and two partial responses, and there were no responses in non-*BRCA* carri-ers (0/33). To date, the data suggest that a monotherapy treat-ment strategy for PARP inhibitors is not active in sporadic TNBC, but preferentially active in *BRCA*-mutated breast cancer. The combination of a PARP inhibitor and DNA-damaging agents for potentiation may still have a role in a specific subset of sporadic TNBC. Given the observed activity of PARP inhibitors in these studies, major phase III clinical trial efforts are underway to evaluate the benefit of PARP in-hibitors in the adjuvant and neoadjuvant settings.

OlympiA (National Surgical Adjuvant Breast and Bowel Project [NSABP] B-55/BIG 6-13, NCT02032823) is a ran-domized, double-blind, placebo-controlled phase III study to evaluate the effect of adjuvant treatment with olaparib in 1,320 patients with germ-line *BRCA1/2* mutations and TNBC who have completed definitive local treatment.[36] This is a global, collaborative effort led by NRG Oncology and the Breast International Group and sponsored by the National Cancer Institute and AstraZeneca. The primary endpoint is invasive DFS. Randomization is 1:1 to either 12 months treat-ment with olaparib 300 mg orally twice daily or matching placebo. Eligible patients are those who did not achieve a pCR following at least six cycles of neoadjuvant chemother-apy followed by surgery or patients with either axillary node-positive disease or axillary node-negative disease with a primary tumor larger than 2 cm, who have undergone sur-gery and have completed at least six cycles of adjuvant che-motherapy. This is a unique trial targeting a rare population, with the potential to change the current adjuvant standard of care of observation for high-risk primary TNBC with *BRCA* mutations.

Another phase III clinical trial (M14-011, AFT-04, ABCSG 44, GBG 81, GEICAM/2014-02, NSABP B56-I, USO 12152, NCT02032277) is the first to evaluate the efficacy of veliparib in combination with chemotherapy for neoadjuvant treat-ment of TNBC.[37] This is a randomized, placebo-controlled, double-blind trial enrolling women presenting with clinical stage T2-4N0-2 or T1N1-2 triple-negative disease, who are candidates for potentially curative surgery. They will be ran-

domly assigned in a 2:1:1 ratio to one of three neoadjuvant treatment arms: (arm A) weekly paclitaxel 80 mg/m^2 for 12 weeks, carboplatin (AUC6), veliparib 50 mg orally twice daily followed by doxorubicin and cyclophosphamide (AC); (arm B) weekly paclitaxel 80 mg/m^2 for 12 weeks, carboplatin (AUC6), placebo followed by AC; or (arm C) weekly pacli-taxel 80 mg/m^2 for 12 weeks, placebo, placebo followed by AC. All patients must have documented *BRCA* germ-line mutation testing. The primary endpoint is pCR in the breast and lymph node. The trial seeks to accrue 624 subjects in about 200 sites. This is another global collaboration with sev-eral groups including the Alliance for Clinical Trials in On-cology, Austrian Breast and Colorectal Cancer Study Group, German Breast Group, Grupo Espanol de Investigacion en Cancer de Mama, NSABP Foundation, and US Oncology, and it is sponsored by Abbvie. The results of this study will help answer the question of the utility of carboplatin with and without a PARP inhibitor in TNBC with and without *BRCA* mutations. Results from these studies will hopefully lead to the availability of PARP inhibitors in routine clinical practice for patients with *BRCA*-mutated breast cancers and TNBC with DNA repair pathway defects.

More effective treatment strategies are needed for sporadic TNBC. Other approaches are being developed to sensitize sporadic TNBC to PARP inhibition. One example is an on-going clinical trial (NCT01623349) that is evaluating olapa-rib and BKM120 (buparlisib) or BYL719, PI3-kinase inhibitors, in advanced sporadic TNBC and high-grade se-rous ovarian cancer.[38] Another trial (NCT01434316) is com-bining veliparib and dinaciclib, a cyclin-dependent kinase inhibitor (CDK) inhibitor, where the hypothesis is that CDK inhibition sensitizes BRCA-proficient breast cancers to PARP inhibition.[39] After the phase I dose-finding portion, the study will enroll patients with *BRCA*-mutated and non-mutated advanced breast cancer in a dose-expansion cohort. These combinatorial approaches of PARP inhibitor and other targeted agents are promising strategies that may ex-pand the clinical utility of PARP inhibitors to sporadic TNBC.

Inhibition of the PI3K/AKT/mTOR Pathway

The PI3K/AKT/mTOR pathway mediates multiple cellular processes including cell survival, metabolism, proliferation, motility, migration, invasion, and angiogenesis.[40] Hyperacti-vation of the PI3K/AKT signaling pathway is frequent onco-genic alteration in TNBC, occurring in approximately 10% of patients.[9] Activating PIK3CA mutations are the most frequent in TNBC.[41] Other alterations that result in PI3K pathway activation include loss of the tumor suppressor phosphatases inositol polyphosphate 4-phosphatase type II (INPP4B) and loss of phosphatase and tensin homolog (PTEN).[9,42] Additionally, amplification of AKT and translo-cation of AKT3 occurs in a small subset of TNBC.[43] The PIK3CA activating mutations appear to be enriched in mes-enchymal and LAR molecular subtypes.[20] Targeting the PI3K/AKT pathway represents a compelling and rational po-tential treatment strategy for a subset of TNBC.

Ipatasertib (GDC-0068) is a novel, selective, ATP-competitive small molecule inhibitor of all three isoforms of the serine/threonine kinase AKT.[44] It shows single-agent activity in several xenograft models with AKT pathway activation via PTEN loss and/or PIK3CA mutation, including breast. In a phase Ib study of ipatasertib and paclitaxel in patients with MBC, the most commonly reported side effects were diarrhea, nausea, fatigue, vomiting, anorexia, and rash.[45] LOTUS (NCT02162719) is a randomized, double-blind, placebo-controlled international phase II study to evaluate the efficacy of ipatasertib combined with paclitaxel compared with placebo with paclitaxel in approximately 120 patients with previously untreated locally advanced or MBC.[46] The primary endpoint is PFS in all patients with TNBC and patients with TNBC with PTEN-low tumors. Randomization is 1:1 to either paclitaxel 80 mg/m^2 intravenously on days 1, 8, and 15 of each 28-day cycle and ipatasertib 400 mg orally daily on days 1 through 21 of each cycle or paclitaxel 80 mg/m^2 intravenously on days 1, 8, and 15 of each 28-day cycle and placebo. The trial is currently accruing.

The combination of weekly paclitaxel and ipatasertib is also being evaluated in the neoadjuvant setting. FAIRLANE (NCT02301988) is a randomized, double-blind, placebo-controlled, multicenter, preoperative phase II study designed to estimate the efficacy of ipatasertib combined with paclitaxel compared with placebo combined with paclitaxel in women with stage IA-IIIA (primary tumors ≥ 1.5 cm) TNBC.[47] The primary endpoint is pCR in the breast and lymph nodes. Approximately 150 patients will be enrolled at approximately 30 centers. Patients will be randomly assigned in a 1:1 ratio, stratified by the following three factors: PTEN status (null, low, medium), prior adjuvant/neoadjuvant treatment including chemotherapy with or without radiation, and disease-free interval from last dose of chemotherapy. Following surgical resection of primary tumor, patients are expected to continue postoperative treatment with a standard adjuvant anthracycline-based chemotherapy regimen. The trial is being conducted in collaboration with the SOLTI Breast Cancer Research Group and is ongoing.

OVEREXPRESSED GROWTH FACTORS IN TNBC

Several growth factor receptors are overexpressed in TNBC, including epidermal growth factor receptor (EGFR) and vascular endothelial growth factor receptor (VEGFR). Phase II and III clinical trials with drugs that interrupt the EGFR and VEGFR signaling pathways have been conducted in breast cancer, but these approaches are no longer being pursued because of limited activity in an unselected TNBC population.[48-52] However, there still is promise in targeting other growth factor receptors, such as the FGFR.

Inhibition of the FGFR

FGFR signaling stimulates cell growth, survival, migration, and differentiation.[53] Approximately 9% of TNBC has *FGFR1* amplification, and approximately 4% of TNBC has amplification of the *FGFR2* gene.[9,54] Mutations in FGFR are less common in TNBC (< 1%).[55] Cell lines with *FGFR1* amplification or *FGFR2* or *FGFR4* mutations were sensitive to a FGFR inhibitor in cell line models.[54] Additionally, inhibition of FGFR in basal-like TNBC cell lines with *FGFR2* amplification led to decreased growth.[56] These data support the clinical investigation of FGFR inhibitors in TNBC, which may only benefit a very small subgroup. To date, there are several multitargeted kinase inhibitors in clinical development with relatively high potencies against FGFRs, and include dovitinib (TKI258), nintedanib (BIBF1120), ponatinib (AP24534), and lucitanib (CO-3810). Selective FGFR TKIs are AZD4547 and JNJ-42756493. Although no current study specifically targets the TNBC population, a phase II trial (NCT02202746) is ongoing in MBC evaluating oral lucitanib in tumors that have an FGFR1-amplification or 11q- amplification, and patients with TNBC are eligible.[57] A phase I trial is evaluating JNJ-42756493 in patients with solid tumors, and one cohort includes patients with breast cancer of any subtype as long as the tumors harbor an FGFR translocation or FGFR activating mutation (NCT01703481).[58] These trials with inclusion criteria more selective to specific FGFR alterations may prove more effective than previous trials treating unselected patients with breast cancer.

OTHER STRATEGIES

Other notable targets have led to additional clinical trial efforts to evaluate more tailored therapies for specific subpopulations within TNBC.

Blockade of the AR

Approximately 10% to 15% of TNBC express the AR.[59] The LAR subclass of TNBC is characterized by luminal gene expression and enriched for AR and AR gene targets.[20] This is the basis for targeting this subset of TNBC with antiandrogen therapy. In a multicenter phase II study by Gucalp et al, 150 mg of bicalutamide, an oral nonsteroidal antiandrogen, was administered daily to 26 patients with AR-positive, ER-negative, and PR-negative MBC, who were determined to be evaluable for the primary endpoint of clinical benefit rate (CBR; complete response + partial response + stable disease > 6 months).[60] A CBR of 18% (95% CI, 6% to 37%), consisting of all stable disease, and a median PFS of 12 weeks (95% CI, 11 to 22 weeks) was reported. The most common treatment-related toxicities were fatigue (21%), hot flashes (21%), limb edema (21%), aspartate aminotransferase elevation (25%), and alanine aminotransferase elevation (21%). Of note, 452 patients with ER-negative and PR-negative breast cancer were screened for AR expression, and 12% tested AR-positive, consistent with an earlier report.[59] The activity of a next-generation antiandrogen, enzalutamide, was evaluated in advanced AR-positive TNBC. In this multicenter trial, 26 patients evaluable for the primary endpoint of CBR (complete response + partial response + stable disease at 16 weeks) received enzalutamide 160 mg orally daily.[61] The

stage I result of this Simon 2-stage, phase II trial was a CBR of 42% (95% CI, 24% to 62%), including one complete response and one partial response. This met the prespecified efficacy endpoint. Study enrollment has been met and final results are expected to be reported later in 2015. In this prescreened sample of 404 patients, 55% of samples expressed AR—a much higher percentage than anticipated. Further analysis of the appropriate diagnostic to assess AR expression in tumor specimens is ongoing. Another androgen-directed therapy under evaluation in AR-positive TNBC is orteronel (TAK-700; NCT01990209), which is a nonsteroidal, androgen synthesis inhibitor that has been shown in preclinical studies to selectively inhibit the 17,20-lyase enzymes, critical to the production of androgens.[62] These studies show that AR is a promising and suitable therapeutic target in a small subset of TNBC, particularly the LAR subtype.

Inhibition of Notch Signaling with Gamma-Secretase Inhibitors

Research is beginning to show the potential of targeting the notch signal pathway as a possible treatment approach for patients with TNBC. The notch signaling pathway affects many cellular processes including proliferation, apoptosis, angiogenesis, and stem cell self-renewal.[63] The notch receptor is activated by the binding of membrane-bound ligand on a neighboring cell. This results in sequential cleavage by the ADAM17/TACE metalloprotease and gamma-secretase, leading to the release of the intracellular domain of notch (NICD). The NICD then translocates to the nucleus, activating downstream target genes, including *HES* and *HEY*.[64]

A preclinical study showed that TNBC xenograft models with *NOTCH1* rearrangements, retaining the gamma-secretase cleavage site, were associated with elevated levels of activated *NOTCH1* and have sensitivity to gamma-secretase inhibitors.[65] However, there were several rearrangements in *NOTCH2* that displayed constitutive signaling and were insensitive to gamma-secretase inhibition. In another study, 13% of TNBC were found to have PEST domain mutations in *NOTCH1*, *NOTCH2*, and *NOTCH3* receptors and patient-derived xenograft models that were highly sensitive to the gamma-secretase inhibitor, PF-03084014.[66] These mutations cause a truncation of the C-terminus of Notch removing the PEST domain, while retaining the gamma-secretase cleavage site. These data suggest that gamma-secretase inhibitors may have promise in treating a subset of TNBC with specific Notch alterations. A number of studies have investigated gamma-secretase inhibitors, such as R04929097 and MK-0752, in unselected metastatic TNBC. Several trials with the oral gamma-secretase inhibitor PF-03084014 are planned. A phase II trial (NCT02299635) will treat 48 patients with metastatic TNBC whose tumors harbor alterations in the NOTCH receptors with PF-03084014 at 150 mg orally twice daily.[67] The primary endpoint is overall response rate. A biomarker study (NCT02338531) will give PF-03084014 for 9 days at 150 mg on day 1 and day 9 and 150 mg twice daily on days 2 through 8 to patients with TNBC who have 1.5 cm of residual disease after neoadjuvant anthracycline and taxane-

based chemotherapy.[68] The primary endpoint of this trial is to assess HES4 gene expression level in tumor tissue samples before study drug and after 9 days of study drug to demonstrate that PF-03084014 is able to modulate the Notch pathway by down-regulating the expression of the tumor HES4 gene in chemoresistant TNBC.

Inhibition of the JAK2/STAT3 Pathway

Janus kinases (JAKs) are tyrosine kinases, and signal transducer and activation of transcription 3 (STAT3) proteins are major components of several cytokine receptor systems that regulate cell growth and survival.[69] Binding of the cytokine to the receptor induces dimerization, which activates the associated JAKs. The JAKs also phosphorylate STATs, which lead to their dimerization, nuclear translocation, and transcriptional regulation of genes that regulate cell differentiation, proliferation, and apoptosis. There is emerging preclinical evidence that disruption of the JAK2/STAT3 signaling could be an effective clinical strategy to treat TNBC. The IM subtype is also enriched with genes involved in immune cell signaling and cytokine signaling.[20] A preclinical study showed the JAK/STAT3 pathway was preferentially active in basal-like breast cancer cells, and inhibition of JAK2 resulted in reduced growth of xenografts.[70] Unlike myeloproliferative neoplasms, mutations in JAKs and STATs have not been well characterized. However, JAK2 amplifications were found more frequent in TNBC treated with neoadjuvant chemotherapy than in primary untreated basal-like breast tumors in the TCGA.[71] This observation may provide rationale to investigate JAK inhibitors in patients who have JAK2-amplified residual disease.

Ruxolitinib, a potent oral inhibitor of JAK1 and JAK2, is approved for the treatment of intermediate or high-risk myelofibrosis and is now being evaluated in breast cancer. A phase I trial (NCT02041429) is evaluating the combination of ruxolitinib given twice daily with weekly paclitaxel 80 mg/m^2, 3 weeks out of 4 weeks, in patients with MBC.[72] Once a recommended phase II dose is determined, the study will treat patients with triple-negative inflammatory breast cancer with ruxolitinib orally twice daily for 21 days in a 28-day cycle and weekly paclitaxel for 12 weeks followed by dose-dense AC for four cycles. The primary endpoint is biologic, and the trial will evaluate expression of pSTAT3 in triple-negative inflammatory breast cancer tumors before and after treatment, with an expected decrease in pSTAT3 expression post-therapy.

Targeting Trop-2

Trop-2, also referred to as M1S1, TACSTD2, EGP-1, is a cell surface protein overexpressed in several epithelial cancers, but not in corresponding normal tissues.[73] Trop-2 is a transmembrane calcium signal transducer and is involved in the regulation of cell-cell adhesion.[74] Membrane-associated Trop-2 was found to be associated with poor prognosis in breast cancer.[75] There is a growing interest in targeting Trop-2 in TNBC. IMMU-132 (isactuzumab govitecan) is an antibody-drug conjugate containing the humanized mono-

clonal antibody, hRS7, against Trop-2, which is linked to the active metabolite of irinotecan, 7-ethyl-10-hydroxycamptothecin (SN-38). The antibody moiety of IMMU-132 selectively binds to Trop-2. After internalization and proteolytic cleavage, SN-38 is delivered preferentially to the tumor cells. Preclinical data shows that IMMU-132 resulted in increased tumor regression in MDA-MD-468 TNBC xenograft models, compared to irinotecan or to the antibody-drug conjugate control.[76] IMMU-132 received Fast Track designation in January 2015 from the FDA for treatment of patients with TNBC who have progressed on prior therapies for metastatic disease. A phase I/II trial of IMMU-132 was conducted in advanced epithelial cancers, including TNBC. There was no prescreening for Trop-2 expression. The recommended phase II dose of IMMU-132 was 10 mg/kg intravenously on days 1 and 8 of a 21-day cycle. The toxicity was mostly neutropenia, and diarrhea was low grade.[76] An expansion cohort enrolled 23 patients with pretreated metastatic TNBC (prior number of median regimens was 4) with a response rate of 30% consisting of 7 partial responses, and a CBR (partial response + stable disease > 6 months) of 40%.[77] Immunohistochemical data on Trop-2 scoring is being collected. A phase II trial will treat 80 patients with metastatic TNBC who have received two or more prior regimens with IMMU-132 alone or in combination with carboplatin (NCT02161679).[78] Further research is necessary to evaluate the strategy of using antitrop-2 therapeutics for breast cancer and the relationship of Trop-2 expression to response.

CONCLUSION

TNBC is a heterogeneous disease. The identification of several specific subtypes characterized by different biologic pathways and various sensitivities to chemotherapy is instrumental in delivering more personalized therapy for TNBC. Ongoing and future clinical research in selected subsets of TNBC will validate the efficacy of such novel treatment strategies.

Neoadjuvant and Adjuvant Therapy for HER2 Positive Disease

Stephen K. Chia, MD, FRCP(C)

OVERVIEW

Since the initial description of the HER2 proto-oncogene as a poor prognostic factor in breast cancer in 1987, to the first randomized trial of a monoclonal antibody directed against HER2 in combination with chemotherapy for the treatment of metastatic HER2-positive breast cancer published in 2001, to the American Society of Clinical Oncology (ASCO) 2005 Annual Meeting in which we saw the unprecedented collective presentations demonstrating the dramatic benefit of trastuzumab in the adjuvant setting—the clinical landscape of HER2-overexpressing breast cancer has forever changed. More recently, there has been increasing use of preoperative chemotherapy and anti-HER2 targeted therapies in primary operable HER2 disease in the research domain and in clinical practice. In the next few years, we will see if dual adjuvant anti-HER2 antibody inhibition produces clinically significant improvements in outcome; understand if there is a role of small molecule inhibitors of the HER family of receptors either in combination or sequential to trastuzumab; further refine the relationship between pathologic complete response (pCR) and long-term clinical outcomes; and find predictive biomarkers to identify cohorts of patients that may need differential combinations and/or durations of anti-HER2 therapies.

From the original description of the human epidermal growth factor receptor 2 (HER2) as a proto-oncogene, to being a prognostic marker, to then being a therapeutic target has revolutionized the categorization, risk assessment, and treatment of breast cancer. Though this subtype of breast cancer represents less than 25% of incident breast cancers, many lessons can be learned from the development of anti-HER2 therapies in early-stage disease. In particular, much work has recently been put forth in neoadjuvant trials assessing combinations of anti-HER2 therapies. This review will touch on the landmark studies in both the adjuvant and neoadjuvant settings and comment on some of the controversies that still remain today in both clinical care and as research questions.

LANDMARK RANDOMIZED TRIALS OF ADJUVANT TRASTUZUMAB

Current clinical guidelines clearly state that standard of care in 2015 recommends the use of the monoclonal anti-HER2 antibody trastuzumab in combination with or after adjuvant chemotherapy in medically fit patients diagnosed with stage I to III HER2-positive breast cancer.[1,2] The four landmark randomized trials investigating the benefit of adjuvant trastuzumab (National Surgical Adjuvant Breast and Bowel Project [NSABP] B-31, North Central Cancer Treatment Group [NCCTG] N9831, HERA, and Breast Cancer International Research Group [BCIRG] 006) in their initial analysis reported outcomes with median follow-ups of 24 to 36 months.[3-5] The range in benefit in disease-free survival (DFS) in favor of trastuzumab was with hazard ratios (HRs) between 0.48 and 0.67 (p < 0.0001), and the range in benefit in overall survival (OS) was between 0.59 and 0.67 (p = NS to p = 0.015). Absolute improvements in DFS ranged from 6% to 11%, with corresponding absolute differences in OS of 1% to 2.5% (Table 1).

With longer follow-up from these trials (now 8-year median follow-up from HERA and from the combined analyses of NSABP B-31 and NCCTG N9831), there continues to be statistically and clinically significant improvements in DFS and OS.[6-8] Though the magnitude of benefit, as measured by HRs, appears to have lessened slightly over time as more events (both relapses and deaths) occur, absolute gains in overall survival are larger now than in earlier analyses (Table 2). The selective crossover of some of the patients initially randomly assigned to the no trastuzumab arm across the trials will have mitigated some of the initial differences seen in the studies. However, relapses unfortunately continue to occur at a relatively constant rate over time in the trastuzumab-treated arm(s)—with an estimated 10-year DFS of 73.7% from the combined analyses of NSABP B-31 and NCCTG N9831.[6] What is encouraging, however, is that with longer follow-up, the cumulative incidence of cardiac adverse events plateaus, with cardiac events rarely occurring following completion of trastuzumab treatment.[7] In the HERA study, at 8-years follow-up, only 4.1% of patients experienced

TABLE 1. Initial Reports from the Large Adjuvant Trastuzumab Trials

Trial	Trastuzumab Duration	Median Follow-up (Months)	Treatment Arms	No. of Patients	HR for DFS (95% CI)	2-3 yr DFS	HR for OS (95% CI)	2-yr OS
HERA[4]	1 yr	24	Chemotherapy	1,698		77.4%		95.1%
			Chemotherapy →H	1,703	0.64 (0.54-0.76)	85.8%	0.66 (0.47-0.91)	96.0%
NSABP B-31[3]	1 yr	24	AC →P	1,679		75.4%		91.7%
NCCTG N9831			AC →P →H	1,672	0.48 (0.39-0.59)	87.1%	0.67 (0.48-0.93)	94.3%
BCIRG 006[5]	1 yr	36	AC →T	1,073		81%		N/A
			AC →TH	1,074	0.61 (0.48-0.76)	88%	0.59 (0.42-0.85)	N/A
			TcarboH	1,075	0.67 (0.54-0.83)	87%	0.66 (0.47-0.93)	N/A

Abbreviations: HR, hazard ratio; DFS, disease-free survival; OS, overall survival; H, trastuzumab; NSABP, National Surgical Adjuvant Breast and Bowel Project; A, doxorubicin; C, cyclophosphamide; P, paclitaxel; NCCTG, National Central Cancer Treatment Group; BCIRG, Breast Cancer International Research Group; T, docetaxel; carbo, carboplatin.

New York Heart Association class I or class II cardiac dysfunction with a left ventricular ejection fraction (LVEF) drop of 10% or more below baseline and to an absolute LVEF of 50% or less. Furthermore, it is felt that the majority of cardiac events secondary to trastuzumab are reversible in nature.

Perhaps the remaining limited questions at hand specific to clinical practice in relation to these landmark trials are (1) treatment of HER2-positive $T1_{a-b}N_0$ breast cancers, (2) anthracycline or no anthracycline-based regimen, and (3) concurrent compared with sequential trastuzumab therapy. A small minority of patients in these four pivotal trials had $T1_{a-b}N_0$ breast cancers. Several retrospective prognostic studies demonstrate a significantly worse prognosis in HER2-positive $T1_{a-b}N_0$ breast cancers compared with HER2-negative $T1_{a-b}N_0$ breast cancers.[9,10] In a recent analysis from the National Comprehensive Cancer Network (NCCN) database examining this exact question, 4,113 patients with $T1_{a-b}N_0$ breast cancers treated between 2000 and 2009 were assessed by biologic subtype and receipt of chemotherapy (or not) and trastuzumab (or not).[11] Within this subgroup not treated

with chemotherapy or trastuzumab, the 5-year distant relapse-free survival (DRFS) ranged between 93% and 96%. The rates of invasive DFS (IDFS), however, was lower, particularly in $T1_{a-b}N_0$ hormone receptor–negative/HER2-positive breast cancers, with an estimated 5-year IDFS of 68%. Thus, the summation of most studies would suggest considering adjuvant chemotherapy and trastuzumab in $T1_bN_0$ HER2-positive (regardless of hormone receptor status) breast cancers in medically fit patients without high competing risks of mortality. However, for $T1_aN_0$ HER2-positive breast cancer, the risks and inconvenience of treatment may potentially outweigh the benefit of therapy—especially for hormone receptor–positive/HER2-positive $T1_aN_0$ breast cancers.

In the same vein, the selection of adjuvant chemotherapy regimen in combination with trastuzumab varies. Based on the risk/benefit ratio, consideration should be made for a limited nonanthracycline-based regimen in stage I disease. Though not studied within a randomized trial, the regimens of weekly paclitaxel (80 mg/m^2 weekly for 12 weeks) concurrent with trastuzumab (for 1 year) or four cycles of docetaxel and cyclophosphamide (75 mg/m^2 and 600 mg/m^2, respectively) every 3 weeks for four cycles concurrent with trastuzumab (for 1 year) both demonstrate a generally low toxicity profile with very favorable clinical outcomes.[12,13] In the recently published phase II study of 406 women with primarily stage I HER2-positive disease (> 90%), the 3-year IDFS was 98.7% with weekly paclitaxel for 12 weeks concurrent with trastuzumab.[12] There was a reported 0.5% rate of symptomatic congestive heart failure and a 3.2% rate of asymptomatic declines in LVEF. Likewise, in the phase II single-arm, open-label study of docetaxel and cyclophosphamide (four cycles) concurrent with trastuzumab, the reported 2-year DFS of 97.8% was quite favorable as well. Otherwise, for stage II to III disease, consideration should be given for the regimens studied in the landmark pivotal trials, the vast majority of which contained an anthracycline (four cycles) sequentially followed by a taxane (four cycles), except for the six cycles of docetaxel, carboplatin, and trastuzumab arm in BCIRG 006.[5]

Lastly, it would seem both practical and potentially more efficacious to deliver the trastuzumab concurrent with the

KEY POINTS

- The treatment of HER2-positive early-stage breast cancer should incorporate 12 months of adjuvant trastuzumab, preferably concurrent with a taxane backbone.
- Neoadjuvant systemic therapies are now routinely delivered in both primary operable and locally advanced breast cancer in the research domain and in clinical practice.
- The combination of lapatinib and trastuzumab inconsistently improved pathologic complete response (pCR) rates across its neoadjuvant trials and ultimately did not improve disease-free survival (DFS) in the large adjuvant ALTTO trial.
- In a large pooled analysis, pCR (with or without the presence of in situ disease) in the breast and nodes most closely correlates with DFS and overall survival.
- Well-designed, randomized, neoadjuvant trials with tissue acquisition are essential to more precisely plan adjuvant trials, assess for predictive biomarkers, and accelerate drug development for early-stage disease.

TABLE 2. Longer-Term Follow-up from the Large Adjuvant Trastuzumab Trials

Trial	Median Follow-up (Years)	Treatment Arms	HR for DFS (95% CI)	DFS	HR for OS (95% CI)	OS
HERA[7]	8 yr	Chemotherapy		76.0%		N/A
		Chemotherapy → H	0.76 (0.67-0.86)		0.76 (0.65-0.88)	N/A
NSABP B-31[6]	8.4 yr	AC → P		62.2%		75.2%
NCCTG N9831		AC → P → H	0.60 (0.53-0.68)	73.7%	0.63 (0.54-0.73)	84.0%

taxane. In the NCCTG N9831 study, one arm delivered paclitaxel (weekly) concurrent with trastuzumab (arm C), whereas in another arm, the trastuzumab was delivered sequential (arm B).[14] Alhtough there was a numerical increase in DFS in favor of the concurrent arm (84.4% vs. 80.1%), it did not meet statistical significance based on the interim analysis criteria (arm C/arm B HR 0.77; 95% CI, 0.53 to 1.11). However, as there was no difference in toxicity between these two arms, and for convenience and earlier completion of therapy, it would be overall advantageous to deliver the trastuzumab concurrent with the taxane.

LANDMARK RANDOMIZED TRIALS OF NEOADJUVANT HER2-TARGETED THERAPIES

The standard clinical use of neoadjuvant chemotherapy today can be categorized into two populations of patients: the locally advanced breast cancers (LABC) and the primary operable breast cancers (POBC). The defined purpose for the use of neoadjuvant chemotherapy for LABC is to convert a baseline inoperable condition to an operable state. Whereas in POBC, the standard clinical utility of neoadjuvant chemotherapy has the potential to downstage a tumor and thus convert a baseline mastectomy candidate into a breast-conservation candidate. However, as individual trials and the Early Breast Cancer Trialists Collaborative Group overview of neoadjuvant trials demonstrated that standard chemotherapy regimens (anthracyclines ± taxanes) whether given preoperatively or postoperatively (adjuvant) provided the same long-term clinical outcomes, one can now potentially deliver standard systemic treatment in either the neoadjuvant or adjuvant setting with similar confidence.[15] The same holds true, if not even more so, for HER2-positive breast cancers. The additional advantages of delivery in the neoadjuvant setting include the ability to study new agents with the utility of a surrogate endpoint for outcome; the ability to obtain tumor tissue for pharmacodynamic assessment, understanding of biology and discovery of predictive biomarkers; earlier initiation of systemic therapies; and the ability to monitor response (which is clearly not possible in the adjuvant setting).

The first landmark trial investigating the benefit of neoadjuvant trastuzumab in the LABC setting was the NOAH trial.[16] NOAH randomly selected 228 patients with HER2-positive disease to receive a neoadjuvant regimen consisting of doxorubicin, paclitaxel, cyclophosphamide, methotrexate, and 5-fluorouracil (CMF) with or without concurrent trastuzumab (throughout the entire chemotherapeutic regimen). This is the largest randomized trial of a true locally advanced and inflammatory population to date. The trastuzumab-treated cohort demonstrated a significantly superior rate of pCR in breast and nodes (total pCR [tpCR]; 38% vs. 19%; p = 0.001), which ultimately translated to an improved 3-year event-free survival (EFS; 71% vs. 56%, HR 0.59; 95% CI, 0.38 to 0.90).[17] Not only was a doubling of the tpCR rate impressive, but also the magnitude of improvement in EFS of a similar degree (HR 0.59) as the landmark adjuvant trastuzumab trials is an interesting observation. Although the use of the specific chemotherapy regimen from NOAH is not likely to be common, the concept of neoadjuvant trastuzumab concurrent with chemotherapy now is.

Lapatinib-Based Neoadjuvant Trials

Lapatinib is a small molecule tyrosine kinase inhibitor (TKI) of the HER1 and HER2 receptors. Despite the lack of a head-to-head trial with trastuzumab in the metastatic setting, several randomized neoadjuvant trials were initiated. All these trials included both POBC and HER2-positive LABC. The GeparQuinto study compared trastuzumab (8 mg/kg loading dose followed by 6 mg/kg every 3 weeks given concurrently with chemotherapy during the preoperative period) with lapatinib (1,250 mg/day continuously for 12 weeks) added to a backbone of four cycles of epirubicin (90 mg/m^2) and cyclophosphamide (600 mg/m^2) followed by four of docetaxel (100 mg/m^2) in 615 patients with HER2-positive disease.[17] A significantly higher tpCR rate (breasts and nodes) was seen in the trastuzumab arm (30.3% vs. 22.7%; odds ratio 0.68; 95% CI, 0.47 to 0.97; p = 0.04). Furthermore, in this study, dose reductions were required in nearly one-third of patients receiving lapatinib, prompting a protocol amendment reducing the lapatinib dose to 1,000 mg/m^2.

The smaller CHER-LOB study was conducted using a chemotherapy backbone of weekly paclitaxel (80 mg/m^2) for 12 weeks followed by three-weekly 5-fluorouracil, epirubicin, cyclophosphamide (FEC; 500/75/500 mg/m^2, respectively)

with either weekly trastuzumab (4 mg/kg loading dose followed by 2 mg/kg weekly) or lapatinib (1,250 mg daily) given concurrently with chemotherapy.[18] This study also examined the efficacy of a trastuzumab-lapatinib doublet with dose-adjusted lapatinib (750 mg/day). Dual HER2 targeting substantially improved pCR (breast and nodes) over either trastuzumab or lapatinib alone. pCR rates were 46% (90% CI, 34.4% to 58.9%), 25% (90% CI, 13.1% to 36.9%), and 26.3% (90% CI, 14.5% to 38.1%), respectively. As was seen in the GeparQuinto trial, gastrointestinal toxicity with lapatinib was a significant adverse event. More than 50% of those receiving lapatinib experienced diarrhea of grade 1 or higher, even after a protocol amendment directing a dose reduction from 1,500 mg/day to 1,250 mg/day in the single-agent arm, and from 1,000 mg/day to 750 mg/day in the doublet arm.

The NeoAdjuvant Lapatinib and/or Trastuzumab Optimization (NeoALTTO) trial was a three-armed study addressing the comparative efficacy of single compared with dual HER2 blockade using trastuzumab (4 mg/kg loading dose followed by 2 mg/kg weekly), lapatinib (1,500 mg daily), or a combination (trastuzumab standard dose and lapatinib 1,000 mg daily), alongside weekly paclitaxel (80 mg/m^2) chemotherapy.[19] This trial scheduled a 6-week lead in period of targeted therapy alone before introduction of paclitaxel for a further 12 weeks of therapy. Dual HER2 targeting induced tpCR (breast and nodes) rates in 46.8% of patients compared

with 27.6% in the trastuzumab alone arm (p = 0.0007). There was no statistically significant difference in pCR rates between the trastuzumab alone and lapatinib alone arms (27.6% and 20%; p = 0.13).

In a fourth trial, the NSABP B-41 study randomly selected 529 patients with HER2-positive disease to receive doxorubicin (60 mg/m^2) and cyclophosphamide (600 mg/m^2) every 3 weeks for four cycles, followed by weekly paclitaxel (80 mg/m^2) for a further 12 weeks with either concurrent weekly trastuzumab (4 mg/kg loading dose followed by 2 mg/kg weekly), 1,250 mg of lapatinib daily, or weekly trastuzumab plus lapatinib (750 mg/day).[20] pCR was achieved for 62% of patients receiving combination HER2 targeting compared with 52.5% in the trastuzumab arm (p = 0.095). There was no significant difference between the trastuzumab and lapatinib alone arms (52.5% vs. 53.2%; p = 0.990).

Lastly, the Cancer and Leukemia Group B 40601, a neoadjuvant phase III trial of weekly paclitaxel (T) and trastuzumab (H) with and without lapatinib (L) in HER2-positive breast cancer, was presented at the 2013 ASCO Annual Meeting.[21] This trial randomly selected 305 patients, of which two-thirds had clinical stage II disease. The pCR rates in the breast alone were 51% (42% to 60%) THL, 40% (32% to 49%) TH, 32% (22% to 44%) TL. The combination arm of THL was not significantly different from the standard arm of trastuzumab and paclitaxel (p = 0.11; Table 3).

TABLE 3. Neoadjuvant Trials of Dual HER2 Targeted Therapies

Trial	No. of Patients	Treatment Arms	pCR (Breast and Nodes)	p	3-yr EFS
GeparQuinto[17]	309	ECH → TH	31.3%	p < 0.05	N/A
	311	ECL → TL	21.7%		N/A
NeoALTTO[19]	149	H → HP	27.6%		76%
	154	L → LP	20.0%	p = 0.13	78%
	152	HL → HLP	46.9%	p = 0.001	84%
CHER-LOB[18]	36	HP → FECH	25%		N/A
	39	LP → FECL	26.3%		N/A
	46	HLP → FECHL	46.7%		N/A
NSABP B-41[20]	177	AC → HP	52.5% (breast)		N/A
	171	AC → LP	53.2% (breast)	p = 0.9852	N/A
	171	AC → HLP	62.0% (breast)	p = 0.095	N/A
CALGB 40601[21]	120	HP	40% (breast)		N/A
	67	LP	32% (breast)		N/A
	118	HLP	51% (breast)	p = 0.11	N/A
NeoSphere[22]	107	TH	29.0% (breast)		N/A
	107	PerHT	45.8% (breast)	p = 0.0141	N/A
	107	PerH	24.0% (breast)		N/A
	96	PerT	16.8% (breast)		N/A
TRYPHENA[23]	73	PerHFEC → PerTH	61.6% (breast)		N/A
	75	FEC → PerTH	57.3% (breast)		N/A
	77	TcarboHPer	66.2% (breast)		N/A

Abbreviations: pCR, pathologic complete response; EFS, event-free survival; E, epirubicin; C, cyclophosphamide; H, trastuzumab; T, docetaxel; L, lapatinib; P, paclitaxel; F, 5-fluorouracil; NSABP, National Surgical Adjuvant Breast and Bowel Project; A, doxorubicin; CALGB, Cancer and Leukemia Group B; Per, pertuzumab; carbo, carboplatin.

Pertuzmab-Based Neoadjuvant Trials

Pertuzumab, a humanized monoclonal antibody that inhibits dimerization of HER2 with other HER receptors, has been evaluated in two randomized phase II studies. In the NeoSphere trial, 417 women with HER2-positive POBC/LABC disease were randomly selected to receive either four cycles of neoadjuvant trastuzumab (8 mg/kg loading dose, followed by 6 mg/kg every 3 weeks), docetaxel (75 mg/m^2 escalating to 100 mg/m^2 as tolerated) and pertuzumab (loading dose 840 mg, followed by 420 mg every 3 weeks), or trastuzumab plus docetaxel, or pertuzumab and trastuzumab without chemotherapy, or pertuzumab plus docetaxel.[22] The combination of dual HER2 targeting and docetaxel induced a pCR (breast) for 45.8% (95% CI, 36.1 to 55.7) compared with 29% of those randomly assigned to trastuzumab and docetaxel (95% CI, 20.6 to 38.5; p = 0.0141). After surgery, all patients received three cycles of FEC and the remainder of 1 year of trastuzumab. pCR was achieved for 24.0% of those receiving pertuzumab and docetaxel and 16.8% of women who were treated with dual HER2 targeted therapy in the absence of chemotherapy. Neither short- nor long-term clinical outcomes (EFS and OS) have been reported yet from NeoSphere.

TRYPHENA was a phase II trial with cardiac safety as the primary endpoint.[23] All 225 participants received dual HER2 targeting with trastuzumab and pertuzumab. The three study arms were randomly assigned to 500 mg 5-fluorouracil, 100 mg epirubicin, and 500 mg/m^2 cyclophosphamide (FEC100) for three cycles, followed by docetaxel (75 mg/m^2) with concurrent with trastuzumab and pertuzumab; FEC for three cycles followed by docetaxel with trastuzumab and pertuzumab given only alongside docetaxel; or six cycles of docetaxel, carboplatin, trastuzumab, and pertuzumab. In this trial, pCR (breast) was a secondary endpoint, with rates ranging between 57.3% and 66.2%, in keeping with results seen elsewhere. The lack of an arm without pertuzumab limits the extrapolation of these results to other studies and to standard clinical practice.

On September 30, 2013, the U.S. Food and Drug Administration (FDA) granted accelerated approval to pertuzumab in combination with trastuzumab and chemotherapy as a neoadjuvant treatment regimen in patients with HER2-positive locally advanced, inflammatory, or early-stage disease (tumor size > 2 cm or with positive lymph nodes).[24] This was a landmark ruling as pertuzumab is the first FDA-approved agent for use in the neoadjuvant setting. The allowance of use in clinical care and guidelines (NCCN[2]) does provide a window of opportunity to potentially prevent relapses in higher-risk cohorts while awaiting results from the confirmatory adjuvant trial (APHINITY). Not only is this of potential benefit to patients today, but it also excites the drug development world about an accelerated path to drug approval in the much larger cohort of early-stage disease.

AREAS OF ONGOING CONTROVERSY

Despite the breadth of the trials and the consistency of results across them, a number of questions remain regarding the op-

timal use of anti-HER2 targeted therapy in early-stage disease. We eagerly wait to see if dual adjuvant anti-HER2 antibody inhibition with trastuzumab and pertuzumab produces clinically significant improvements in outcome. Results from both the metastatic setting and the neoadjuvant trials (in particular NeoSphere) would predict that the large adjuvant trial APHINITY (NCT01358877) will likely be significant. The question will then be how significant will the result need to be to alter standard clinical practice and be cost-effective. The following are other remaining questions.

Duration of Adjuvant Trastuzumab

At present the standard of care is for 1 year of adjuvant trastuzumab therapy. In the HERA study, 2 years of trastuzumab did not produce any additional benefit compared with 1 year of trastuzumab, but it did increase the secondary cardiac event rate.[7] The PHARE study was a noninferiority study comparing 6 months of trastuzumab to 12 months of trastuzumab sequential to at least four cycles of adjuvant chemotherapy.[25] A total of 3,384 patients were randomly selected, with a median of 42.5 months of follow-up at time of reporting. Two-year DFS was 93.8% in the 12-month group and 91.1% in the 6-month group (HR 1.28; 95% CI, 1.05 to 1.56; p = 0.29). The trial did not meet its noninferiority endpoint, solidifying 12 months of trastuzumab therapy as the current standard of care, until other clinical trials comparing 6 months to 12 months of trastuzumab therapy (PERSEPHONE, NCT00615602) report.

The FinHER study was a phase III, randomized adjuvant trial of 1,010 women, of which 232 had HER2-amplified tumors.[26] In the HER2-positive cohort, patients randomly assigned to 9 weeks of trastuzumab or not concurrent with three cycles of docetaxel or vinorelbine followed in all groups with three cycles of FEC (600 mg, 60 mg, 600 mg/m^2, respectively). The 3-year RFS was significantly greater in the trastuzumab-treated cohort (HR 0.42; 95% CI, 0.21 to 0.83: p = 0.01) versus no trastuzumab. However, because this is a small study relative to the landmark adjuvant trastuzumab trials, and the chemotherapy regimen is not standard (including the lower dose of FEC), we await the results from the confirmatory phase III trials—SOLD and Short-HER—before considering 9 weeks of trastuzumab therapy as standard of care.

Role of HER2-Targeted Tyrosine Kinase Inhibitors

Potent small molecule TKI inhibitors exist, both reversible and irreversible, that block some members (e.g., lapatinib reversibly blocks primarily HER1 and HER2) or all members (e.g., neratinib irreversibly blocks HER1 to HER4) of the HER family of transmembrane receptors. The neoadjuvant trials (as discussed above) with lapatinib failed to demonstrate greater efficacy of lapatinib as monotherapy compared to standard trastuzumab. The combination of lapatinib and trastuzumab inconsistently demonstrates a higher pCR rate, although with a need to dose reduce lapatinib because of gastrointestinal toxicity. The NeoALTTO trial has recently reported at 3.8 years of follow-up, and although a numerical

trend was seen, there was no significant difference in EFS between the combination arm and the trastuzumab arm (HR 0.78; 95% CI, 0.47 to 1.28; p = 0.33).[27]

The ALTTO trial randomly assigned 8,381 patients, of whom 40% had node-negative disease and 57% had hormone receptor–positive disease.[28] The four arms of the study were trastuzumab for 12 months (T), lapatinib for 12 months (L), trastuzumab for 12 weeks followed sequentially by lapatinib for 34 weeks (T→L), and the combination of trastuzumab and lapatinib for 12 months (TL). Although the study was powered for 850 DFS events, the study was analyzed at 4.5 years (median) of follow-up as per protocol stipulation but with only 555 DFS events. At the first efficacy interim analysis, the comparison of L to T crossed the futility boundary, and as such, the L arm was crossed over to a recommended course of trastuzumab for 12 months. At the time of reporting of the efficacy of the primary endpoint at the 2014 ASCO Annual Meeting, the 4-year DFS for the T, T→L, and TL arms were 86%, 87%, and 88%, respectively. The HR comparing TL and T was 0.84 (0.70–1.02; p = 0.048), which was not significant, for a p ≤ 0.025 was required for statistical significance. The interaction test for hormone receptor status and for schedule of anti-HER2 therapy was not significant. However, numerically, the sequential administration of anti-HER2 therapy arms had some difference (T vs. TL 4-year DFS of 83% vs. 86%, respectively), whereas the combination arms did not (T vs. TL 4-year DFS of 90% vs. 90%, respectively). Lapatinib was also associated with a greater rate of adverse events, which subsequently led to only 60% to 78% of patients in the lapatinib treatment arms receiving at least 85% of the intended dose intensity of L. These factors, in addition to a time-driven analysis (rather than the initial powering of the study for an event-driven analysis) may have affected the true efficacy of the dual anti-HER2 combination arm.

Neratinib has been studied in a neoadjuvant manner as part of the I-SPY 2 program, as well as in an extended manner in a placebo-controlled trial in a population of patients following 1 year of standard adjuvant trastuzumab-based therapy. In the I-SPY 2 trial, neratinib was given in combination with weekly paclitaxel (80 mg/m² for 12 weeks) in both the HER2-positive and HER2-negative cohorts.[29] All patients subsequently received sequential doxorubicin (60 mg/m²) and cyclophosphamide (600 mg/m²) for four cycles without neratinib or trastuzumab before proceeding to definitive surgery. In the HER2-positive signature cohort, the pCR rate was 39% in the neratinib plus paclitaxel arm, compared to 23% in the trastuzumab plus paclitaxel arm. The magnitude of improvement in pCR was similar regardless of the hormone receptor status in the HER2-positive cohort. No significant difference in pCR rates was seen in the HER2-negative signature cohort. A significant rate of grade 2–3 diarrhea was seen, however, in the neratinib arms resulting in dose reductions/holds in 65% of cases for neratinib (vs. 15% in the control arm).

ExteNET is a double-blind phase III trial of neratinib (240 mg orally once daily) versus placebo in 2,821 women with early-stage HER2-positive (local confirmation) breast cancer after adjuvant treatment with trastuzumab. The primary endpoint of the study was DFS. The results of the study have not yet been presented in a peer review forum, but a press release from July 22, 2014, stated, "The results of the trial demonstrated that treatment with neratinib resulted in a 33% improvement in disease free survival versus placebo. The hazard ratio was determined to be 0.67, which was statistically significant with a p value of 0.0046. The secondary endpoint of the trial was disease free survival including ductal carcinoma in situ (DFS-DCIS). The results of the trial demonstrated that treatment with neratinib resulted in a 37% improvement in disease free survival including ductal carcinoma in situ versus placebo. The hazard ratio was determined to be 0.63, which was statistically significant with a p value of 0.0009."[30] Results from this potential practice-changing trial are expected to be presented at the 2015 ASCO Annual Meeting as we await the details of the absolute improvements in DFS and other clinical endpoints as well as the associated toxicities on trial.

Correlation of pCR and Long-Term Clinical Outcomes

There remains an ongoing debate regarding the correlation of pCR status and long-term clinical outcomes such as DFS, EFS, and OS. The attractiveness of an early surrogate marker of efficacy in early-stage disease allows for the use of the neoadjuvant space to test new drugs for efficacy (and toxicity) to expedite development and approval of new therapies in early-stage disease. Multiple studies have repeatedly demonstrated a prognostic effect for the cohort of patients achieving a pCR—particularly those achieving a pCR in breast and lymph nodes (tpCR). Recently, a pooled analysis of 12 large trials of 11,955 patients treated with preoperative chemotherapy with available data on pCR and at least 3-year follow-up data on EFS and OS was performed by the FDA (CTNeoBC pooled analysis).[31] The analysis concluded several points. First, the definition of eradication of tumor in breast and lymph nodes, with or without presence of in situ disease (ypT0/is ypN0) was most closely associated with improved EFS (0.48; 95% CI, 0.43 to 0.54) and OS (HR 0.36; 95% CI, 0.31 to 0.42). Moving forward this should be the consistent and standard definition used as the primary endpoint in neoadjuvant trials. Second, the association between pCR and long-term outcomes was strongest in triple-negative breast cancer and HER2-positive/estrogen receptor–negative breast cancers treated with trastuzumab. Last, in their analysis, they found little association between the degree of increase in pCR response and EFS. The German Breast Group performed a similar analysis with seven of their trials involving 6,366 patients.[32] These patients were also included in the CTNeoBC pooled analysis. Their overall conclusions were similar to the FDA analysis but with some slight differing results. They found that no invasive and no in situ disease in breast and nodes (ypT0ypN0) was the greatest discriminator with long-term outcome. They also concluded that pCR was perhaps not a suitable surrogate endpoint for hormone receptor–positive/HER2-positive breast cancer.

CONCLUSION

In conclusion, in the post-adjuvant trastuzumab era, the outcome of HER2-positive breast cancer has now evolved from a subtype with the worse prognosis to one with arguably the best long-term outcomes. Current standard of care should incorporate 12 months of adjuvant trastuzumab and preferably be concurrent with a taxane backbone. Moving forward we must continue embracing the neoadjuvant model as both standard of care and an important strategy to test new therapeutic agents and accelerate drug development. Well-designed, randomized, neoadjuvant studies importantly allow us to more intelligently guide and support the trial design of adjuvant studies and, by doing so, will minimize overall timelines for drug development in early-stage disease. Although an adequate signal from preoperative trials may not necessarily predict the outcome in a confirmatory adjuvant trial, the lack of a signal should halt further development in a more resource-intensive adjuvant trial.

Addressing Barriers to Uptake of Breast Cancer Chemoprevention for Patients and Providers

Katherine D. Crew, MD, MS

OVERVIEW

Breast cancer is the most common malignancy among women in the United States, and the primary prevention of this disease is a major public health issue. Because there are relatively few modifiable breast cancer risk factors, pharmacologic interventions with antiestrogens have the potential to significantly affect the primary prevention setting. Breast cancer chemoprevention with selective estrogen receptor modulators (SERMs) tamoxifen and raloxifene, and with aromatase inhibitors (AIs) exemestane and anastrozole, is underutilized despite several randomized controlled trials demonstrating up to a 50% to 65% relative risk reduction in breast cancer incidence among women at high risk. An estimated 10 million women in the United States meet high-risk criteria for breast cancer and are potentially eligible for chemoprevention, but less than 5% of women at high risk who are offered antiestrogens for primary prevention agree to take it. Reasons for low chemoprevention uptake include lack of routine breast cancer risk assessment in primary care, inadequate time for counseling, insufficient knowledge about antiestrogens among patients and providers, and concerns about side effects. Interventions designed to increase chemoprevention uptake, such as decision aids and incorporating breast cancer risk assessment into clinical practice, have met with limited success. Clinicians can help women make informed decisions about chemoprevention by effectively communicating breast cancer risk and enhancing knowledge about the risks and benefits of antiestrogens. Widespread adoption of chemoprevention will require a major paradigm shift in clinical practice for primary care providers (PCPs). However, enhancing uptake and adherence to breast cancer chemoprevention holds promise for reducing the public health burden of this disease.

Unlike cardiovascular disease, limited pharmacologic options exist for the primary prevention of cancer. Antiestrogens, such as SERMs and AIs, have been shown to reduce breast cancer incidence by up to 50% to 65% among women at high risk.[1-5] Based on this evidence, the U.S. Preventive Services Task Force (USPSTF) and other professional organizations recommend that clinicians discuss chemoprevention with women at high risk.[6-8] An estimated 15% of women age 35 to 79 in the United States may be eligible for chemoprevention,[9] but less than 5% of women at high risk who are offered an antiestrogen for primary prevention agree to take it.[10] Compounding this underutilization is the large proportion of women who may be unaware of their high-risk status because of an inability to routinely screen for high risk in the primary care setting. Other reasons for low chemoprevention uptake include insufficient knowledge about antiestrogens on the part of clinicians and patients, multiple competing demands for PCPs, and concerns about side effects.[10,11] Even the term "chemoprevention" has negative connotations, because it sounds like "chemotherapy." The perception among patients and PCPs is that medications used to treat cancer and prescribed by oncologists may have

many toxicities. The risks and benefits of chemoprevention need to be placed in the context of pharmacologic interventions used to treat or prevent other chronic conditions (e.g., aspirin or statins for cardiovascular disease, bisphosphonates for osteoporosis). Further research is needed to determine how knowledge about breast cancer risk and chemoprevention options are best communicated to women to promote breast cancer prevention strategies.

BREAST CANCER RISK ASSESSMENT

Based on age and breast cancer risk, an estimated 15% of women in the United States meet high-risk criteria and may be eligible for chemoprevention.[9] Known breast cancer risk factors include family history, reproductive history, and lifestyle factors, such as alcohol intake and obesity.[12] Women with benign breast disease, such as atypical hyperplasia (AH) and lobular carcinoma in situ (LCIS), have up to a 4- to 10-fold increased risk of breast cancer.[13] Genetic determinants, such as germ-line mutations in the *BRCA1* and *BRCA2* genes, confer the greatest effect on breast cancer risk. The Gail model, or Breast Cancer Risk Assessment Tool, which takes

into account a woman's age, race, reproductive history, first-degree family history of breast cancer, and benign breast disease including atypia, is the most commonly used model in the United States and has been well validated at the population level.[14] It can be administered to women age 35 or older and provides an individual's absolute 5-year and lifetime risk of invasive breast cancer compared to women of the same age and race in the general population. High-risk criteria used to determine eligibility in chemoprevention trials are at least a 1.67% 5-year risk or 20% or greater lifetime risk of invasive breast cancer. To account for differences in breast cancer risk by race and ethnicity, the Gail model incorporated data from the Women's Contraceptive and Reproductive Experiences[15] and Asian American Breast Cancer Study[16] to provide more sensitive estimates for African American and Asian women, respectively. Few studies have used this model in Hispanic populations.[17,18] Hispanic women have significantly lower breast cancer risk compared to non-Hispanic white women; however, risk differs among Hispanic subgroups in the United States: according to the Gail model, Cubans have a higher 5-year risk (p < 0.05) and Dominicans have a higher lifetime risk than Mexicans (p < 0.001).[19] Interestingly, eligibility for chemoprevention among U.S. women varies dramatically by race and ethnicity, with 18.7% of whites, 5.7% of blacks, and 2.9% of Hispanics meeting high-risk criteria according to the Gail model.[9]

In women with a strong family history of breast cancer (i.e., two or more affected family members, particularly those with early-age onset), the Tyrer-Cuzick model is useful because it also accounts for second- and third-degree family history of breast and ovarian cancer and age at diagnosis.[20] This model may be particularly relevant for estimating risk in women with multiple affected family members, as well as LCIS. Women who had a 10-year risk of breast cancer of 5% of more according to the Tyrer-Cuzick model were included in the International Breast Cancer Intervention Study-I (IBIS-I) of tamoxifen and IBIS-II trial of anastrozole compared with placebo.[2,5] A comparison of the breast cancer risk factors included in the Gail and Tyrer-Cuzick models are summarized in Table 1.

High-risk benign breast disease is an important and under-recognized breast cancer risk factor.[21] Over one million benign breast biopsies are performed in the United States each year,[22] with approximately 10% showing AH or LCIS—conferring a relative risk of breast cancer of up to 4 to 10.[23-27] Long-term studies indicate that absolute breast cancer risk in women with AH is approximately 30% at 25 years of follow-up.[25,28] Of note, the Gail model significantly under-predicts breast cancer risk in women with AH (p < 0.001),[29] whereas the Tyrer-Cuzick model tends to over-predict risk.[30] Because of the high estrogen receptor (ER) expression in AH and the fact that the majority of breast cancers that develop in women with AH are ER+,[31] these high-risk women derive a greater benefit from chemoprevention than the general high-risk population. In the randomized, placebo-controlled chemoprevention trials, relative risk reduction of breast cancer among the subgroup of 2,009 women with AH ranged from 41% to 79%.[1,2,4,5,21] In a cohort study of women with atypical breast lesions, 10-year breast cancer risk with chemoprevention was 7.5%, compared to 21.3% without chemopreven-

KEY POINTS

- Breast cancer chemoprevention with antiestrogens is underutilized despite several randomized controlled trials demonstrating up to a 50% to 65% relative risk reduction of breast cancer incidence among women at high risk.
- Approximately 10 million women in the United States may be eligible for breast cancer chemoprevention, but less than 5% of women at high risk who are offered an antiestrogen for primary prevention agree to take it.
- Reasons for low chemoprevention uptake include lack of routine breast cancer risk assessment in the primary care setting, insufficient knowledge about antiestrogens on the part of clinicians and patients, and concerns about side effects.
- Interventions designed to increase identification of women at high risk and chemoprevention uptake, including written materials, decision aids, and incorporating breast cancer risk assessment tools into clinical practice, have met with limited success.
- Because of the proven efficacy of breast cancer chemopreventive agents, widespread use of antiestrogens for primary prevention among women at high risk has the potential to significantly improve the public health burden of this disease.

TABLE 1. Comparison of Breast Cancer Risk Factors in the Gail and Tyrer-Cuzick Models

Gail Model	Tyrer-Cuzick Model
Age (35 or older)	Age
Race/ethnicity (white, black, Hispanic, Asian American [Chinese, Japanese, Filipino, Hawaiian, other], unknown)	Ashkenazi Jewish descent
Age at menarche	Age at menarche
Age at first live birth	Age at first live birth
	Menopausal status
	Age at menopause
	Use of hormone replacement therapy
	Body mass index
Number of benign breast biopsies	
Benign breast biopsy with atypical hyperplasia (excludes LCIS, DCIS, or invasive breast cancer)	Benign breast biopsy including hyperplasia with or without atypia and LCIS
Number of first-degree relatives with breast cancer	Number of first-, second-, and third-degree relatives with breast or ovarian cancer, bilateral breast cancer, and age at diagnosis
	BRCA mutation status

Abbreviations: DCIS, ductal carcinoma in situ; LCIS, lobular carcinoma in situ.

tion.[24] Despite this evidence, chemoprevention uptake remains low among these women at high risk.[32]

BREAST CANCER CHEMOPREVENTIVE AGENTS
Selective Estrogen Receptor Modulators

Table 2 summarizes results of the major randomized controlled trials of SERMs and AIs for the primary prevention of breast cancer. In 1998, the Breast Cancer Prevention Trial (BCPT) demonstrated that the SERM tamoxifen taken for 5 years reduced breast cancer incidence in women at high risk by 49% (number needed to treat [NNT] to prevent one invasive breast cancer was 95 at 5 years and 56 at 10 years).[33,1] The overall results from three additional randomized controlled trials confirmed that tamoxifen decreased breast cancer risk by 30% to 40% compared to placebo.[34-37] In particular, long-term follow-up data (median of 16 years) from the IBIS-I trial demonstrated a persistent protective effect of tamoxifen (NNT was 22 at 20 years).[2] The magnitude of this risk reduction is comparable to what has been observed with preventive agents for cardiovascular disease.[38-40]

Another SERM, raloxifene, has been shown to reduce the incidence of breast cancer in postmenopausal women for the treatment and prevention of osteoporosis.[41,42] Updated analyses from the Study of Tamoxifen and Raloxifene (STAR) trial demonstrated that raloxifene had 76% of the efficacy of tamoxifen for breast cancer prevention among postmenopausal women at high risk with a more favorable side effect profile.[3] Based on the results of these trials, tamoxifen was approved by the U.S. Food and Drug Administration (FDA) for breast cancer risk reduction among women at high risk in 1998 and raloxifene in 2007.

Aromatase Inhibitors

Data from adjuvant trials have proven to be a useful model for assessing the chemopreventive effects of endocrine therapies, since results of antiestrogens in the primary prevention setting closely mirrored those for adjuvant treatment.[37] In 2011, results from the Mammary Prevention Trial-3 (MAP.3) demonstrated that the AI exemestane given to postmenopausal women at high risk reduced invasive breast cancer incidence by 65% compared to placebo (NNT was 26 at 5 years).[4] High-risk criteria included age 60 or older (49%), a 5-year Gail risk score 1.66% or greater (40%), AH or LCIS (8%), and ductal carcinoma in situ treated with mastectomy (3%).[4] After a median follow-up of 35 months, 11 invasive breast cancers occurred in the exemestane arm compared to 32 in the placebo group (annual incidence of 0.19% vs. 0.55%; p = 0.002).[4] In the group comparing exemestane compared to placebo, more grade 2 or higher arthritis (6.5% vs. 4.0%) and hot flashes (18.3% vs. 11.9%) were seen. However, overall quality of life did not differ between the two arms, and no significant differences in new-onset osteoporosis, clinical skeletal fractures, cardiovascular events, or other malignancies were seen.

Another third-generation AI was investigated in the IBIS-II trial, which randomly assigned postmenopausal women at high risk, age 40–70, to receive either anastrozole or placebo for 5 years.[5] With a median follow-up of 5 years, 40 breast cancers (invasive and noninvasive) occurred in the

TABLE 2. Updated Results from Major Randomized Controlled Trials of Selective Estrogen Receptor Modulators and Aromatase Inhibitors for Breast Cancer Chemoprevention

Trial	No. of Participants	Eligibility, High-Risk Criteria for Breast Cancer	Intervention	Median Follow-up (Months)	Breast Cancer Incidence	Breast Cancer Risk Reduction RR or HR (95% CI)
BCPT, 2005[1]	13,388	Age ≥ 35, 5-yr Gail risk score > 1.66% if age 35-59 or ≥ 60 or LCIS	Tamoxifen 20 mg/d x 5 yrs versus placebo	84	3.59 versus 6.29[a]	0.57 (0.46-0.70)
IBIS-I, 2014[2]	7,154	Age 35-70, 10-fold risk if age 35-39, or 4-fold risk if age 40-44, or 2-fold risk if age 45-70	Tamoxifen 20 mg/d x 5 yrs versus placebo	192	7.0% versus 9.8%[b]	0.71 (0.60-0.83)
STAR, 2010[3]	19,747	Age ≥ 35, postmenopausal, 5-yr Gail risk score > 1.66%	Raloxifene 60 mg/d versus tamoxifen 20 mg/d x 5 yrs	81	5.02 versus 4.04[a]	1.24 (1.05-1.47)
MAP.3, 2011[4]	4,560	Age ≥ 35, postmenopausal, 5-yr Gail risk score > 1.66% if age 35-59 or age ≥ 60 or AH, LCIS, DCIS with mastectomy	Exemestane 25 mg/d x 5 yrs versus placebo	35	0.19% versus 0.55%[c]	0.35 (0.18-0.70)
IBIS-II, 2013[5]	3,864	Age 40-70, postmenopausal, 4-fold risk if age 40-44, or 2-fold risk if age 45-59, or 1.5-fold risk if age 60-70	Anastrozole 1 mg/d x 5 yrs versus placebo	60	2% versus 4%[b]	0.47 (0.32-0.68)

Abbreviations: SERM, selective receptor estrogen modulators; AI, aromatase inhibitor; AH, atypical hyperplasia; BCPT, Breast Cancer Prevention Trial; CI, confidence interval; DCIS, ductal carcinoma-in-situ; HR, hazard ratio; IBIS, International Breast cancer Intervention Study; LCIS, lobular carcinoma in situ; MAP, Mammary Prevention Trial; RR, relative risk; STAR, Study of Tamoxifen and Raloxifene.
[a]Invasive breast cancer incidence rate/1,000 women.
[b]All breast cancers, invasive and noninvasive.
[c]Annual incidence of invasive breast cancers.

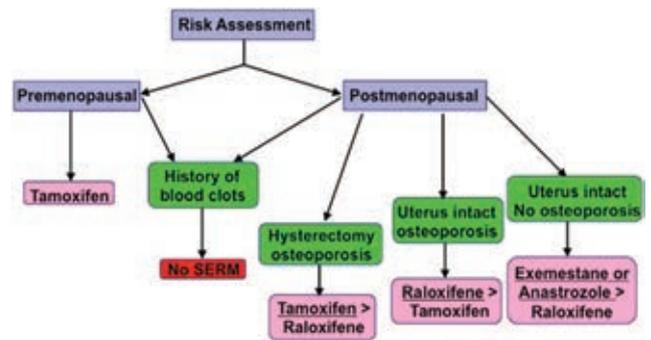
anastrozole arm compared to 85 in the placebo group (hazard ratio 0.47; 95% confidence interval 0.32–0.68; p < 0.0001). In the anastrozole group compared to placebo, more arthralgia (51% vs. 46%), vasomotor symptoms (57% vs. 49%), vaginal dryness (19% vs. 16%), and hypertension (5% vs. 3%) occurred. In general, there appear to be fewer serious side effects with AIs compared to tamoxifen.

To date, there are no head-to-head trials comparing SERMs to AIs or evaluating extended hormone therapy for up to 10 years in the primary prevention setting. Also, these antiestrogens have no effect on the incidence of ER– tumors, which are associated with a poorer prognosis compared to ER+ breast cancer and are more common in younger women, black women, and *BRCA1* mutation carriers. In addition, limited data exist on the efficacy of antiestrogens for breast cancer risk reduction in women with hereditary breast cancer syndromes, such as *BRCA1* and *BRCA2* mutation carriers.[43,44] Of note, none of these chemoprevention trials were adequately powered to detect a difference in breast cancer–specific or overall mortality.

Chemoprevention Guidelines

Based on this evidence, the USPSTF, American Society of Clinical Oncology, and the National Comprehensive Cancer Network published consensus guidelines on breast cancer chemoprevention.[6-8] Premenopausal and postmenopausal women at high risk, defined as a 5-year Gail risk 1.67% or greater or LCIS, may take tamoxifen for 5 years for the primary prevention of breast cancer. Younger women (age 35–50), those without a uterus, and those at higher risk for breast cancer derive the greatest clinical benefit from tamoxifen. Postmenopausal women at high risk also have the options of raloxifene, exemestane, and anastrozole for breast cancer risk reduction. Because of the increased risk of uterine cancer, follow-up for women on tamoxifen should include annual gynecologic examinations with a timely work-up of abnormal vaginal bleeding, but routine endometrial biopsies in the absence of vaginal symptoms is not recommended. SERMs are contraindicated in women with a history of thromboembolism, such as deep vein thrombosis, pulmonary embolus, stoke, or transient ischemic attack. In addition, the STAR trial excluded women with uncontrolled diabetes or hypertension, those with atrial fibrillation, and those on hormone replacement therapy.[45]

Figure 1 depicts a potential algorithm for clinical decision making about antiestrogens for breast cancer chemoprevention based on menopausal status, history of thromboembolism, risk of osteoporosis, and prior hysterectomy. For premenopausal women at high risk, tamoxifen is currently the only FDA-approved drug for the primary prevention of breast cancer. Younger women (age 35–50) at high risk derive the greatest clinical benefit from tamoxifen because the risk of serious side effects, such as thromboembolism and uterine cancer, is negligible compared to placebo. For postmenopausal women at high risk with an intact uterus, raloxifene may be favored over tamoxifen, whereas tamoxifen may be preferable in women with a prior hysterectomy because of

FIGURE 1. Choice of Selective Estrogen Receptor Modulator or Aromatase Inhibitor for Breast Cancer Chemoprevention


Choice is based on menopausal status, history of thromboembolism, prior hysterectomy, and risk of osteoporosis (based upon the author's personal algorithm and not a guideline recommendation).

its greater efficacy in breast cancer risk reduction.[3] Both SERMs are contraindicated in women with a prior history of thromboembolism, but AIs may be offered to postmenopausal women. SERMs may be favored over AIs among postmenopausal women at high risk with low bone density, although presence of osteoporosis is not an absolute contraindication to taking an AI. Overall, both SERMs and AIs are effective chemopreventive agents; therefore, the choice will depend on personal preferences and acceptable toxicity profiles.

BARRIERS TO UPTAKE OF BREAST CANCER CHEMOPREVENTION

Low Uptake of Breast Cancer Chemoprevention

An estimated 10 million U.S. women age 35 to 79 are eligible for breast cancer chemoprevention.[9] Based on a systematic review and meta-analysis of patient decisions about chemoprevention, less than 5% of women at high risk who are offered an antiestrogen for primary prevention agree to take it.[10] The main reason for this is the perception of patients and physicians that chemoprevention does not offer a favorable risk–benefit profile.[46-49] After the 1999 FDA approval of tamoxifen for primary prevention in women at high risk, data from the National Health Interview Survey indicated that the prevalence of tamoxifen use among women without a personal history of breast cancer was 0.2% in 2000 and decreased to 0.08% in 2005.[32] Similarly, after raloxifene's FDA approval in 2007, its use for breast cancer risk reduction decreased.[45] It remains to be seen whether there will be greater acceptance of AIs for primary prevention.

Lack of Routine Breast Cancer Risk Assessment in Clinical Practice

Despite the online availability of both the Gail and Tyrer-Cuzick models, only 18% of PCPs report use of software to calculate breast cancer risk.[50] In a cross-sectional survey of over 300 PCPs, use of the Gail model for breast cancer risk

assessment varied by medical specialty (37% internal medicine, 33% family medicine, 60% gynecology), as well as ever recommending or prescribing breast cancer chemoprevention (9% internal medicine, 8% family medicine, 30% gynecology).[51] Barriers to routine breast cancer risk assessment in the primary care setting include time constraints during clinic visits and lack of familiarity with risk assessment tools and chemoprevention.[52] There may also be concerns about the accuracy of breast cancer risk prediction models.

Risks and Benefits of Chemoprevention

Concerns about potential side effects, such as uterine cancer, thromboembolic events, and menopausal symptoms, are the main contributors to a woman's unwillingness to initiate chemopreventive agents for breast cancer and a physician's reluctance to prescribe them.[46-48,53-56] In the BCPT, the net benefit achieved with tamoxifen varied by age, race, and level of breast cancer risk, such that an estimated 2.5 million women in the United States could derive a net benefit from the drug.[1] In the STAR trial, raloxifene was associated with a lower risk of thromboembolic events, benign uterine complaints, and cataracts than tamoxifen.[45,57] Although women on tamoxifen reported more gynecologic and vasomotor symptoms,[45] overall quality of life was similar for both SERMs.[57] In the MAP.3 and IBIS-II trials, AIs decreased bone mineral density compared to placebo but did not increase the risk of fractures.[4] In contrast, SERMs have a favorable effect on bone density with about a 32% reduction in fracture incidence.[33,41,42]

The general perception among patients and providers is that use of antiestrogens for primary prevention does not confer a favorable risk–benefit profile. Based on results from the STAR trial, per 1,000 women at high risk, tamoxifen would prevent 40 breast cancers compared with causing 2.25 uterine cancers and 3.3 thromboembolic events, whereas raloxifene would prevent 31 breast cancers compared with causing 2.47 thromboembolic events.[3] Freedman et al developed a model to predict the risks and benefits of SERMs for women older than 50 based on age, race/ethnicity, breast cancer risk, and presence of a uterus, which may provide a more personalized risk–benefit profile.[58] Whereas the side effects diminish after stopping chemoprevention, the protective effect on breast cancer risk persists after discontinuation.[36] Unlike preventive therapies for other chronic diseases, which often require life-long treatment, breast cancer chemoprevention for 5 years can confer long-term benefits with side effects limited to during active treatment.

Low chemoprevention uptake occurs because of the lack of effective strategies to inform both PCPs and women at high risk about the risks and benefits of antiestrogens. Physicians who felt insufficiently informed about risk-reducing options were less than half as likely to prescribe a SERM for breast cancer prevention than physicians who felt sufficiently trained.[59] Physician recommendation and health care provider communication are among the most influential factors to influence chemoprevention uptake.[46,48,60]

Lack of Intermediate Biomarkers to Predict Response to Chemopreventive Agents

The lack of well-validated intermediate biomarkers for short-term breast cancer risk assessment, analogous to low-density lipoprotein cholesterol for cardiovascular disease or T-score on a bone density scan for osteoporosis, is another barrier to uptake of antiestrogens. Even if a woman at high risk agrees to take chemoprevention, there is no way to assess whether she is deriving a benefit from the agent except with long-term follow-up to determine whether she remains free of breast cancer. Mammographic density (MD), a strong predictor of breast cancer risk,[61,62] may also serve as a predictive biomarker of response to breast cancer chemoprevention. In the IBIS-I trial, tamoxifen given for 18 months caused a significant decrease in MD compared to placebo, particularly among premenopausal women (p < 0.001).[63] Cuzick et al demonstrated that at least a 10% reduction in MD with tamoxifen was associated with a 63% reduction in breast cancer risk.[64] Compared to other qualitative methods of measuring MD, the Cumulus technique provides quantitative measurements and has been strongly associated with breast cancer risk in epidemiologic studies.[65,66] However, more automated methods for measuring MD or volumetric density are needed, which would be applicable in the clinical setting.[67,68]

Measurement of endogenous hormone levels, such as plasma estrone sulfate, testosterone, prolactin, and sex hormone-binding globulin, have been shown to improve breast cancer risk prediction in postmenopausal women.[69] Changes in estradiol and testosterone levels may also serve as good breast cancer risk biomarkers for weight loss interventions.[70] However, assay variability with low hormone levels, particularly in postmenopausal women, may hamper their clinical utility.[71]

Predictors of Poor Adherence to Endocrine Therapy

The effectiveness of chemoprevention depends not only on initiation of therapy but also on long-term adherence. In the chemoprevention trials, adherence at 5 years ranged from 64% to 85%[1,4,36,57]; however, clinical trial participants are often more compliant than the general population. Veronesi et al reported that women in a chemoprevention trial were less likely to adhere to tamoxifen than patients with breast cancer treated in the adjuvant setting.[72] In the Sister Study cohort, 46% of women taking tamoxifen for primary prevention discontinued within 4.5 years.[73] In BCPT and MAP.3, ethnic minorities and women with low income had less drug adherence.[74,75] Women from racial/ethnic minorities and those who are uninsured are less likely to seek breast cancer preventive care, perhaps contributing to higher rates of late-stage diagnosis.[76,77] Understanding predictors of poor uptake and adherence to breast cancer chemoprevention will aid in the development of targeted interventions for certain patient subgroups.

INTERVENTIONS TO INCREASE UPTAKE OF BREAST CANCER CHEMOPREVENTION

Results from recent intervention trials to increase chemoprevention uptake targeting both patients and providers are summarized in Table 3. In a recent randomized controlled trial of a web-based decision aid that informed women about the risks and benefits of SERMs,[78] only 0.5% of eligible participants had started raloxifene and none had started tamoxifen. In a study called the "Ready, Set, GO GAIL!" project, PCPs systematically screened more than 5,700 women age 35–70 with the Gail model; 868 (15.2%) met high-risk criteria and were eligible for chemoprevention, only 128 (14.7%) of these women were referred for specialized risk counseling, 60 (6.4%) completed the consultation, and 17 (2%) started a SERM.[79] In the BreastCARE intervention trial, women in the primary care setting were randomly assigned to usual care or a tablet-based patient intake tool that generated individualized breast cancer risk profiles for patients and their physicians.[80] Although more women at high risk were referred for specialized risk counseling with the intervention compared to the control arm (18.8% vs. 4.1%), discussions about chemoprevention were still limited (1% vs. 0%).

Interventions designed to increase chemoprevention uptake, involving reading materials or decision aids, met with limited success, ranging from 0.5% to 5.6%.[48,49,55,78,81] Few studies have assessed the effect of automated decision support for PCPs.[82,83] Two studies used a computer-based tool to improve referrals for genetic testing, but they were not integrated into clinic workflow.[84] Given that breast cancer chemoprevention is not widely diffused in the primary care setting, more effective tools are needed to accurately identify women at high risk and educate both patients and providers about the risks and benefits of chemoprevention options. Studies that involved consultation at a breast clinic reported chemoprevention uptake ranging from 11% to 58%.[46,53,54,60,85-87] Therefore, higher chemoprevention uptake may be achieved with health professionals who have sufficient knowledge and training about breast cancer risk and risk reduction strategies. Given that many community practices may not have access to high-risk clinics, PCPs need to be at the front line of chronic disease prevention, including breast cancer chemoprevention.

Strategies to minimize toxicities to antiestrogens include administering lower or intermittent dosing, developing alternative drug delivery methods such as topical therapy, and identifying novel chemopreventive agents with fewer side effects. For example, clinical trials of oral low-dose tamoxifen of 1, 5, or 10 mg daily or 10–20 mg weekly have demonstrated similar biologic efficacy to standard-dose tamoxifen (20 mg daily) with fewer side effects.[88-95] Since tamoxifen is a prodrug that requires hepatic activation, Mauvais-Jarvis et al developed a topical form of trans-4-hydroxytamoxifen (4-OHT), the active metabolite of tamoxifen, which would maximize local drug levels with fewer systemic side effects.[96] Thus far, topical tamoxifen has been tested for the treatment of mastalgia[97] and in two presurgical (window of opportunity) trials in women with breast cancer.[98,99] Finally, novel chemopreventive agents—including aspirin, NSAIDs, metformin, vitamin D, and vaccines to tumor-associated antigens—which may have a more favorable side effect profile compared to SERMs and AIs and perhaps activity against ER– breast cancers, are currently under investigation.[100]

CONCLUSION

Breast cancer chemoprevention with antiestrogens has proven efficacy in high-risk populations, but uptake remains low. Preventive therapy for cancer is currently less well established compared to other chronic conditions, such as cardiovascular disease, and could benefit from lessons learned.[101] Health care providers can do more in the area of cancer prevention by identifying high-risk populations in the primary care setting. Chemoprevention needs to be integrated into broader strategies of preventive care, which may include nonpharmacologic interventions such as lifestyle modification. Given the high compliance rates for breast cancer screening, incorporating formal risk assessments at the time of screening mammography may represent a "teachable moment" when women are already engaging in a health behavior related to breast cancer. Novel health information technologies such as electronic health records and patient health portals may be a method for integrating information about breast cancer risk and chemoprevention into clinic workflow.

TABLE 3. Intervention Trials to Increase Uptake of Breast Cancer Chemoprevention

Authors, Year	No. of Participants	Eligibility	Intervention	Outcomes
Fagerlin et al 2011[79]	1,197	Age 40-74, postmenopausal, 5-yr Gail risk score > 1.66%	Tailored online decision aid "Guide to Decide"	0% tamoxifen and 0.5% (2 patients) raloxifene uptake with intervention
Owens et al 2011[80]	868	Age 35-70, 5-yr Gail risk score ≥ 1.7% or lifetime risk ≥ 20%	"Ready, Set, GO GAIL!" project, clinic-based intervention to implement Gail model in women's health clinic	Completion of high-risk consultation, 6.4% (60 patients); chemoprevention uptake, 2% (17 patients)
Kaplan et al 2014[81]	1,235	Age 40-74, scheduled for clinic visit at two primary care practices, spoke English, Spanish, or Chinese	BreastCARE, tablet-based breast cancer risk assessment that generated individualized reports for patients and their physicians	Referral to high-risk clinic, 18.8% versus 4.1% among women at high risk (307 patients); discussion of chemoprevention, 1% versus 0%

Breast cancer incidence continues to increase in most countries,[102] and the economic burden of cancer in the United States is expected to substantially increase[103] because of greater intensity of health care usage[104,105] and increasing costs of cancer care.[106-109] These rising medical costs will disproportionately affect racial/ethnic minorities and low-income and under-insured individuals. U.S. health care providers can do more in the area of cancer prevention by targeting high-risk populations. Promoting chemoprevention uptake among women at high risk will require a major paradigm shift in clinical practice if antiestrogens are to be widely adopted in the primary care setting.

Disclosures of Potential Conflicts of Interest

The author(s) indicated no potential conflicts of interest.

Decision Making in the Context of Breast Cancer Chemoprevention: Patient Perceptions and the Meaning of Risk

Christine Holmberg, PhD, MPH

OVERVIEW

Chemoprevention with selective estrogen receptor modulators (SERMs) is considered one of the most promising risk reduction options to date in the United States. Tamoxifen and raloxifene are both approved by the U.S. Food and Drug Administration (FDA) for breast cancer risk reduction. However, despite endorsement from the American Society for Clinical Oncology and the National Comprehensive Cancer Network, uptake remains low. Decision aids have been successful in improving women's understanding and knowledge about the risk–benefit trade-offs in decision making regarding SERMs. However, increased knowledge does not lead to increased uptake of chemoprevention for the purpose of reducing breast cancer risk; instead, women become more reluctant to take medication that is itself associated with risks. Reasons for this include a lack of awareness that SERMs are effective in reducing breast cancer risk, an unwillingness to increase the risk of other disease, reluctance to take a daily medication, and the perception of tamoxifen as a "cancer drug." In studies on hypothetical decision making in the context of chemoprevention women indicate greater willingness to take a SERM when they are determined to be at risk. These findings suggest a differential understanding of what risk means among the general public, health professionals, and researchers. *Feeling* at risk is related to bodily signs and symptoms and not to population-derived probabilities. Such differential understanding may in part explain women's perception of the low efficacy of SERMs and their decision making regarding SERM use.

Breast cancer is the leading cancer in females and is responsible for the greatest number of cancer deaths among women worldwide,[1] including the United States.[2] According to data for 2008 to 2010 collected in the Surveillance, Epidemiology, and End Results (SEER) program, 12.3% of women in the United States will be diagnosed with breast cancer during their lifetime. There is conflicting evidence as to whether changing behavioral factors such as a sedentary lifestyle, smoking, or regular alcohol consumption can reduce the risk of breast cancer.[3-6] Risk reduction efforts for breast cancer therefore pose a challenge, especially as the most effective options (young age at first live birth and having multiple children) conflict with other public health messages and efforts.[7] In this context, chemoprevention with selective estrogen receptor modulators (SERMs) is considered one of the most promising risk reduction options to date in the United States. At the present time two SERMs—tamoxifen and raloxifene—are approved by the U.S. FDA for breast cancer risk reduction, although other medications are under investigation.[8] Leading oncologic organizations such as the American Society for Clinical Oncology and the National Comprehensive Cancer Network recommend the use of these medications for prevention of breast cancer. Uptake, however, has lagged behind expectations.[9]

Tamoxifen was the first medication to be approved for breast cancer risk reduction. The Breast Cancer Prevention Trial (BCPT) conducted between 1992 and 1998 in the United States showed that among women with an increased risk of developing breast cancer, those who had taken tamoxifen saw a risk reduction of 50% compared to those in the control group.[10] The risk reduction among women with a diagnosed atypia such as lobular carcinoma in situ (LCIS) or atypical hyperplasia (AH) was even greater: 56% and 86% respectively. Since these findings, a range of other drugs to reduce breast cancer risk have been under investigation.[8] Thus far, only raloxifene has been approved, after the Study of Tamoxifen and Raloxifene (STAR) conducted in the early 2000s in the United States established the efficacy of raloxifene in reducing breast cancer risk.[11] Risk reduction among women with LCIS or AH was lower in the STAR than in the BCPT, although these women still showed a higher level of risk reduction than women whose increased risk assessment was based on the Gail score alone. As follow-up of both of these studies continues, the risks and benefits associated with both drugs and their effects on breast cancer risk reduction are expected to change over time.[12]

PREVALENCE OF SERM USE FOR BREAST CANCER RISK REDUCTION

In a series of studies conducted using data from the National Health Interview Study, Waters et al[13,14] estimated the prev-

alence of tamoxifen and raloxifene use in the United States. In 2010, only 0.03% of women age 35 to 79 reported taking tamoxifen and 0.21% of women age 50 to 79 reported taking raloxifene for the prevention of a primary invasive breast tumor.[14] This compares to the approximately 15% of all U.S. women age 35 to 79 who would have been eligible to take tamoxifen in 2000 and the 5% who would have had a positive risk/benefit index.[15]

The abovementioned studies provide the only available population-based data on the use of SERM drugs for breast cancer risk reduction. However, several studies have investigated the uptake of SERMs by individuals in high-risk clinics and primary care. Uptake in these studies is variable.[16] For example, Tchou et al. studied the medical records of women who sought risk evaluation at a breast clinic in a metropolitan area of the United States and found that 42% of women who were offered tamoxifen by their physicians actually took the drug.[17] Older age and a history of LCIS or AH were predictive of tamoxifen acceptance. In a separate study conducted by Kay et al.,[18] women who had been evaluated in a breast clinic in Canada and who showed either an increased risk of developing breast cancer or had a diagnosis of AH were approached and given a decision guide on the risks and benefits of tamoxifen. In this sample, among which 60% of women had a diagnosis of AH, only 6 out of 51 eligible women (11.8%) chose to take tamoxifen.[18,19] Finally, uptake was 10.6% in a more recent study in a high-risk breast clinic in the United Kingdom. Eligibility criteria for women to participate in the study were based on an increased risk as calculated by the Tirer-Cuzick model, and all women had previously been monitored for their breast cancer risk.[20] Those who decided to take tamoxifen were older and showed a trend toward higher risk scores compared to those who chose not to take the drug.

DECISION MAKING ON SERM USE

Decision making in the context of breast cancer risk and SERM use includes the evaluation of complex risk–benefit trade-offs.[21,22] Both of the approved medications, tamoxifen

and raloxifene, carry significant risks, including endometrial cancer (particularly for tamoxifen), thromboembolic events, stroke, and cataracts.[8,12,21]

Several decision aids have been developed that aim to provide neutral information and present the involved risk–benefit trade-offs in SERM decision making. Few of them, however, include personalized risk and benefit information; exceptions are the decision aids developed by Fagerlin et al[23,24] and Ozeanne et al.[25,26]

The two decision aids developed by Fagerlin et al are particularly aimed at helping women decide whether to take tamoxifen and/or raloxifene as a treatment option to reduce breast cancer risk. They both consist of personalized information on breast cancer risk; in addition, one also includes information on the risks and benefits associated with taking tamoxifen whereas the second provides comparative information on the risk–benefit profiles of tamoxifen and raloxifene.[23,24] For the decision aid looking at tamoxifen alone, overall the women who participated in testing the decision aid were not interested in taking the drug. Among those who were interested (5.8% indicated that they were likely to take the drug in the next year), fewer women had high knowledge scores than in the overall sample. Thus, increased knowledge of tamoxifen and its associated risks seemed to decrease women's willingness to take the chemoprevention agent. The same was true for the decision aid that offered information on both tamoxifen and raloxifene.[23] The authors investigated the reasons why women may not be interested in taking the drugs and found that the majority did not perceive them as likely to reduce their breast cancer risk. Furthermore, the study sample had a majority of women with a risk score for developing breast cancer within the next 5 years of 3% or lower according to the Gail model. The authors hypothesized that for the women in the study, this risk was considered so low that it simply did not warrant taking medicines, especially ones that have potentially significant side effects.[23] It has also been suggested that lack of knowledge about the option of chemoprevention is one reason for the low uptake. Although this may be the case, it is important to consider that increased knowledge about tamoxifen and/or raloxifene may in fact lead to a decrease in willingness to take either drug.[22]

The main goal of the decision aid developed by Ozeanne et al is to provide breast cancer risk information in context, and this aid therefore includes a range of treatment options such as chemoprevention and mastectomy, as well as other disease risks.[25,26] Although the feasibility and usability of the tool have been tested, full evaluations have not yet been published. Deciding on treatment options for breast cancer risk reduction is considered a preference-sensitive decision because of the complex risk–benefit trade-offs that are involved.[27] This means that the decision is, and should be, based on an individual's preferences rather than on population-based standards. Such a decision nevertheless also presupposes an individual's understanding of the risks and benefits involved. The existing decision aids do seem to be able to educate women adequately about the risks and

---

KEY POINTS

- Decision making in the context of breast cancer chemoprevention includes complex risk–benefit trade-offs.
- The decision should be based on individual preferences.
- Increased knowledge on chemoprevention may deter women from taking drugs for breast cancer prevention.
- Perceptions of low efficacy, worries about side effects, and the notion of tamoxifen as a cancer drug have all been suggested as factors influencing women's decision making regarding chemoprevention for breast cancer risk reduction.
- Understandings of risk differ between health care providers and laywomen.

benefits.[22] However, to truly understand, evaluate, and predict the uptake of SERM drugs, it may be crucial to understand women's perceptions of chemoprevention, as these are likely to influence decision making.

PERCEPTIONS OF CHEMOPREVENTION

Below are presented some of the prevailing perceptions, assumptions, and beliefs about chemoprevention, as revealed by research to date. However, most of this research has looked only at tamoxifen. The study of Fagerlin et al[23] provides one of the few exceptions, from which we may also learn about perceptions of raloxifene.

What's in a Name? Tamoxifen and Chemoprevention

Tamoxifen has been used for several decades in the treatment of breast cancer to prevent the recurrence of disease. For some women, tamoxifen is therefore associated with cancer and is considered a "cancer drug."[20] These women expressed the fear that if they took tamoxifen, others may conclude that they have breast cancer. Because of the perception of tamoxifen as a cancer drug and confusion over the difference between chemotherapy and chemoprevention, some women have expressed fear of hair loss or other side effects that are more often associated with chemotherapy.[20,28]

Side Effects

Several studies have shown that women are concerned about the side effects of SERM use.[18,29] Moreover, these concerns are not only related to the severe side effects such as endometrial cancers, but also to the more common but less serious effects of taking the drugs, such as hot flashes. For example, one nested qualitative study reported that participants in focus group discussions were reluctant to end hormone replacement therapy in favor of chemoprevention.[29] SERMs may induce hot flashes, which are reduced by hormone replacement therapy. Although hot flashes may not be considered serious from a medical point of view, they can impair a woman's day-to-day activities and reduce quality of life.

Risk Perception

Many women's perception of their breast cancer risk differs from the objective risk estimates derived from personalized risk assessments such as the Gail score or Claus model. Indeed, when objective breast cancer risk estimates are compared to women's own estimates, women regularly overestimate their personal risk level.[30] This generally high level of risk perception may influence a woman's decision making about chemoprevention. When women receive their objective personalized risk estimate they may be surprised by the relatively low values, and this may deter them from taking preventive action that could increase the risk of other diseases.[23,24,31-33]

On the other hand, there is evidence that women may not necessarily believe the risk levels provided through personalized risk estimates.[34] Furthermore, women's personal assessments of their risk have been shown to be extremely persistent and may not change through counseling. In one study, for example, among women attending a high-risk clinic in the United States to discuss their breast cancer risk and treatment options the women's preferences regarding chemoprevention were shown to be stable over time. The women were surveyed before and after the consultation, and their level of breast cancer risk that would indicate chemoprevention uptake was similar at both points.[27] In this study, 75% of the women indicated that they would take chemoprevention for breast cancer risk reduction if their lifetime risk of developing breast cancer was estimated at 60%. In comparison, the actual average risk in this sample of high-risk women was 18.5% (as determined by the Gail score).

Efficacy

It has been suggested that women might not believe that taking a chemopreventive agent will substantially reduce their breast cancer risk.[18,23] Such assumptions may be related to the low absolute risk scores of most of the women whose decision making patterns regarding chemoprevention have been studied. An accurate understanding of one's risk of developing breast cancer may therefore lead to the belief that the risk is too small to warrant action, particularly if such action in itself involves risks.

Taking Medicines

The idea of taking medication on a daily basis over a period of 5 years may be seen by some women as a constant reminder of their breast cancer risk and the potential of developing the disease.[20] This has been shown to be considered a drawback by some women when considering chemoprevention. Other studies have found that women are reluctant to take medicine in general because it is seen as "unnatural."[28] A general aversion to taking medicines has also been described in other contexts. This reluctance might be heightened for medicines that are not perceived as "necessary." Such generalized attitudes toward medications are likely to influence the perception of chemoprevention drugs and thus affect the overall acceptance of their use. This example also highlights the importance of viewing something (such as a medicine) as necessary in order to consider taking it.

WHAT CONSTITUTES A RISK?

Findings of the numerous studies and papers that have been published on women's decision making approaches to chemoprevention for breast cancer can be summarized as follows: increased knowledge and understanding of the risks and benefits involved in taking SERMs does not lead to increased uptake of chemoprevention for the purpose of reducing breast cancer risk[16]; instead, women become more reluctant to take medication with risks involved.[23,24,35]

At the same time, studies that have looked at the *intention* to take chemoprevention have regularly found higher num-

bers of women interested in and willing to take chemoprevention drugs compared to studies that have assessed *actual* behavior.[16,31,35,36] Kaplan et al[35] and Salant et al[37] present studies that may be illuminating in this regard. To study potential acceptance of chemoprevention in a sample of women with diverse ethnic and racial backgrounds, Kaplan et al surveyed women through their primary care networks. The authors developed a generic information guide on tamoxifen that included information on who is at high risk for breast cancer, the ability of tamoxifen to reduce breast cancer risk, and the drug's side effects. These facts were all presented as probabilities using an easy to understand visual format. In this study, more than 40% of women indicated that they would be likely or very likely to take tamoxifen if they were determined to be at high risk of breast cancer. When reading these study results, however, one must take into account the fact that the women sampled were not high risk, but women in the general population, and thus they merely *hypothesized* that *if* they were at high risk, they would be likely to take the drug. Given this fact, and in the light of some of the previously presented studies, one may ask what "to be at risk of developing breast cancer" actually means to laywomen, health professionals, and researchers.

The study of Salant et al[37] found that risk meant different things to the medical staff and to the women deemed to be at risk by the medical staff. Although the women were aware of their objective risk estimate level, they were more concerned about their personal feelings regarding being at risk, which were influenced by bodily signs and symptoms and not by population-derived probabilities. *Feeling* at risk is thus likely to be very different from being *told* that one is at risk.[38]

The term "risk" means very different things in epidemiology and medical care compared to everyday language. In everyday language, risk is typically associated with danger.[39] A probability of 1.66% may therefore not feel like much of a risk at all. When women answer that they would take action if determined to be at risk, it is thus very likely that they have other constructs in mind than the probabilistic concepts of the Gail model. For example, Dillard et al[40] found an association between anxiety and women's intention to gather additional information about tamoxifen and take the drug in the next few months. The psychological construct of anxiety may be more similar to individuals' connotations of risk than probabilistic concepts of risk and risk perception.

DECISION MAKING

As discussed above, decision making about whether or not to take chemoprevention to reduce breast cancer risk involves complex risks and trade-offs and should be based on an individual's preferences rather than on population-based standards. The prerequisite to enable such decision making is presentation of the involved risks and benefits in a way that is understandable, even to low-numerate populations.[41] Nevertheless, even when risks and benefits appear to be understood, willingness to take chemoprevention remains low among women who are eligible on the basis of their Gail score. Other research has shown that health decision making may not be based on an accurate understanding of risk information, but perhaps more on heuristics and feelings.[42,43] Feelings, assumptions, and experiences influence how risk information is perceived. As such, individuals may not always use the risk information presented to them in the ways that health care providers intend.[44]

The accumulating evidence that personalized risk information may not be as successful as previously thought in initiating particular health behaviors may also point to an increasing gap between approaches to treatment decision making using personalized risk information as advocated in health care, and the approaches of the individuals, which rely on feelings and heuristics. Various perceptions surrounding chemoprevention—that tamoxifen is a "cancer drug," fear of medication side effects, differences in the understanding of risk between laywomen and health care providers, a lack of knowledge about chemoprevention, and societal opinions of medication intake—provide the framework within which decision making takes place. Health care providers should be aware that counseling may be neither as effective nor as influential in terms of decision making as they assume,[27] since decisions may be based on perceptions that are influenced by an individual's family history, societal assumptions, and culture as much as, or even more than, the information and guidance offered by individual health care providers.[45]

IMPLICATIONS

There are several avenues through which women may be diagnosed as being at an increased risk for developing breast cancer and offered SERM treatment for risk reduction. For example, a family history of the disease, positive genetic evaluation, a history of LCIS or AH, or a Gail score higher than 1.66% are all indications for offering women SERMs as a treatment option. The risk–benefit trade-offs vary depending on the avenue through which a woman comes to be at risk for breast cancer. These different reasons for being or becoming at risk may also be important for decision making in this context since they may influence how an individual perceives the risk and, perhaps more importantly, to what degree she *feels* at risk.

OVERVIEW

Screening in both healthy and high-risk populations offers the opportunity to detect cancer early and with an increased opportunity for treatment and curative intent. Currently, a defined role for screening exists in some cancer types, but each screening test has limitations, and improved screening methods are urgently needed. Unfortunately, many cancers still lack effective screening recommendations, or in some cases, the benefits from screening are marginal when weighed against the potential for harm. Here we review the current status of cancer screening: we examine the role of traditional tumor biomarkers, describe recommended imaging for early tumor surveillance, and explore the potential of promising novel cancer markers such as circulating tumor cells (CTC) and circulating tumor DNA. Consistent challenges for all of these screening tests include limited sensitivity and specificity. The risk for overdiagnosis remains a particular concern in screening, whereby lesions of no clinical consequence may be detected and thus create difficult management decisions for the clinician and patient. If treatment is pursued following overdiagnosis, patients may be exposed to morbidity from a treatment that may not provide any true benefit. The cost-effectiveness of screening tests also needs to be an ongoing focus. The improvement of genomic and surveillance technologies, which leads to more precise imaging and the ability to characterize blood-based tumor markers of greater specificity, offers opportunities for major progress in cancer screening.

Perhaps no topic in oncology generates as much energy, angst, and debate as cancer screening and surveillance. Nearly all patients, clinicians, and researchers hope for medical tests that might diagnose cancer earlier or detect recurrence sooner, improve prognosis, and thus allow for increased cure rates. The effect of cancer on society is enormous— over 1.6 million individuals are diagnosed with cancer every year in the United States,[1] and one-half of men and one-third of women have a lifetime cancer risk. Screening in both healthy and high-risk populations offers the opportunity to detect cancer early, at a stage before symptom onset, and ideally before metastasis. Early detection of cancer may lead to decreased morbidity with improved survival, and in some situations treatment may require only surgery if identified early enough. This review covers three aspects of screening and early tumor surveillance including tumor biomarkers, imaging, and circulating tumor cells and DNA.

INTRODUCTION TO CANCER SCREENING AND TUMOR MARKERS FOR EARLY CANCER DETECTION

Tumor markers have been used for decades in oncology. Tumor markers are biomarkers found in blood, urine, cerebrospinal fluid, or other body tissues that are elevated in association with cancer. Tumor markers can, in theory, be used for screening, diagnosis, staging, or disease monitoring. However, to date, many tumor markers have demonstrated poor accuracy and efficacy, particularly among the most prevalent cancers. To understand biomarkers and other tests employed for earlier detection of new or recurrent cancer, one needs to understand a number of epidemiologic concepts.[2] Simply defined, screening is the use of a test among individuals with a population risk for or higher probability of cancer in order to detect that cancer sooner (secondary prevention) or prevent its complications (tertiary prevention). Rarely, a screening test is used to prevent cancer (primary prevention), such as the Papanicolaou (Pap) test to find precancerous cellular changes in the cervix. When screening is used to monitor for cancer recurrence, the term surveillance is commonly used instead.

For screening to be efficacious, a number of conditions are necessary. The cancer should be an important cause of morbidity and mortality. A proven, safe, and acceptable test should exist to detect early-stage disease. The natural history of the cancer should be understood. The cancer should have a recognizable latent or early asymptomatic stage. In the absence of intervention, all or most cases in a preclinical phase should progress to a clinical phase. Pseudocancer, or even overdiagnosis of a benign cancer that would never progress, can be problematic in this situation. Safe and effective treatment must be available. Finally, the screening test should be

economically balanced in relation to the total expenditure on medical care.

Among patients with undiagnosed cancer, a number of screening biases must always be remembered. Volunteers for screening are often healthier. Screening is susceptible to lead-time bias, that is, simply advancing the time of cancer diagnosis without changing the ultimate outcome. Length bias allows screening to detect more protracted, slower cancers, than rapid, severe forms, which leads to better outcomes in screened-detected cases because cancers with a better prognosis are being detected through the very screening modality being studied. Finally, screening can overdiagnose, which means it can detect premalignant lesions or early invasive cancers that would have never required any medical intervention in the lifetime of the patient. The latter has resulted in an epidemic of prostate cancer and ductal carcinoma in situ, many of which may never have been symptomatic or lethal.

When evaluating the utility of screening, one must always consider the test's accuracy (or relative lack of error). Sensitivity indicates the ability of the test to identify correctly those who have cancer among the population with cancer (true-positives/[true-positives + false-negatives]), whereas specificity indicates the ability of the test to identify correctly those who do not have cancer among the population without cancer (true-negatives/[true-negatives + false positives]). No screening test can have 100% sensitivity and 100% specificity,

and in general for many cancer screens, sensitivity hovers in the 70% to 80% range with specificity slightly lower at approximately 60% to 70%.

Perhaps most vexing about screening for cancer is the paradox of cancer epidemiology: cancer in the aggregate over a lifetime is common, while at any one time one specific cancer is rare. That is, at any given time, cancer prevalence by specific type is low, and a single asymptomatic individual has a low risk of cancer. This is crucial to understanding the limitations of screening tests, since the positive predictive value (PPV) of a test (the number of cancers among all the positive tests, i.e., true-positives/[true-positives + false positives]) is directly tied to cancer prevalence in the screened population. The lower the prevalence, the lower the PPV. PPV has been very low among traditional tumor markers and has led to their failure as mass cancer screening tests. Among a number of traditional cancer biomarkers (Table 1), we will look at studies of men undergoing asymptomatic prostate cancer screening with prostate-specific antigen (PSA), and women with breast cancer in remission under surveillance with carcinoembryonic antigen (CEA), CA-15.3, and CA-27.9. Although these biomarkers have failed to demonstrate utility, we look ahead to improvements in the PPV with novel imaging techniques in high-risk populations and circulating DNA and tumor cells to identify at-risk patients with greater precision.

Prostate-Specific Antigen as an Example for New Diagnosis of Cancer

PSA (kallikrein-3 [KLK3]) is a glycoprotein secreted by epithelial cells of the prostate gland, and is elevated in prostate cancer as well as benign prostatic hypertrophy and prostatitis. Although prostate cancer is an important cause of morbidity and mortality, the PSA test, which is both safe and acceptable, has led to the diagnosis of more cancers at an

---

KEY POINTS

- "Screening" is the use of a test to detect cancer sooner (secondary prevention) or prevent its complications (tertiary prevention) among individuals at high risk for cancer. When screening is offered for patients already diagnosed with cancer, the term "surveillance" should be used instead.
- Tumor markers, such as prostate-specific antigen, carcinoembryonic antigen, CA-15.3, and CA-27.29, have not demonstrated accuracy and efficacy in neither diagnosing prostate cancer nor detecting breast cancer relapse sooner than other screening tools.
- Mammography in women age 50 to 70 (even possibly starting at age 40) and colonoscopy in the healthy population over age 50 play an important role in the early detection of cancer and are part of recommended guidelines for cancer screening.
- For patients at high genetic or familial risk for cancer, the addition of breast MRI is recommended for women in their early to mid-20s and colonoscopy is recommended for individuals in adolescence to their mid-20s (based on specific mutation or family history). For patients with a previous or active smoking history, an annual low-dose CT scan can be considered starting in their 50s.
- Circulating tumor cells and circulating tumor DNA offer novel genomic approaches to detect cancer through liquid biopsies and early screening programs, and further studies establishing their clinical utility are now required.

TABLE 1. Tumor Markers Commonly Used for Screening or Surveillance

Biomarker	Cancers
Alpha-fetoprotein	Germ cell tumors and hepatocellular carcinoma
Beta-human chorionic gonadotropin	Choriocarcinoma and testicular cancer
Beta-2 microglobulin	Multiple myeloma, chronic lymphocytic leukemia, and some lymphomas
CA-125	Ovarian
CA-15.3, CA2-7.29	Breast
CA-19.9	Pancreas, gall bladder and bile duct, and gastric
CD20	Non-Hodgkin lymphoma
Calcitonin	Medullary thyroid
Carcinoembryonic antigen	Ovarian, cervix, breast, urinary tract, gastrointestinal, and lung
Lactate dehydrogenase	Germ cell tumors
Prostate-specific antigen	Prostate

early stage. In fact, the poorly defined natural history of the disease has simply led screening to detect pseudocancers that would never have been problematic in most men. The positive predictive value (PPV) of the PSA test has been estimated at 30%.[3] The large majority of men who test positive with PSA at over 4.0 ng/mL do not have clinical prostate cancer. Although zero to one man in 1,000 might not die because of PSA screening, 110 would be diagnosed and, if treated, placed at risk of substantial morbidity. Of this group, 29 would develop erectile dysfunction, 18 urinary incontinence, two a serious cardiovascular event, and one deep venous thrombosis or pulmonary embolism.[4] The U.S. Preventive Services Task Force (USPSTF) thus concludes "that there is moderate certainty that the benefits of PSA-based screening for prostate cancer do not outweigh the harms," and discourages the routine use of this test.[4] The American Society of Clinical Oncology (ASCO) and the American Cancer Society take a more temperate recommendation stating that "men who have at least a 10-year life expectancy should have an opportunity to make an informed decision with their health care provider about whether to be screened."[5,6]

Carcinoembryonic Antigen and Other Markers for Detection of Breast Cancer Recurrence

CEA is a set of highly related glycoproteins involved in cell adhesion and is elevated in adenocarcinomas of ovarian, cervical, colorectal, lung, urinary tract, and breast origin. Elevated levels of the cell surface antigens CA-15.3 and CA-27.29 can identify breast cancer recurrence and metastases before symptoms occur. Risk of relapse and mortality from breast cancer is high, these tests are cheap and acceptable, and the natural history of the cancer is well understood, therefore employing these markers seems logical. Moreover, since cancer surveillance involves patients with a high chance of recurrence, that is, high cancer prevalence, these tests have high positive predictive value (PPV) and should have utility. However, use of these markers has not translated to any survival benefit. In serial guidelines, most recently in 2007, ASCO stated that there is insufficient evidence regarding disease-free survival, overall survival, quality of life, toxicity, or cost-effectiveness to support the routine use of CA-15.3 and CA-27.29 in clinical practice.[7] However, a recent study suggested that the use of these markers to predict breast cancer relapse remains a common practice among oncologists.[8] Among oncologists, factors associated with this overuse of surveillance testing include providers who are older age, low provider self-efficacy, international medical graduates, and greater perceptions of ambiguity about survivorship care.[9] Patients who are more likely to be tested serially for these markers are younger at diagnosis, have advanced stage at diagnosis, and reside on the East or West Coast.[8]

IMAGING AS AN APPROACH TO SCREENING FOR CANCER

Screening for cancer using radiographic imaging has been available for decades, and multiple clinical studies having demonstrated its efficacy in specific instances. Despite the evidence for the role of imaging as part of an early cancer screening and surveillance program, debate continues about the specific timing and imaging modalities that provide the most benefit with least harm to general and high-risk populations. The three cancers with the best consensus for benefit from early cancer detection using imaging include breast cancer, colorectal cancer (CRC), and most recently, lung cancer.

Breast Cancer Imaging

General population. In 2014, over 235,000 new cases of breast cancer were diagnosed in the United States and over 40,000 deaths attributed to the disease.[1] Several guidelines exist for screening for early detection of breast cancer in the average-risk, asymptomatic general population. Breast self-examination starting in the third decade of life can be considered part of screening for breast cancer, although clinical breast examination by a health care provider every 3 years is essential. Some organizations discourage breast self-examination because of the risk for increased biopsies and lack of evidence of benefit. Women should be advised to report any breast changes to their health care provider.

Mammography plays a crucial role for early detection of breast cancer. Pace and Keating published an outstanding review that includes a systematic assessment of mammography benefits and risks.[10,11] Based on over 50 years of published evidence, they concluded that regular mammography screening reduces breast cancer mortality by 19% (nearly 15% for women in their 40s and 32% for women in their 60s).[10] However, the cumulative risk for false-positive results is extremely high at over 60% for a woman who receives 10 years of annual mammograms in her 40s to 50s, and this can lead to increased anxiety, biopsies, and medical expenses.[10,11] The starting age and frequency of mammography must be balanced with an individual's risk for breast cancer and an awareness of a high likelihood of false-positive findings.[10-13]

Mammography guidelines have been proposed by various organizations with clear overlap, but also clear distinctions. Each organization recommends at a minimum that women between the age of 50 and at least 70 should receive mammography at least every 2 years (with consideration of annual screens by some groups starting at age 40).[1,14-18] When discussing this topic with patients, Pace and Keating[10] suggest to highlight: (1) mammography is not a perfect screening test, (2) mammography saves lives (five of 10,000 women age 40 to 49, 10 of 10,000 women age 50 to 59, and 42 of 10,000 women age 60 to 69), (3) mammography can overdiagnose and there is potential for false-positives (at least half of women undergoing annual mammography will be incorrectly told they might have cancer over 10 years, and 20% will require biopsy to prove it is not cancer), and (4) informed decision should rely on family history, individual risk, preferences, and expert recommendations.

High-risk populations (hereditary breast and/or ovarian cancer). Lifetime risk for breast cancer for women with hereditary breast and/or ovarian cancer (HBOC) syndrome (*BRCA1/BRCA2* germ-line mutations) approaches 40% to 65%, and some women are diagnosed as early as in their 20s. Recommended screening includes mammography plus breast MRI.[19,20] Compared with mammography, breast MRI offers better visualization of denser breast tissue often found in younger women.[21-24] In addition, exposure to mammography before the age 30 has been associated with increased risk for breast cancer in women with *BRCA1/BRCA2* mutations.[25] Mammography plus breast MRI in women who are *BRCA1/BRCA2* carriers offers comparable survival benefit with prophylactic bilateral mastectomy at age 25 and prophylactic bilateral salpingo-oophorectomy at age 40.[26] Sensitivity, metastasis-free survival, and overall survival was higher in patients with familial breast cancer treated with MRI compared with mammography-based screening for invasive cancer, but not ductal carcinoma in situ.[27] Many guidelines now suggest performing an annual MRI at age 25 and then alternating with digital mammography beginning at age 30 so that imaging of the breasts occurs every 6 months.[16,28]

Colorectal Cancer Imaging

General population. In 2014, nearly 140,000 new CRC cases were estimated to be diagnosed in the United States and over 50,000 deaths were attributed to the disease. Early CRC detection is known to improve clinical outcomes with multiple iterations of surveillance trials throughout the past 4 decades. Adenomatous polyps represent precursors to CRC, and the National Polyp Study in 1978 demonstrated that their removal dramatically reduces CRC risk.[29-31] Winawer et al later showed in a randomized clinical trial that colonoscopy 3 years after polyp removal was as effective as annual colonoscopy and urged a 3-year interval before colonoscopy after adenomatous polyp removal.[29] In more recent years, multiple population-based studies using case control, cross-sectional, and cohort designs have demonstrated that CRC risk and mortality are substantially reduced with regular colonoscopy screenings with odds ratios and standardized mortality ratio ranging from 0.23 to 0.71.[32-38] Additionally, the protective effects of screening using colonoscopy was noted to be more pronounced in the distal versus proximal colon.[32-34,36-39] U.S. gastroenterologists now offer screening in the general population at 5-year intervals beginning at age 50 and have begun discussing whether 10-year intervals could be effective.[32,40] The U.S. Multi-Society Task Force on CRC recently updated their guidelines to recommend 10-year intervals for surveillance after negative screening in individuals at average CRC risk.[41] The National Comprehensive Cancer Network (NCCN) recommends screening for CRC at age 50 if the patient has no family history of CRC and no personal history of adenoma or sessile serrated polyps (SSP), CRC, or inflammatory bowel disease.[42] NCCN guidelines suggest screening for CRC using colonoscopy, stool-based guaiac/immunochemical testing, or flexible sigmoidoscopy.[42] If no polyps or hyperplastic/non-SSP smaller than 1 cm are detected at colonoscopy, then rescreening with any modality is recommended in 10 years. If sigmoidoscopy is negative, then rescreening with any modality is recommended in 5 years. If adenoma/SSP is detected, then depending on number, size, and completeness of resection, repeat colonoscopy may be required every 2 to 6 months, 3 years, or 5 years. Results from the first two CRC screening examinations predict future CRC risks.[43] Despite the widespread adoption of colonoscopy for CRC screening, Samadder et al recently described in a population-based study that 6% of all patients with CRC still developed interval tumors within 6 to 60 months of colonoscopy (associated with higher rate of adenomas and CRC family history).[44] Three current randomized clinical trials in Europe and the United States are now investigating screening for CRC using colonoscopy and comparing colonoscopy with fecal immunochemical testing (or no screen) with 10- to 15-year CRC mortality. The reader is referred to the following consensus update by the U.S. Multi-Society Task Force on CRC[41] and in-depth review article[32] for excellent summaries of recent trials and discussions of CRC surveillance.

High-risk population (hereditary CRC syndromes). Patients at risk for hereditary CRC benefit the most from a rigorous screening program for early detection and polyp removal. Samadder et al offer an in-depth discussion about the evidence for screening for CRC in patients at high risk.[45] Specific recommendations are based on the CRC lifetime risk and earliest age of presentation unique to each syndrome. The NCCN offers excellent guidance on this topic organized by specific mutations.[42,46] For *MLH1* or *MSH2* mutations (Lynch syndrome/hereditary nonpolyposis colorectal cancer [HNPCC]), colonoscopy is recommended every 1 to 2 years beginning at age 20 to 25, or 2 to 5 years before the earliest colon cancer diagnosis before age 25. For *MSH6* or *PMS2* mutations (Lynch syndrome/HNPCC), colonoscopy is recommended every 1 to 2 years beginning at age 25 to 30, or 2 to 5 years before earliest colon cancer diagnosis before age 30. For an *APC* mutation resulting in familial adenomatous polyposis (FAP), if no symptoms are present, flexible sigmoidoscopy or colonoscopy every 12 months beginning at age 10 to 15 with consideration of prophylactic colectomy once the patient reaches an adult age. For an *APC* mutation resulting in attenuated FAP, colonoscopy is recommended during the late teen years, then every 2 to 3 years (Samadder et al suggest starting later at age 20 to 25). For *MUTYH* mutation (MUTYH-associated polyposis [MAP]), colonoscopy and polypectomy is recommended every 1 to 2 years, starting at younger than age 21 if there is a small adenoma burden. For *STK11* mutations (Peutz-Jeghers syndrome), colonoscopy and upper endoscopy is recommended every 2 to 3 years starting in the late teens (risk for stomach cancer is nearly 30%). For *SMAD4* mutations (juvenile polyposis syndrome), colonoscopy starting at approximately age 15 is recommended and should be continued annually if polyps are detected or every 2 to 3 years if no polyps are identified, with the same strategy for upper endoscopy (risk for stomach cancer is over 20% if multiple polyps are present).

Lung Cancer Imaging

High-risk smoking population. In 2014, more than 224,000 people in the United States were diagnosed with lung cancer and almost 160,000 patients died from lung cancer, making it the deadliest adult cancer. As imaging technology has advanced, so too has lung cancer screening and early detection using annual low-dose CT (LDCT),[47] which has led to both controversy and excitement in the field of early cancer detection. The National Lung Screening Trial (NLST) is the largest randomized clinical trial to be published. It demonstrated a 20% reduction in death in current or former smokers.[48,49] Six other lung cancer screening trials have been published or are ongoing.[50-56] Several recent reviews and editorials, as well as the current screening guidelines, summarize the benefits and harms associated with LDCT.[47,57-60] Similar to breast cancer and CRC, several professional societies have offered overlapping, but still distinct, recommendations and guidelines on screening for lung cancer (USPSTF,[61] American College of Chest Physicians/American Society of Clinical Oncology,[62] American Association of Thoracic Surgeons,[63] NCCN,[64] American Cancer Society,[65] and American Lung Association).[66] The majority of these organization recommend annual LDCT for high-risk individuals, which includes patients who are age 55 to 79 with a more than 30 pack-year smoking history, former smokers who have quit within the past 15 years, or patients age 50 to 79 with more than a 20 pack-year smoking history who have additional risk factors. Many cost-effectiveness analyses are being modeled for the national adoption of LDCT as the preferred method of screening for lung cancer in current or former smokers. In one study, the heath care expenditures were estimated to reach $1.3 to $2 billion with 50% to 75% screening uptake and $240,000 in additional costs to avoid one cancer death.[67] The authors argue that LDCT will prevent over 8,000 annual deaths from lung cancer, but they, and others, recognize that careful cost-effectiveness analyses will be key to understanding the true value of screening for lung cancer.[67,68] Nevertheless, the Centers for Medicare & Medicaid Services (CMS) recently announced that Medicare will cover LDCT in current or previous smokers, a move strongly supported by the American Lung Association. Similar to breast cancer, informed decision making—with understanding of the high likelihood for false-positives (one in five LDCT screening examinations may detect false-positive results, with each LDCT test 20 times more likely to yield a false-positive result than an actual lung cancer)—is key to initiating a lung cancer screening program.[58,69] Although LDCT now plays a more accepted and arguably standard role in the early detection of lung cancer, the best prevention is still to encourage smoking cessation.

CIRCULATING DNA AND CIRCULATING TUMOR CELLS IN CANCER SCREENING

Recent major advances in our ability to detect and characterize CTCs and cancer-specific (mutated) cell-free, circulating tumor DNA (ctDNA) have introduced the possibility of utilizing either or both as tests to screen for cancer. Particularly attractive is the possibility of simultaneous screening for multiple primary cancers, including tumor types for which no early detection method is currently available. Such a test should also prove complementary to any current standard organ-specific screening tests. Importantly, each of the current tests has multiple limitations, and poor compliance is a consistent challenge as a result of the unpleasant and/or invasive nature of many investigations. However, many obstacles must be overcome before a blood-based screening test, incorporating either CTCs or ctDNA, is proven to make a valuable contribution to early cancer diagnosis.

Liquid Biopsy in the Advanced Disease and Minimal Residual Disease Setting

Both CTCs and ctDNA are yet to be used in routine clinical practice. A major advantage of using CTCs in the management of cancer is that tumor cells can be isolated, which allows for morphologic identification and molecular characterization,[70] whereas ctDNA analysis is currently limited to mutation detection.[71] In advanced disease, both have demonstrated prognostic significance in multiple tumor types,[71-74] and initial changes in marker levels on therapy also provides an early indicator of treatment response.[73-76] Serial CTC and ctDNA analysis during therapy can also inform treatment resistance, including ctDNA-based detection of emerging mutations under the selective pressure of targeted therapies.[71] In the context of minimal residual disease, recent larger studies using CellSearch have found no or limited prognostic significance of CTCs across multiple tumor types.[74,77-79] In contrast, emerging data from studies of ctDNA for CRC[80] and breast cancer[81] indicate that ctDNA detected after definitive therapy for early-stage disease has powerful prognostic significance.

Potential Role for CTCs and ctDNA in Cancer Screening

Specificity. The specificity of any cancer screening test is of critical importance, as false-positive tests create patient anxiety and lead to further investigation with associated financial cost and morbidity. Studies of the U.S. Food and Drug Administration (FDA)–approved CTC testing platform, CellSearch by Veridex, indicate limited specificity with CTCs detectable in 4% to 15% of controls that either have no evidence of disease or benign conditions.[78] Many groups have recently reported improvements in the methods for detection, isolation, and characterization of CTCs that promise greater yield and improved specificity.

The early promise is that ctDNA should be a highly specific test,[71] because mutant DNA appears to be only released into the circulation, via apoptosis or necrosis, once there is an invasive tumor. In addition, and most relevant to the context of screening, more than one mutation should be detected for most tumor types of interest, with two false-positives an exceedingly unlikely finding. For the patient in whom only a single mutation is detected, the ability to readily repeat testing to confirm a positive result is advantageous. A repeat test

could also include an extended panel informed by the initial positive result. For example, where the initial panel reveals a mutated *RAS*, further testing might reveal an *APC* mutation in the circulation of the individual being screened. Detecting this *APC* mutation would provide reassurance that the initial screening result was a true positive, but also indicates the primary source is likely to be a CRC.

Sensitivity. When CTCs are assayed utilizing CellSearch, they can only be detected in about half of advanced cancers, and detection rates in patients with early-stage malignancy are no higher than in people without cancer. ctDNA provides a more sensitive marker since it is present in over 80% of advanced cancers, including in many patients in whom CTCs are not detectable.[71] The approximate 50-fold yield for ctDNA also provides a far greater dynamic range to assess changes over time. Most relevant to screening, ctDNA appears to be detectable in 73%, 57%, 48%, and 50% of early-stage colorectal, gastroesophageal, pancreatic, and breast cancers, respectively, including in 47% of patients with stage I tumors and increasing to 55% and 69% for stage II and III disease.[71] Other groups have also reported high detection rates in small series of patients with early-stage non–small cell lung cancer[81] and breast cancer.[82]

Optimizing and Tailoring the ctDNA Screening Panel

Unlike studies of ctDNA in patients with a known and characterized cancer, screening for an occult cancer will require an extended panel that covers the hotspots of genes frequently mutated in common cancers. The concept and feasibility of such a panel were demonstrated in a recent series in which liquid-based Pap smears were examined for somatic mutations known to accumulate in the cervix after shedding from endometrial or ovarian cancers.[83] A prototype test based on 12 frequently mutated genes in these tumors identified between one and five mutations in all 14 samples from patients with known cancer but unknown molecular profile (12 endometrial cancers, two ovarian cancers). No mutations were identified in samples from 14 women without cancer.

A panel of ctDNA mutations could be defined that would screen for the cancers of most interest in the general community population. Alternatively, a customized panel could be defined for particularly high-risk groups, such as hereditary syndromes. For example, a panel for patients with Lynch syndrome would include screening for gene mutations common in CRC and endometrial cancer. For any screening population, overlapping mutation profiles would mean that patients with any specific mutation would be screened for multiple cancers, including common *RAS* mutations in the HNPCC panel, which complements screening for CRC using colonoscopy and screening for pancreatic cancer.

Determining Further Investigation

Although ctDNA-based testing is attractive given the broad range of cancers that could be screened for using a single test, this advantage comes with a challenge— determining the source of a positive test. Medical oncologists are familiar with tissue-of-origin molecular profiling, which has an important role in the diagnosis of cancers of unknown primary. For a patient with a positive ctDNA result, a search for a primary tumor is also required, albeit with very different goals.

When ctDNA is detected, further investigation could be guided by the type of mutation(s) found, cancer risk factors, and the relative incidence of each cancer type. Smoking history would indicate an increased yield from lung imaging, and a family history or genetic syndrome would also suggest likely primary sites. Although $BRAF^{V600E}$ mutations are uncommon in CRC (present in approximately 8% of tumors) and ubiquitous in hairy cell leukemia,[83] this mutation is more likely associated with CRC as a result of the relative incidence of the two malignancies.

Alternate search strategies can be envisaged that should prove complementary to an organ-specific approach. CTC analysis should prove increasingly useful with the anticipated improvements in technology, potentially providing further confirmation of a true-positive ctDNA result. CTC detection would also provide opportunity for further characterization of the detected cells, which could guide the hunt for the primary site. Alternatively, whole body imaging, structural and/or functional, may prove to be a viable alternative to an organ-by-organ approach, given the high pretest probability. However, with each new investigation there is discomfort, cost, and the possibility of a false-positive result, therefore the value of each test needs to be carefully defined in prospective studies.

Combining ctDNA with Current Screening Modalities

The most exciting application of ctDNA is creation of a viable screen for many cancers for which no method of early detection is currently available. For tumors such as CRC or breast cancer, ctDNA-based testing should be complementary to the current screening modalities, as each test has a miss rate and is challenged by limited uptake. Importantly, for the 50% or more of patients who fail to comply with colonoscopic screening or the 30% or so who do not undergo regular mammography, it could provide an acceptable initial screening option. ctDNA testing could also prove helpful in characterizing indeterminate findings from routine screening tests, such as small lung lesions found using a screening CT scan in a patient who is a smoker.

OTHER ctDNA CONSIDERATIONS AND CONCLUSIONS

Although stage at diagnosis is the dominant prognostic factor for malignancies, the early diagnosis of a particular cancer type does not necessarily lead to higher rates of cure, and potential risks include overdiagnosis and/or overtreatment of cancers. It is presumed that for each primary cancer there will be a typical window from the point at which ctDNA is initially detectable to when the lesion is incurable, a window that may be only a few months or may be several years, and potentially may vary widely within a particular cancer type. There is much still to be learned.

A multitude of blood-based biomarkers have previously been proposed as cancer screening tests, but none have yet proven to be clinically useful, demonstrating the many challenges of translating initially promising data to a clinical reality. ctDNA-based cancer screening tests would appear feasible, given the available data regarding sensitivity and specificity. From here, carefully conducted clinical studies are required to determine the risks and benefits of early diagnosis across a broad range of tumor types, the optimal frequency of testing, the most desired ctDNA panel, the most efficient algo-

rithms for further investigation of any positive test, and the patient populations that will benefit most from screening.

Can Diet and Lifestyle Prevent Breast Cancer: What Is the Evidence?

Michelle Harvie, PhD, Anthony Howell, MSc, and D. Gareth Evans, MD, FCRP

OVERVIEW

Breast cancer is the most common cancer among women in both developed and less-developed countries. Rates of breast cancer are increasing worldwide, with a particular increase in postmenopausal and estrogen receptor-positive cases. The World Cancer Research Fund (WCRF) and American Cancer Society (ACS) cancer prevention guidelines recommend maintaining a healthy weight, undertaking at least 150 minutes of moderate intensity exercise per week, limiting alcohol consumption, and eating a plant-based diet. Observational data link adherence to physical activity and alcohol guidelines throughout life to a reduced risk of developing pre- and postmenopausal breast cancer. Weight control throughout life appears to prevent cases after menopause. Adherence to a healthy dietary pattern does not have specific effects on breast cancer risk but remains important as it reduces the risk for other common diseases, such as cardiovascular disease (CVD), diabetes, and dementia. Emerging data suggest that smoking during adolescence or early adulthood increases later risk of breast cancer. Lifestyle factors appear to modify risk among high-risk women with a family history and those with typical risk of the general population, although their effects among carriers of *BRCA* mutations are not well defined. Recent expert reports estimate that successful lifestyle changes could prevent 25% to 30% of cases of breast cancer. These reductions will only be achieved if we can implement targeted prevention programs for high-risk women and women in population-based breast screening programs during childhood, adolescence, and early adulthood when the rapidly developing breast is particularly susceptible to carcinogenesis.

Breast cancer is the most common cancer among women in both developed and less-developed countries, with an estimated 1.67 million new cases diagnosed worldwide in 2012 (25% of all cancers).[1] Breast cancer is a major cause of mortality in both developed (198,000 deaths, 15.4% of total; ranking second after lung cancer) and less-developed (324,000 deaths, 14.3% of total; ranking first) countries.

Incidence rates vary nearly fourfold among different regions of the world, with age-standardized rates of 29 to 36 per 100,000 in Asia and Africa compared with 91 to 96 per 100,000 in North America and Western Europe. These rates reflect differences in reproductive factors (late age of first pregnancy, fewer pregnancies, short or no breast-feeding, early menarche, late menopause) and lifestyle risk factors (obesity, inactivity, alcohol, Western-style diet, and use of hormone replacement therapy [HRT]).

More developed countries typically have fivefold higher rates of postmenopausal cancer than less developed countries (approximately 308 vs. 65 per 100,000), and twofold higher rates of premenopausal cases (29 vs. 13 per 100,000).[2] Global trends for the accumulation of risk factors are particularly associated with postmenopausal breast cancer. In the West, rates of estrogen receptor (ER)-positive cancers are increasing whereas those of ER-negative cancers are decreasing in all age, racial, and ethnic groups, and it is likely that global rates will follow these trends.[3,4]

Prevention of breast cancer must target both ER-positive and ER-negative subgroups and will be best achieved through preventive therapies for high-risk groups and lifestyle changes across all risk strata. Trends for an association between ER-positive breast cancer and a Western lifestyle suggest that this subtype may be particularly amenable to lifestyle prevention. Selective estrogen receptor modulators (SERMs) and aromatase inhibitors can prevent 50% to 80% of ER-positive breast cancers[5]; however, availability and uptake of these prevention therapies is currently low (1 to 40%, reviewed in Donnelley et al[6]). Despite apparent reductions in the rate of ER-negative cancer, its poor prognosis and high burden of breast cancer mortality make this subtype a priority for prevention. There are several promising, but as yet unproven, preventative agents for ER-negative cancer, including inhibitors of ErbB receptor, COX-2, or poly (ADP-ribose) polymerase, metformin, retinoids, and statins.[7]

This article summarizes current cancer prevention guidelines and current evidence for the links between diet and life-

style factors and breast cancer risk. We will present the sum of evidence of any specific links with pre- and postmenopausal breast cancer, ER-positive and ER-negative disease, and among women with familial risk, including those with the high-risk *BRCA1* and *BRCA2* breast cancer susceptibility genes.

CANCER PREVENTION GUIDELINES

The World Cancer Research Fund/American Institute for Cancer Research (2007) and the ACS (2012) have produced guidelines for prevention of a range of cancers that focus on weight control, regular exercise, reduced alcohol consumption, and a plant-based diet (Table 1). These guidelines are mainly informed by large cohort studies (i.e., prospective studies of 20,000 to 40,000 unaffected individuals), but also include some limited randomized data. Cohort studies include less recall and selection bias than case control studies; however, they can only highlight associations between lifestyle behaviors and cancer risk and cannot provide definitive proof of their role in cancer etiology. Healthy lifestyle behaviors tend to cluster, thus someone who eats a healthy diet is often a healthy weight, exercises regularly, has a moderate alcohol intake, and does not smoke. Researchers attempt to adjust for other confounding risk factors in analyses but residual confounding cannot be ruled out.

Defining the true anticancer effects of lifestyle choices without confounding factors can only be achieved through randomized controlled trials. Such trials would need to be large (approximately 26,000 to 36,000 patients) and are therefore potentially prohibitively expensive.[6] Testing

---

KEY POINTS

- Breast cancer is the most common cancer in women in both developed and less-developed countries. Rates of breast cancer are increasing worldwide, with particular increases in postmenopausal breast cancer and estrogen receptor-positive disease.
- Overweight, obesity, and weight gain are linked to postmenopausal breast cancer, whereas alcohol consumption and lack of exercise increase the risk for both pre- and postmenopausal breast cancer.
- Rapid height growth or exposure to smoking and alcohol in the period between menarche and first pregnancy may increase risk because the rapidly developing breast is particularly susceptible to carcinogenesis.
- Adherence to a healthy dietary pattern does not have specific effects on breast cancer risk but remains important for women because it reduces the risk of other common diseases, such as cardiovascular disease, diabetes, and dementia.
- Excess weight, alcohol, and lack of exercise increase risk among women with a family history, but their specific associations with carriers of *BRCA1* and *BRCA2* mutations requires further study.

---

whether lifestyle interventions can prevent breast cancer is a bigger challenge than investigating their effects on CVD because cancer does not have the well-defined surrogate endpoints available for CVD such as cholesterol and blood pressure. The absence of good markers for breast cancer risk makes it unlikely that randomized data will be available to support or refute cancer prevention recommendations in the near future.

So what is the evidence that general cancer prevention guidelines can prevent breast cancer? Several large cohort studies have reported lower rates of breast cancer among women who adhere to these guidelines. Five studies of postmenopausal women reported 16% to 60% risk reductions, mainly linked to reduced body fatness and alcohol intake rather than specific differences in dietary patterns.[8-11] In contrast, studies of a cohort of both pre- and postmenopausal women showed 31% lower rates of breast cancer in women who adhered to specific dietary recommendations of increased wholegrain products and reduced meat and alcohol, rather than other lifestyle factors.[12] Adherence to cancer prevention guidelines have been reported to reduce risk among women with and without a family history of breast cancer[9,13] and to reduce the risk for both ER-positive and ER-negative breast cancers.[8,11]

WEIGHT, WEIGHT GAIN, AND WEIGHT LOSS

Cohort studies consistently link overweight, obesity, and adult weight gain to risk for postmenopausal breast cancer. Women who gain 20 kg or more during adulthood double their breast cancer risk.[14] These gains are also associated with large increases in the risk for diabetes (12-fold),[15] CVD (threefold),[16] and colorectal cancer (1.5-fold).[17] Modest weight loss (5 to 10%) reduces risk. In the Iowa Women's Health Study of 34,000 women, a weight loss of at least 5% either before or after menopause reduced the risk for breast cancer by 25% to 40% compared to women who continued to gain weight, whereas Eliassen et al. reported a 50% reduction in risk in women with a 10% weight loss compared with weight-stable women in the Nurse's Health Study of 37,000 women.[18] Excess weight is mainly linked to the risk of developing ER-positive and ER-negative breast cancer after menopause and appears to be a factor among women with and without a family history.[14,19,20]

ALCOHOL

Consumption of an additional 10 g of alcohol (1 unit; e.g., 284 mL of 4% strength beer or cider, 25 mL of 40% strength spirits, or 80 mL of 12% strength wine) on a daily basis is estimated to increase risk by 2% to 12%,[20] with no further increase beyond 60 g of alcohol per day.[21] The increased risk is thought to be related to acetaldehyde-induced DNA strand deletions, chromosomal aberrations, and DNA adducts, downregulation of the tumor suppressor gene *BRCA1*, and increased estrogen and prolactin receptor activity. Data sug-

√√ = Association in three or more observational studies.
√ = Association in one or two observational studies.

gest that alcohol intake before the first term of pregnancy is particularly associated with cumulative risk.[20] Unresolved questions include the specific effects of binge drinking, whether dietary folate intake can reduce the excess risk of higher alcohol intake, and interactions with genes involved in alcohol metabolism/detoxification and folate metabolism.[22] Light drinking (10 g/day) is also linked to breast cancer risk; however, zero alcohol intake is not recommended because light drinking is consistently linked to reductions in overall (17%)[23] and cardiovascular (20%)[24] mortality.

Alcohol increases risk of breast cancer among both pre- and postmenopausal women and for both ER-positive and ER-negative disease. Studies have suggested that alcohol affects risk equally or to a greater extent among women with a family history (defined as an affected first-degree relative) compared to women with no family history.[20]

PHYSICAL ACTIVITY

The American College of Sports Medicine recommends a total of 150 minutes per week of moderate intensity cardiorespiratory exercise to reduce all-cause mortality and improve quality of life.[25] The optimal level of physical activity for breast cancer risk reduction appears to be greater than these recommendations, with an estimated 3% reduction in risk for every additional 180 minutes of moderate intensity exercise per week.[26] Physical activity is associated with reduced risk among pre- and postmenopausal women and among women with a family history, albeit with an apparent smaller effect than for the general population, and reduced risk of both ER-positive and ER-negative cancers.[27] Potential anticancer effects of physical activity include reductions in endogenous sex hormone concentrations, insulin resistance, and chronic low-grade inflammation. In addition, other pathways are emerging as potentially important, including those involving oxidative stress and telomere length, global DNA hypomethylation, immune function,[28] and

increased gene expression of *BRCA* and other DNA repair genes. Although being "fit but fat" appears to protect against heart disease,[29] this is not the case for breast cancer, in which cancer protective effects of exercise are mainly seen in women who are a healthy weight and not among the overweight and obese.[26]

DIETARY FACTORS AND BREAST CANCER RISK

If a women is a healthy weight, exercises regularly, and moderates her alcohol intake does the actual composition of her diet matter?

Fruit, Vegetables, and Fiber

The 5-a-day campaign was launched in the United States in 1991 by the National Cancer Institute and the Produce for Better Health Foundation with the aim of preventing cancer. Since these initial campaigns, emerging evidence has consistently linked fruit and vegetable intake, particularly vegetable intake, to reduced overall and cardiovascular mortality but not specifically to cancer mortality.[30] The WCRF Continuous Update Project recently stated there is no convincing evidence that fruits and vegetables play a role in the etiology of colorectal, breast, and pancreatic cancers.[31]

Recent systematic reviews have linked higher fiber intake with a lower risk of breast cancer, with a 5% risk reduction for every additional 10 g of fiber per day. Fiber may reduce risk by reducing the reabsorption of estrogen and androgens in the bowel and hence their circulating levels. Soluble fiber appears to be the most protective, possibly through its beneficial effects on insulin sensitivity.[32]

Meat, Fish, and Dairy Foods

Vegetarian or vegan diets do not specifically reduce risk. Women with a higher consumption of meat are at slightly increased risk; each additional 100 g of red meat per day increases risk by 4% (relative risk [RR] 1.04 [1.00 to 1.07]) and

each additional 30 g of processed meat per day increases the risk by 3% (RR 1.03 [1.00 to 1.06]).[33,34] It is not clear why meat has this effect. Risk of breast cancer does not appear to be related to its saturated fat or carcinogenic heterocyclic amine content. Heterocyclic amines are also found in poultry and fish, which respectively have neutral and protective effects on breast cancer risk. It is possible that meat may be an innocent bystander in these studies, and a marker of an overall unhealthy lifestyle.[33,34] Marine omega-3 fats, eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA) are associated with reduced breast cancer risk; each additional 0.7 g of marine omega-3 polyunsaturated fat per week reduces risk by 5%. Two portions of oily fish per week provide 3.5 g of n-3 fatty acids and a potential 25% risk reduction; however, the vegetarian n-3 fat alpha-linolenic acid does not reduce risk.[35]

Dairy foods are perceived to be a cause of breast cancer by many populist websites and patient advocacy groups as they contain the potentially cancer promoting hormones estrogen and insulin like growth factor.[36] These concerns are not supported by evidence. A recent meta-analyses including 1,063,471 participants and 24,187 cases found a 16% lower rate of breast cancer among high (> 3 servings/day) versus low (< 1 serving/day) dairy consumers. Risk reduction may be related to the content of calcium, conjugated linoleic acids, or vitamin D, which is found in fortified milk products.[37]

SOY FOODS AND ISOFLAVONES

Eight out of 10 breast cancers are estrogen dependent. Soy foods contain isoflavones, which have weak estrogenic and antiestrogenic effects in addition to nonhormonal effects that inhibit cancer cell growth in the laboratory. Not surprisingly, many studies have examined the links between soy and risk of breast cancer. A recent meta-analysis summarized 14 studies involving 369,934 participants and 5,828 cases of breast cancer. This study showed that women who consume moderate amounts of soy throughout their life have a lower breast cancer risk; intake of 5 g of soy protein/day (10 mg of isoflavone, equivalent to 170 mL of soy milk or 120 g of soy yoghurt) was associated with a 4% reduction in risk.[38] This effect was mainly seen within Asian, but not Western, populations, in postmenopausal versus premenopausal breast cancer and for both ER-positive and ER-negative cancers. Risk reduction may largely be related to the biologic effect of soy on the developing breast, which leads to a more differentiated breast phenotype in adulthood.[39] Hence, soy intake as a child or adolescent may be more important than its introduction to the adult diet. These data are based on intakes of soy food rather than over the counter isoflavone supplements. The effects of these supplements on breast cancer, or indeed on cholesterol lowering, have not been demonstrated.[40]

Healthy Dietary Patterns

Adherence to a Mediterranean diet (MD), which typically includes legumes, cereals, fruits/nuts, vegetables, extra-virgin olive oil, red wine in moderate quantities, and low amounts of red meat, poultry, and dairy products, is consistently linked to reductions in the risk of CVD, diabetes,[41] and dementia.[42] These reductions appear to be diet specific and independent of weight and other lifestyle risk factors. Adherence to a MD has been associated with significant reductions in the risk of overall (10%), colorectal (14%), and prostate (4%) cancer, but not specifically with breast cancer, even when alcohol intake is removed from the MD score (RR 1.01, 95% CI, 0.88 to 1.16, p = 0.89).[43] Energy balance and adiposity seem to be more important for preventing breasting cancer than the specific composition and quality of the diet. After a breast cancer diagnosis, adherence to a healthy diet is not linked to breast cancer mortality but is linked to reduced mortality from other causes.[44,45] Therefore, adherence to a healthy dietary pattern remains important for women at risk of breast cancer and women who have already been diagnosed, as both groups are at risk of developing other health conditions that are affected by diet.

Vitamin Supplements

One in three adults in the United States take vitamin supplements in the hope of protecting themselves against ill health and cancer. Large-scale randomized trials of supplement use have mainly yielded negative findings, with some notable adverse and beneficial effects. For example, beta-carotene increases the risk of lung and stomach cancer, vitamin E increases the risk of prostate cancer and colorectal adenoma, and selenium reduces the rates of gastric and lung cancer in populations with low selenium levels but increases rates in those with higher levels. Both beta-carotene and vitamin E supplementation increase overall mortality.[46] Supplementation with vitamin D,[47] calcium,[48] folic acid,[49] or multivitamins[50] neither decrease or increase the risk of breast cancer. The best advice is to avoid nutritional supplements unless indicated for a specific reason.

SMOKING

The 2004 Surgeon General Report concluded, "It would be false to tell women they will prevent breast cancer if they quit smoking." Accumulating evidence from the better-designed epidemiologic studies suggests an increased breast cancer risk among women with the highest exposure, i.e., the longest duration and highest pack years of smoking. The updated 2014 Surgeon General Report concluded that current evidence was suggestive, but not sufficient, to infer a causal relationship between active or passive smoking and breast cancer.[51] Smoking appears to have adverse effects if initiated during adolescence or early adulthood before the first pregnancy because of heightened susceptibility to chemical carcinogens before full differentiation of the breast. Smoking appears to have more consistent links with premenopausal breast cancer but has also been linked to postmenopausal breast cancer.[52,53] Multivariate adjusted relative risks between the highest exposure category and never active smok-

TABLE 2. Breast Cancer Prevention across the Life Course[66,67]

↑ Increased risk.

ers in positive cohort studies are between 1.1 and 1.4. The effect of smoking appears to be mainly linked to ER-positive cancers and among individuals with polymorphisms in genes involved in the metabolism of tobacco products, such as *NAT2*, although the current evidence is equivocal.[52]

LIFESTYLE MODIFICATION OF RISK AMONG *BRCA1* AND *BRCA2* CARRIERS

Rates of breast cancer have increased among high-risk populations with mutations in the *BRCA1* and *BRCA2* breast cancer susceptibility genes, mirroring the increase in rates among the general population over the last century. A published data set from Iceland reported a fourfold increase in the cumulative incidence of breast cancer (before age 70 years) between 1920 and 2000 among *BRCA2* carriers (18.6% to 71.9%) and women in the general population (1.8% to 7.5%).[54]

A marked increased penetrance of *BRCA* mutations over the years has been shown in a number of cohorts and is thought to reflect increased reproductive and lifestyle risk factors, although the exact causes remain unknown. High-quality large-scale genome-wide association studies have identified genetic variation in loci that affect *BRCA* penetrance. In contradistinction, modifiable risk factors have mainly been studied in small case-control studies with retrospective collection of lifestyle risk information, which are often confounded by ascertainment bias in clinic-based settings and survival bias, and the findings have not been validated in independent replication sets. These studies have produced equivocal evidence that risk among *BRCA1* and *BRCA2* carriers is increased with weight and smoking and

reduced with physical activity (especially if undertaken during adolescence and early adulthood), with consistent null effects of alcohol.[55,56] The limitations of these studies are well recognized and large-scale prospective studies are required. Recent prospective data from a New York cohort showed that adherence to cancer prevention guidelines for a healthy weight, reduced alcohol, and high physical activity reduced breast cancer mortality by 61% (hazard ratio 0.39; 95% CI, 0.16 to 0.97) among *BRCA1* and *BRCA2* carriers.[57]

THE ROLE OF LIFESTYLE AND RISK REDUCTION IN THE GENOMIC ERA

Genome-wide association studies have identified more than 90 single nucleotide polymorphisms that are linked to breast cancer risk.[58] Gene–environment interactions are an area of increasing research interest with the potential to identify women for whom particular risk factors and/or lifestyle changes may be beneficial. There are few data on gene–environment interactions. An interaction between the *CASP8-rs1045485* polymorphism, which modifies breast cancer risk, and alcohol consumption has been replicated in a few datasets.[59]

LIFESTYLE PREVENTION OF BREAST CANCER ACROSS THE LIFE COURSE

Although 75% to 80% of breast cancer cases in Western cohorts occur after menopause, successful prevention of these cases, and the 20% to 25% that are premenopausal, must start earlier in life. Breast cancer risk can accumulate during childhood, adolescence, and particularly in the period between the menarche and first pregnancy before the breast cells become differentiated and less susceptible to carcinogenesis (Table 2). Rates of growth in childhood and excess alcohol and smoking in early adulthood increase risk, whereas soy intake during these years may reduce risk. Weight gain during pre- and postmenopausal years increases the risk of postmenopausal (but not premenopausal) breast cancer.[60,61] Breast cancer prevention interventions should therefore focus on preventing weight gain during the premenopausal years. Greater adiposity in childhood or early adulthood does not increase breast cancer risk, and can sometimes put women at lower risk. The reason for this weight paradox in breast cancer is not clear but most likely reflects the fact that heavier young women do not experience as much weight gain during adulthood, and it is adult weight gain that appears to put women at particularly high risk. Also, young overweight women have lower serum progesterone concentrations.[62]

HOW CAN WE ENGAGE WOMEN IN BREAST CANCER PREVENTION?

Recent expert reports estimate that successful lifestyle changes could prevent 25% to 30% of cases of breast cancer.[63] However, there is a general public skepticism about whether an individual's actions can influence whether they develop cancer. The most commonly cited perceived causes of breast cancer are mainly out of the individual's control, for example genetics, environmental pollutants, pesticides, and God's will (Table 3). Although many women who develop breast cancer have a genetic disposition, this is not the sole reason why they develop breast cancer; in most cases a complex interaction between genetic, reproductive, and lifestyle factors is involved.[54]

There is a need for consistent evidence-based cancer prevention messages that are supported by good mechanistic data to allow the public to understand and visualize the risk information they receive.[64] Current evidence-based messages are summarized in Table 4. These messages need to be backed up with effective programs to support adherence at key time points across the life course. There is increasing interest in whether women attending breast screening can be engaged in a healthy lifestyle to prevent breast cancer.[65] The overlap between lifestyle recommendations for preventing breast cancer and CVD (Table 1), as well as diabetes and dementia, may be exploited to develop prevention programs for multiple diseases in women.

Disclosures of Potential Conflicts of Interest

The author(s) indicated no potential conflicts of interest.

Reform of the Buy-and-Bill System for Outpatient Chemotherapy Care Is Inevitable: Perspectives from an Economist, a Realpolitik, and an Oncologist

Blase Polite, MD, MPP, Rena M. Conti, PhD, and Jeffery C. Ward, MD

OVERVIEW

Treating patients with cancer with infused or injected oncolytics is a core component of outpatient oncology practice. Currently, practices purchase drugs and then bill insurers, colloquially called "buy and bill." Reimbursement for these drugs is the largest source of gross revenue for oncology practices, and as the prices of cancer drugs have grown over time, these purchases have had significant impact on the financial health of practices and pose a risk that jeopardizes the ability of many practices to operate and provide patient care. Medicare Part B spending on drugs is under political scrutiny because of federal spending pressures, and the margin between buy and bill, lowered to 6% by the Medicare Modernization Act and further decreased to 4.3% by sequestration, is a convenient and popular target of budgetary discussions and proposals, scored to save billions of dollars over 10-year budget windows for each percentage-point reduction. Alternatives to the buy-and-bill system have been proposed to include invoice pricing, least costly alternative reimbursement, bundling of drugs into episode-of-care payments, shifting Part B drugs to the Medicare Part D benefit, and revision of the failed Competitive Acquisition Program. This article brings the perspectives of policy makers, health care economists, and providers together to discuss this major challenge in oncology payment reform.

Many alternatives to oncology's current buy-and-bill system for infused or injected oncolytics have been proposed. Although no single solution has been selected, reform of the system is inevitable. Here we present observations on the current system and its possible reform from the perspectives of an economist looking at the market forces inherent in average sales price (ASP)-based pricing, a realpolitik focusing on what is possible in a U.S. Congress fractured by ideology and partisanship, and an oncologist.

THE ECONOMIST

Treating patients with cancer with infused or injected anticancer prescription drugs (oncolytics) is a central component of an outpatient oncology practice. Practices purchase these drugs and then bill insurers for their use to treat specific patients, a system known as "buy and bill." Spending on these drugs by third-party payers is also increasingly important—Medicare spent approximately 5% ($125 billion) of the 2013 federal budget on the use of these drugs.[1]

From an economic perspective, reform of the buy-and-bill system is inevitable for two reasons. First, these purchases have had a substantial effect on practices' financial health and have created significant practice risk, jeopardizing many practices' abilities to operate and provide patient care in the community.[2] Second, there is widespread perception in policy circles that the system creates a perverse incentive for outpatient oncology practices to use more expensive oncolytics rather than pursuing more cost-effective treatment strategies. These incentives may also place upward pressure on the launch prices of new drugs. This section is a review of the economic rationales and extant supportive evidence underlying these drivers of reform.

An Overview of the Buy-and-Bill System

Fee-for-service (FFS) Medicare is the most prominent U.S. payer for oncolytics, followed by commercial insurers, and then state Medicaid programs. FFS Medicare pays for physician-administered oncolytics through the medical Part B benefit. By law, Medicare does not directly negotiate with drug manufacturers on the prices for prescription drugs covered under the Part B benefit, nor the oral oncolytics largely covered under Medicare's pharmacy Part D benefit. Section 1861 of the Social Security Act, which requires that the Medicare program cover reasonable and necessary medical services, precludes consideration of cost or cost-effectiveness in coverage decisions.[3] The Centers for Medicare & Medicaid Services (CMS) and commercial insurers rely on U.S. Food

and Drug Administration approval and authoritative compendia to determine what uses of physician-administered drugs to reimburse, including "off-label uses determined by expert assessments of available supportive evidence."[4,5]

Currently, Medicare pays for Part B– covered drugs using an ASP of cancer drugs plus the 6% facilities/operations services fee reimbursement system, implemented in 2006 after the passage of the Medical Modernization Act (MMA) in 2003. ASPs for each Part B– covered drug are calculated and reported by pharmaceutical companies to CMS.[6] The MMA sets CMS' reimbursement for these drugs at ASP plus 6%, which preserved the buy-and-bill system while reducing the potentially substantial spread between Part B– covered drugs' acquisition costs and reimbursement rates. Medicare beneficiaries treated with these drugs are subject to a 20% coinsurance requirement, which is covered under secondary insurance plans for the majority of FFS Medicare beneficiaries.

The Challenges of Using ASP to Reimburse Outpatient Oncology Practices

Although ASP-based MMA reimbursement has led to some of the greatest reductions in Medicare Part B spending in its

KEY POINTS

- Reform of buy-and-bill chemotherapy is inevitable due to the financial risks it poses on practices and the widespread perception that it incentivizes increased utilization of the most expensive oncolytics.
- Challenges imposed by ASP-based reimbursement include underwater drugs, generic drug shortages, direction of underinsured and uninsured patients from private practice to more expensive hospital outpatient departments, and consolidation of oncologists into mega-practices and hospital employment.
- Although the U.S. Congress has not yet heeded regular calls for reductions in ASP plus 6% by presidential budgets and MedPAC, neither has it succeeded in removing prompt pay discounts from its calculation after 10 years of lobbying, and calls to fix the disproportionate impact of sequestration on oncology have been given only lip service by legislators.
- Though the failings of the buy-and-bill system impact all oncologists, small independent practices shoulder the greater burden, and their very existence, and with it access to care for many of our most vulnerable patients, is threatened.
- Oncologists are encouraged to be engaged and innovative in seeking alternative payment systems for buy-and-bill chemotherapy that will complement reforms of fee-for-service medicine. Possibilities include bundled payments, least costly alternative reimbursement, shifting Medicare Part B drugs into Medicare Part D, invoice pricing with management fees, government/payer-negotiated drug pricing, value-based payment formulas, and revamping the Competitive Acquisition Program.

history, several flaws in the methodology have become apparent to practitioners and policy makers.

First, CMS posts a new ASP every quarter based on information submitted by drug manufacturers 6 months earlier. As a consequence, drug prices commonly increase, whereas physician reimbursement remains stagnant because of the lag in ASP reimbursement policy.[7] This mismatch between acquisition costs and Medicare reimbursement for a particular drug can result in it being underwater (meaning the buy costs more than the bill) among providers—price increases are borne by outpatient practices until Medicare reimbursements catch up two quarters later.

Second, the lag in ASP-based reimbursement may have some perverse effects on the supply of generic oncolytics that commonly act as the backbones of chemotherapy with more novel agents. Once multiple manufacturers produce a given generic drug, competitive market forces drive their acquisition costs to levels that leave manufacturers very thin margins. If a generic drug manufacturer faces increases in the prices of raw material acquisition or costs of manufacturing and/or distribution, they may wish to pass these cost increases in whole or in part to drug purchasers. The lag in ASP reimbursement, however, forces generic manufacturers to assume all or some of the financial consequences of increased production costs for a defined period of time. Facing this option, generic manufacturers may opt to cease production of these drugs or outsource them to contract manufacturers. This may have contributed to ongoing generic cancer drug shortages.[8]

Third, reliance on ASP as the basis of outpatient oncology practice drug reimbursement has had heterogeneous and unequal effects across providers. On the bill side, practices can have substantially different payer mixes because of socioeconomic characteristics of their location. Commercial payers were slow to adopt ASP pricing and generally continue to reimburse more generously than Medicare, making practices that have richer, commercially insured patients less vulnerable to ASP and its changes.

On the buy side, ASP rewards practices enjoying substantial purchasing advantages that others do not immediately enjoy. For example, institutions that are eligible for 340B drug discounts access drugs at relatively low costs, insulating them from many of the financial pressures independent practices face.[9] When calculating ASP for purposes of Medicare reimbursement, regulations instruct manufacturers to exclude sales to 340B providers. Hence, Medicare reimbursement rates are not affected by growth in the 340B discount program, although providers' acquisition costs are reduced. Large group and institutional practices with lower drug-acquisition costs have a competitive advantage compared with smaller practices. Large practices typically have better access to capital and favorable commercial contracts compared with smaller practices, allowing them to more easily benefit from any spread between insurer reimbursements and the acquisition costs of drugs.

The risks and inequities in the ASP system have become exacerbated in recent years as the acquisition costs for newly launched Part B– covered oncolytics have increased expo-

nentially. Many small- to medium-size practices recognize that they cannot risk providing new, expensive therapeutics in the office. An entire clinic can be jeopardized by a failure to be wholly or partially reimbursed in a reasonable time frame for a given dose or cycle of an expensive drug. This is particularly problematic in rural and other underserved areas, where disadvantaged practices must seek size, capital, and management to survive.

Perceptions of Perverse Behavior in Response to Buy and Bill

There are several actors and associated behaviors that policy makers point to as being both related to buy and bill and symptomatic of its unintended consequences.

First, buy and bill sets up a system where oncologists who provide care to patients with cancer face financial incentives to administer intravenous anticancer drugs. In most industries, there is not much difference between wholesale and retail prices, and so they send consistent signals. But when wholesale and retail prices for drugs diverge systematically, incentives for dysfunctional behavior may be created. Oncologists and hospitals profit on the spread between the reimbursed price and the wholesale cost. Malin et al reported that many oncologists report that they face financial incentives to administer anticancer drugs.[10] Evidence also suggests oncologists' drug choices do appear to be responsive to profit margins (for examples, see Jacobson et al 2010 and Conti et al 2012), although there remains controversy about the quality of this evidence.[11,12]

On a related noted, a number of authors have also questioned whether some novel, high-cost chemotherapies are being used inappropriately in clinical practice related to the incentives in buy and bill.[13,14,15,16] The extent of inappropriate chemotherapy use is a public policy concern because of the cost and potential harms to patients from the use of toxic agents with little likelihood of clinical benefit.[17,18] It is important to note that the results of the most recent study suggest that physician-administered oncolytics are used off label with a frequency similar to other commonly used medication classes in the nononcology setting (20% to 50%).[19]

Second, on the buy side, downward pressure on reimbursement levels in buy and bill may incentivize outpatient practices to substantially shift the risks associated with the buy-and-bill system and/or to seek the lowest acquisition costs available for a given drug. A recent report suggested the share of physician-owned private practices in oncology decreased 10 percentage points between 2010 and 2011, and merger and acquisition activities between community oncology groups and hospitals and large provider groups have increased substantially. According to one estimate, between 2005 and 2011, the amount of chemotherapy infused in community doctor offices decreased from 87% to 67% even as the share of Medicare FFS payments for chemotherapy administered in hospitals (as opposed to outpatient oncology practices) increased from 16.2% to 41%.[20]

Furthermore, mergers between 340B providers and non-340B providers have substantially expanded the program's reach. One industry source (Biotechnology Industry Organi-

zation 2013) predicts that the volume of drug sales under the 340B program will increase from $6 billion in 2010 to $12 billion in 2016. This figure includes anticancer and non-cancer drugs. Industry sources indicate that the two therapeutic classes having the largest 340B sales are anticancer drugs and anti-infectives. These decisions influence the number of available oncology practices in a community, and places upward pressure on the prices paid for the provision of similar services.[21,22,23]

Finally, ASP-based reimbursement does not appear to curb the initial pricing of a branded cancer drug, most of which now meet or exceed $10,000 per month of treatment.

Howard and colleagues[24] reported that the launch prices of cancer drugs increased 9% to 17% between 1995 and 2012, after controlling for inflation. Because many rebates and discounts are based on a drug's average price, the expansion of rebate and/or discount availability presents pharmaceutical companies with an incentive to set higher list prices to offset discounts. In this way, increases in the number of 340B-eliglble providers may have led to upward pressure in the prices paid by noneligible providers.[24] This incentive likely acts to inflate the launch prices of new drugs, in part because manufacturers understand that practices may face substantial financial risk if drug prices increase after launch because of the lag in ASP-based reimbursement.

THE REALPOLITIK

It is an open secret in Washington, D.C., that when the Congress or the President are looking for substantial savings to pay for tax cuts or other spending priorities, they go to the Medicare program for the same reason that Willie Sutton robbed banks: that is where the money is. In an ideal world, savings would be achieved through careful consideration of the intended and un-intended consequences of the proposed policy reform, but that is not how the process usually works. Typically, a savings target (the amount of money needed to pay for other policy priorities) is established, and the policies that are most likely to be scored by the Congressional Budget Office to achieve this target are chosen. Formulas such as ASP and ASP plus are an ideal target for this type of approach because the math is straightforward. Combine simple math with a strong feeling by many health policy analysts and economists that ASP plus–based reimbursement creates perverse incentives for oncologists to preferentially choose drugs with the highest ASP to maximize revenue, and you have an irresistible target.

Although there are certainly members of Congress who are sympathetic to the havoc that would be created to the financial viability of oncology practices if ASP were to be eliminated, this sympathy has not led to a strong defense of cuts that have already gone into effect. As part of the 2012 budget sequester, Congress mandated CMS to cut Part B drug reimbursement by 2%—the result of which is that drugs are now paid at ASP plus 4.3%. Congress has had two subsequent opportunities to fix this problem with bipartisan budget agreements in November 2013 and November 2014, but not only did the problem go unfixed, Congress extended the cuts to

2024. Specific legislation, HR 1416, was introduced to fix this cut in the 113th Congress and never made it out of any of the three committees to which it was referred, despite having 124 cosponsors. In addition to lack of Congressional support, ASP reductions to ASP plus 3% have been part of the President's annual budget for the last several years. Finally, in a November 2014 hearing of the Medicare Payment Advisory Commission (MedPAC), the commissioners were in agreement that ASP policy creates a perverse incentive for providers to use more expensive medications rather than trying to control costs.

This leaves two choices for the oncology community: fight any further cuts to ASP and hope that we, as a community, have enough political clout to stop further cuts to ASP, or offer alternatives to ASP that shift our financial model from margins on drugs to one where we get paid to care for complicated medical patients. Receiving new budget allocations from Congress to do this is highly unlikely in the current environment. This means that money already in the system must be reapportioned. The ASP plus formula is not the only source of that revenue, but it is a logical one. However, we can only reapportion that money if it is actually in the system. If we wait too long, and ASP receives further cuts, then that is money we will never get back.

Recent proposals for the reform of outpatient oncology care, including the American Society of Clinical Oncology's (ASCO's) Consolidated Payments for Oncology and the Community Oncology Alliance's oncology medical home–based payment reform, have not received the serious attention that they should have garnered from policy makers, in part because they did not include a proposal for the direct reform of the outpatient chemotherapy administration reimbursement.

Freeing oncologists from dependency on drug revenues while keeping outpatient oncology viable requires a focus on reimbursement for services that are uncompensated or undercompensated in the current system. By seizing on the opportunity to participate in policy makers' active debate on the reform of the outpatient oncology reimbursement system, we can ensure the long-term sustainability of community-based outpatient oncology practice for current and future providers and patients.

THE ONCOLOGIST

At the core of cancer medicine is the delivery of oncolytic therapies and supportive care. For the medical oncologist this means pharmaceuticals, the majority of which are administered in hospitals and clinics. In contrast to oral medications, where direct physician ownership of pharmacy is largely prohibited, oncologists in private practice buy and bill the drugs that they then prescribe and administer. These drugs represent the largest single item expenditure and the largest source of gross revenue for these practices, and, until recently, the margin between purchase price and sale price was the financial driver of oncology infusion suites and oncologist incomes.[25] Similarly,

hospital- and institutionally-owned oncology clinics gain substantial revenues through outpatient administration of oncolytics, which contributes to the growth of hospital-based cancer programs.[20]

It would be naive to expect that the medical oncology community would be represented by a single sentiment or opinion about the buy-and-bill system. Varied sentiment may be shaped by physician experience and philosophic or political leanings, site of service, geography, and practice demographics. Likewise, it is naive to believe that payment reforms will impact only one sector of oncology. ASP-based pricing was developed initially for private practice oncology and Medicare, and now it permeates all oncology sites of practice and all payers.

Before the implementation of the MMA in 2003, chemotherapy was paid as a percentage of Average Wholesale Price (AWP). AWP was anything but average wholesale pricing, and it could better be characterized as a suggested retail price set by the manufacturer. Before MMA, there had been steady decreases in Medicare drug payments, and by 2003 Medicare paid AWP — 15%. The mechanics of the process, however, allowed manipulation of the system, and physician margins were commonly 30% to 50% of their purchase price and even sometimes up to 200% to 300% in well-publicized, isolated circumstances.[26]

With implementation of the MMA's ASP plus 6% drug reimbursement, the margin between buy and bill for Medicare patients substantially decreased for oncologists in private practices. The effect was initially buffered by Medicare demonstration projects, temporary increases in infusion fees, and relatively lucrative commercial contracts. However, over time Medicare discontinued the demonstration projects and allowed deadlines to permanently adjust infusion fees to fall by the wayside, and commercial payers, in efforts to combat escalating oncolytic drug prices, adopted ASP-based reimbursement contracts of their own. Further, the inclusion of approximately 2% prompt-pay discounts to distributors in the ASP calculation, in addition to the inexorable inflation in drug prices combined with a 6-month lag in ASP updates, meant that the margin on Medicare was never really 6%. In 2012, the application of the budget sequester to Medicare reimbursement decreased reimbursement to ASP plus 4.3%. The cumulative effect on the average oncologist's drug margin is such that it is less than 2.3%.[27]

As margins decreased, the risks inherent to the buy-and-bill system increased. Underwater drugs became common. On the surface, expensive drugs may appear more attractive than a cheaper alternative, but when a drug costs $5,000 and margins are ASP plus 6% minus 2% (prompt-pay discount), minus 1.7% (sequestration), minus 1.3% (price increase), the reimbursement equals 2% or $100. If a patient fails to inform the practice of a new Medicare Advantage Plan with a 20% or $1,000 copay that they cannot pay, the risks are too high. Increasingly, small practices, and even larger ones, report sending some therapies—and more often certain patients, such as those with Medicaid, Medicare with no supplement, and Medicare Advantage Plans with copays on Part B drugs—to

hospitals for infusion.[28] Brown bagging, the practice of having patients acquire chemotherapy through their pharmacy benefit and bringing it to the clinic to have it infused, or white bagging, the outsourcing of chemotherapy to a specialty pharmacy that delivers it to the practice for infusion, has become increasingly attractive for small practices, some of whom have had difficulty obtaining credit.[29]

Larger practices, particularly those in mid-size metropolitan communities with a large community presence, have survived and may continue to thrive in this environment. They have greater buying power and may be able to buy drugs at less than ASP, though the average in ASP requires that their largess be to the detriment of the smaller practice who will find that they then buy at more than ASP. The mega-practice may also have an upper hand in negotiations with commercial payers and benefit from diversification of revenues, capturing downstream revenues such as imaging and pharmacy.[30] Likewise, hospitals with 340B discounts, facility fees, inpatient and outpatient downstream revenue, and commercial contracting leverage do not feel the same pain wrought by the decreasing margins in buy-and-bill chemotherapy.[31]

Given the history, it should be no surprise that the oncologist's sentiment is shaped by personal circumstances. Stereotypical as it may be, it appears that there are four popular responses to the notion of reforming the way we pay for chemotherapy: (1) discouraged and resigned, (2) embittered and angry, (3) removed and aloof, and (4) engaged and innovative.

Discouraged and resigned oncologists have seen and are dismayed by an inexorable increase in the price of oncolytics. The only response they see from policy makers and payers is to decrease the margins available to physicians. They take note that every White House budget proposes paying a lower margin on ASP and they fully anticipate that there will eventually be no margin. Many of them practice in small groups of less than five medical oncologists. They already shift as much risk as possible to hospitals, are acutely aware that they cannot administer the drugs that are underwater this month, brown bag when necessary and are arranging for white bagging, and have a tenuous, at best, line of credit with their distributors. They have or plan to cut staff to bare bones and are actively exploring retirement or negotiating a new employment arrangement. They are too busy generating Evaluation and Management Services to participate in ASCO or state societies. They just wish buy and bill would go away.

To be embittered and angry, physicians have to have practiced long enough to remember buy and bill the way it used to be. Many of the most successful and largest private practices are populated by the embittered and angry. Proud of their independence and the good care that they give their patients, community oncology is a way of life to be defended and fought for. To criticize buy and bill is to criticize their culture, and they feel that ASCO has failed to adequately defend and fight for it. As hospitals grow through acquisition of independent oncologists, they feel further threatened by the relative wealth afforded by facility fees and 340B and angrily seek to level the playing field.

Removed and aloof could be used to characterize many of our young oncologists, indifferent because they do not know better and are content with avoiding the fray through employment. These terms could also be used to describe some oncologists who have left independent practices for the refuge of hospitals, but these should be lumped in with the discouraged and resigned; instead, think of the oncologist who has always been employed and has felt above the fray because of it. They can be found among new hospital partners and in academic institutions. They are proud that their salaries are not tied to how much chemotherapy they prescribe or how expensive the drugs they use are, and they are convinced that their private practice brothers and sisters have succumbed to practice by the margins. They seem oblivious to the fact that the administrators who negotiate their institutional contracts are very much aware of the margins on the drugs they order, or that, should the profit center they work in become a cost center, it may well turn their well-ordered world upside down.

Many oncologists are engaged and innovative. They are growing medical oncology homes, communicating with their local accountable care organizations, engaging with payers to explore payment reform pilots, and building relationships with their representatives in Congress. Many have recovered from discouragement and resignation or evolved beyond bitter and angry, and the lines between community and institution have been blurred. Work is being done by the Clinical Practice Committee's Payment Reform Workgroup to explore alternatives to ASP-based reimbursement to include bundled payments, least costly alternative, shifting Medicare Part B drugs into Medicare Part D, invoice pricing with oncolytics management fees, government/payer negotiation of drug prices, value-based payment, and revamping the Competitive Acquisition Program.

The Patient-Centered Medical Home in Oncology: From Concept to Reality

Ray D. Page, DO, PhD, Lee N. Newcomer, MD, John D. Sprandio, MD, and Barbara L. McAneny, MD

OVERVIEW

In recent years, the cost of providing quality cancer care has been subject to an epic escalation causing concerns on the verge of a health care crisis. Innovative patient-management models in oncology based on patient-centered medical home (PCMH) principles, coupled with alternative payments to traditional fee for service (FFS), such as bundled and episodes payment are now showing evidence of effectiveness. These efforts have the potential to bend the cost curve while also improving quality of care and patient satisfaction. However, going forward with FFS alternatives, there are several performance-based payment options with an array of financial risks and rewards. Most novel payment options convey a greater financial risk and accountability on the provider. Therefore, the oncology medical home (OMH) can be a way to mitigate some financial risks by sharing savings with the payer through better global care of the patient, proactively preventing complications, emergency department (ED) visits, and hospitalizations. However, much of the medical home infrastructure that is required to reduced total costs of cancer care comes as an added expense to the provider. As best-of-practice quality standards are being elucidated and refined, we are now at a juncture where payers, providers, policymakers, and other stakeholders should work in concert to expand and implement the OMH framework into the variety of oncology practice environments to better equip them to assimilate into the new payment reform configurations of the future.

Under our current health care system, the care and management of patients with cancer comes with exponentially increasing costs along with compromises in quality of care. Today there are several payment reform models that are being designed and piloted intended to address the desire for evidence-based, value-driven cancer care. One element of this is the OMH concept, which is rooted in the National Commission on Quality Assurance (NCQA) standards originally created for primary care and expanded into specialty medicine. In 2010, Sprandio established an oncology patient–centered medical home (OPCMH) model that showed the ability to control cancer care costs by improving overall management of patients with cancer throughout their treatment.[1] Consultants in Medical Oncology and Hematology (CMOH) became the first oncology practice to be recognized by the NCQA as a level III PCMH, with their OPCMH model. Through NCQA standards, CMOH implemented efforts and aspects of care to target costs, quality, and patient care processes. Results showed that ED visits decreased by 68%, hospital admissions per patient treated with chemotherapy per year decreased by 51%, and the length of stay for admitted patients decreased by 21%. CMOH has shown substantial overall cost savings estimated at $1 million per physician annually. The OPCMH emphasizes the importance of delivery reform in oncology.[2] However, the improved total

costs initially resulted in detrimental financial effect on CMOH. This is partly because the predominant FFS payment system is inadequate to compensate a practice that has implemented the added ancillary services beyond physician-patient interaction and procedures. To comprehensively treat patients with cancer with a well-orchestrated clinical oncology team that enhances care coordination and quality improvements, supporting payment reforms beyond FFS are necessary for the an OPCMH to be sustainable.

To show that community oncology practices can refine patient management processes in a way that manages the care of patients in a cost-effective manner that also improves outcomes with better patient satisfaction, a Centers for Medicare & Medicaid Services (CMS) Innovation Grant of $19.8 million was awarded to Barbara McAneny, MD, through Innovative Oncology Business Solutions (IOBS).[3] Known as the COME HOME Program involving seven community oncology practices in the United States, patients on Medicare are managed under an OMH structure, which includes centralized, protocol-driven triage nurses; extended office hours and 24/7 access to clinical staff; treatment pathways development and compliance; and laboratory/molecular diagnostics efficiency. The purpose of the grant was to show that community oncology practices can become a medical home for patients with cancer, manage the care of these patients in a

cost-effective manner that produces improved outcomes, and provide better patient satisfaction and cost savings. The cost savings were anticipated to come from decreased utilization of more expensive sites of care, such as the ED and inpatient hospital facilities. A small amount of cost savings were to come from the utilization of pathways to standardize triage, diagnosis, and treatment of patients with cancer. This 3-year project is at maturity and preliminary data has shown advantages to the OMH structure as carried out in the COME HOME grant.

Alternatives to the standard FFS and buy and bill practices in the United States have been explored. Gordon Kuntz published first year results of a multipractice, community OPCMH demonstration project in Michigan.[4] The project reduced costs associated with unnecessary ED visits and inpatient hospitalizations. The study suggested that community oncology practices will embrace the transformation to a patient-centered model with properly aligned incentives and administrative assistance.

Newcomer et al of UnitedHealthcare compared five community oncology practices with a large national payer registry of FFS patients and proved that through a gain sharing, episodes of care chemotherapy management coupled with sharing of best-of-practice quality benchmarks resulted in a 34% savings in the community practices compared with matched controls under FFS.[5] The University of Texas MD Anderson Cancer Center has contracted with UnitedHealthcare to manage all aspects of head and neck cancer care from diagnosis to death under a true yearly bundled payment system. This payment method conveys a much higher risk to the provider, but with the potential for greater financial rewards for optimal patient management. The inherent risk of this payment model may be acceptable by large institutions but adverse for most independent practices.

Recently, CMS has clearly announced their intent to accelerate payment structures that move away from FFS and into accountable, value-based bundled payments.[6] For oncology practices to remain viable going forward, successful management of the financial risks that are intrinsic to bundled payments can be lessened by incorporating OMH processes. These are directed at maximizing global patient management according to appropriate accredited benchmarks.

REWARDING PERFORMANCE IN MEDICAL ONCOLOGY

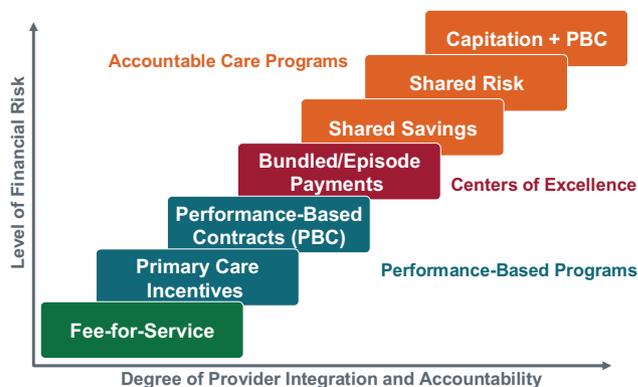
A basic economic principle states that higher risk should have the potential for higher rewards. Building an OMH requires additional time and resources and this investment does not make sense unless there is potential return for the extra effort. This section discusses the new funding mechanisms being employed to compensate for better medical oncology performance. Potential, however, is not a guarantee of reward. Installing the processes is not enough. The outcomes must be better than standard performance to earn higher rewards.

There are several options being used for performance-based compensation (Fig. 1). The lowest risk form is pay for performance. In this model, a bonus is paid for attaining predetermined targets. Typically these targets are process measures rather than outcomes. These process measures are expected to produce better outcomes, but time and data limitations often prevent the actual outcomes measurement. Generally, the payments are small and the measures can be obtained using claims data. The pay-for-performance model has been popular for providers with large populations like primary care practices or accountable care organizations. The model does not work as well for medical oncology because of the small patient numbers and the relatively small payments for an individual practice.

Anthem uses an interesting variation of the pay-for-performance model that pays a management fee for treating patients with predefined chemotherapy regimens.[7] No measurement is required because the payment begins immediately for each compliant patient. The payment is also larger than most pay-for-performance programs (approximately

KEY POINTS

- As we look at fee-for-service (FFS) alternatives, several performance-based payment options exist with ranges of financial risk, reward, and accountability.
- Oncology medical homes (OMHs) have been shown to improve patient care, patient outcomes (less emergency department and hospital admissions), patient satisfaction, and with substantial cost savings to the payers.
- The OMH practice infrastructure required to create cost savings is not covered under traditional FFS. Rewards for OMH performance should be based on a small number of meaningful quality performance measures.
- To cover practice costs of an OMH, practices will need to enter payer contracts that recognize the value of all services provided.
- An OMH infrastructure gives the best opportunity for sustaining contracted bundled payments with risk sharing/shared savings, which are anticipated in the near future.

FIGURE 1. Reinforcing Engagement of the Physician: Value-Based Provider Contracting


$350 per month per patient). The regimens were selected by an expert physician panel based on outcomes from the medical literature. Anthem expects the lower total cost of the selected regimens to fund the program payments. There is no penalty for using other regimens.

Risk sharing or gain sharing is the next progression of payment risk. Physicians in these programs have their managed patient's outcomes measured and compared with another similar population. Any savings in the managed group is shared between the payer and the clinicians. Gain sharing is participation only in savings, whereas, risk sharing often implies that the physician would share in losses as well. The key to an accurate program assessment is the quality of the comparison group. Many risk-sharing contracts utilize a year over the previous year comparison within the same practice. This method often cannot adjust for the change in patient diagnosis mix resulting in an inaccurate assessment of savings. The ideal comparison group is treated during similar timeframes and can be risk adjusted to match those patients in the managed practice. The approach is no different than a well-conducted clinical trial.

The next progression of risk is the bundled payment, which is the ambulatory equivalent of the Diagnosis Related Group (DRG) used for hospital reimbursement. A fixed payment is made to the provider for the services required to care for a specific diagnosis. These payments often include multiple disciplines and facilities. The recent MD Anderson Cancer Center contract with UnitedHealthcare illustrates the components of a bundled payment. Patients with head and neck cancer are evaluated at the cancer center and assigned to one of four risk categories. All of the services required for the complete treatment of this patient are included under a single payment from the payer. The bundle covers a 1-year time period including complications. Bundles provide the incentive to remove all of the unnecessary or nonvalue services to maximize profit. The MD Anderson Cancer Center used a systematic approach to map the processes for head and neck cancer treatment and activity-based accounting to identify and remove unessential care. Similar to the DRG, the elimination of complications is the other substantial way to improve profits under this payment system. Quality pays in bundled payments.

Capitation is the highest form of risk. The capitated provider assumes complete financial responsibility for all cancer care in a population of patients within a fixed budget. The population must be well defined with risk profiling, and actuarial expertise is essential to manage this type of payment. Very few organizations are capable of undertaking this type of contracting and the authors discourage providers from attempting this approach until they have mastered other lower-risk programs.

IMPORTANCE OF ESTABLISHING PERFORMANCE MEASURES

Medical practices who assume risk need infrastructure to understand the processes they use to evaluate and treat their patients. Mapping those processes will be both enlightening and startling because inconsistency is usually the norm. Adopting and driving standard approaches to common problems eliminates waste and increases productivity—changes that make risk contracting a profitable approach. At the same time, the new understanding of patient care performance drives higher quality with fewer errors, better communication, and rapid identification of patient problems.

Those new changes are managed with internal performance measures. No practice should assume things are changing because they signed a risk contract; the change must be measured and managed. These internal, quality improvement measures can be less rigorous than external measures and they can be adjusted frequently. The purpose of these measures is not to obtain complete accuracy, but rather to identify trends quickly and make adjustments. Adopting this type of measure is difficult for physicians who are used to exact measures of performance.

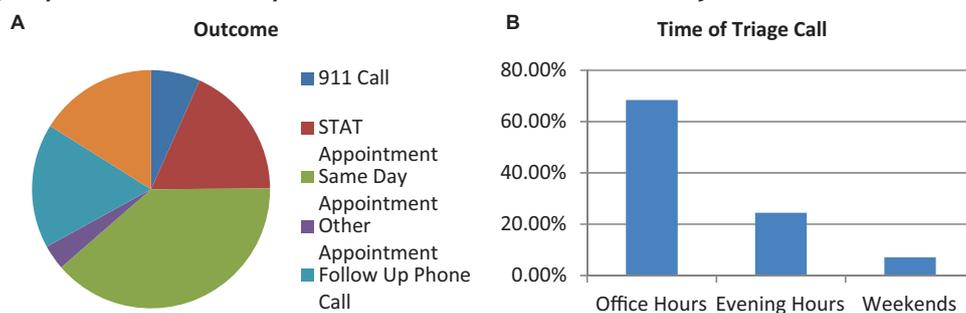
External measures are more rigorous and are often tied to compensation. These measures should be limited to the vital few because the data collection and analysis are time consuming. Regulators often require multiple measures as an assurance of quality in risk programs, but if too many measures are required it can discourage participation by physicians. Further, risk payment should not be hindered by measures that are not required of FFS providers. The best external measures are quite simple: survival, either disease-free or overall, and total cost of care. Adding process measures that contribute to these two ultimate measures distract physician resources during the risk contract.

These principles have moved beyond the theoretical. A recent pilot for a gain-sharing episode payment demonstrated a 34% savings in the trial cohort compared to matched controls in FFS payment models.[5] The MD Anderson Cancer Center has initiated a full bundled payment for patients with head and neck cancer. Models like these have the potential to drive higher quality care while simultaneously saving money by eliminating unnecessary care.

COME HOME OUTCOMES AND SUSTAINABILITY

OMHs have been shown by the COME HOME Program to meet the triple aim: Patient care is improved, and patient outcomes are better (lower ED visit rate, lower inpatient admission rate, fewer inpatient days) with consistently high patient satisfaction, all at an equal or often lower cost than local comparator groups.

Participating oncology practices provide all outpatient cancer care, including triage pathways that ensure patients receive the right care in the right place at the right time for symptoms related to cancer and cancer treatment (Fig. 2), and clinical pathways that address appropriate imaging, pathologic testing, and molecular diagnostics, and delineate chemotherapy, radiation oncology, supportive care, and surgery (when applicable). The best practices offered by OMHs include patient education and medication management counseling, team-based care, 24/7 practice access (telephone

FIGURE 2. Triage System Utilization by (A) Outcome and (B) Time of Triage Call


triage, evening/weekend clinic hours, electronic health record [EHR] access through patient portals and on-call clinicians), on-site or near-site imaging and laboratory testing, and admitting physicians who shepherd patients through inpatient encounters, avoiding handoffs and readmissions, to ensure seamless, safe, and efficient care. Further, the COME HOME program offers physicians and administrators from community oncology practices unprecedented access to real-time quality, pathway adherence, and utilization data, including provider-level measures and benchmarking within each practice and within the COME HOME Program.

The medical home infrastructure creates four sets of costs that are not covered under traditional FFS and must be addressed using an alternative payment model.

1. Medical homes need triage nurses, patient care coordinators, data analysts, lab technicians, and other staff to meet the goal of providing the right care at the right time in the right place. However, most of the services provided by these staff are not billable under a FFS contract.

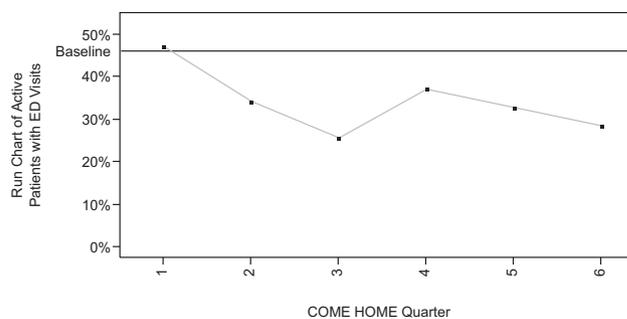
2. The medical home relies on leaving daytime physician time available, thus, running the risk that a valuable commodity (physician time) will go unused and, therefore, generate no revenue (opportunity cost).

3. Treating patients with the hydration and symptom control treatments instead of using the infusion center overhead for chemotherapy replaces better paying services with services given at a loss.

4. Offering evening and weekend clinic hours for the infusion of antibiotics, symptom control medications, and hydration will keep patients out of the ED and hospital, but does not generate sufficient evaluation and management and infusion codes to cover the salaries of personnel. During these after-hours clinics, at least two nurses and associated support staff must be present, but the services provided, such as hydration and intravenous antibiotics administration, generate very low reimbursements.

Under the medical home infrastructure as described above, participating practice sites have shown a 23% to 28% reduction in the percent of patients with ED visits (Figs. 3 and 4). Treating patients in a physician's office after hours rather than sending them to the ED saves payers money, but it actually costs physicians more money to provide the care than they are reimbursed. To cover practice costs of a medical home, the COME HOME program practices will need to enter into contracts with payers that recognize the value of the services provided. These services generate savings through reduced ED and inpatient use, but these savings only accrue to the payer. We see bundled payments, with options for risk sharing/shared savings as the best contracting option for sustaining the medical home infrastructure.

Oncology bundled payments and other risk-sharing arrangements are highly innovative, untested, and financially risky to physician practices. COME HOME is now beginning to develop the necessary knowledge base to support bundled payments/shared savings in this arena. Together with the COME HOME practices, the team at IOBS has launched two related efforts to support future oncology bundled payments with shared savings. First, they are developing a data analytics infrastructure that will allow for the participating practices to track improved outcomes, understand their costs for treating common cancer types (breast, lung, and colon) and be familiar with sources of savings from the medical home model to set bundled price targets/shared savings in a transparent and data-driven way. Second, IOBS is conducting a series of limited bundled payment pilots with small patient pools. These pilots allow the participating practices to become familiar with bundled payment mechanisms while limiting overall risk. Both of these activities are ongoing at the moment, and they often inform each other.

FIGURE 3. The COME HOME Beta Site Percent of Patients with Emergency Department Visits


The COME HOME beta site shows a 23% reduction in the percent of patients with emergency department visits.

BEYOND THE CONCEPT: THE ONCOLOGY PATIENT-CENTERED MEDICAL HOME

OPCMHs, like other emerging models of cancer care, delivers value by improving quality through standardized processes, minimizing the variation of care, and lowering cost by reducing the overutilization of services associated with the variable delivery of care. Oncology Management Services (OMS) served the CMOH, as it became the first medical oncology practice to be recognized by the NCQA as a level III PCMH in 2010. Since then, CMOH has continued to demonstrate reduction in unnecessary utilization, while driving the consistency and quality of care. The practice reports an ongoing, cumulative reduction in ED utilization rates of 78% and reduction in hospitalization rates of 50% per patient on chemotherapy per year (2007 to 2013). This progressive improvement is attributed to ongoing standardization of process, workflow, data collection, data presentation, documentation of response to data, and communication, along with improved patient engagement and enhanced access. CMOH's current rates of ED utilization and hospital admission remain substantially below the market as confirmed by collaborating regional payers.

Currently, 48% of CMOH's patient base is covered with OPCMH-related contracts that align payment with the demonstration of results. CMOH has sustained a staff:physician full-time equivalent ratio of 5.6 since 2011 (previously 8.3 in 2008). Furthermore, as a result of progressive enhancement of patient engagement and education, there has been a change in patient behavior to the point where CMOH no longer provides extended hours of operation. The majority of symptom-related calls within their patient population occur during normal hours of operation.

OMS provides consultation services and supports the transformation of community- and hospital-based oncology practices by leveraging the current NCQA Patient-Centered Specialty Practice (PCSP) recognition standards, as well as a comprehensive and proprietary set of transformation tools, optionally supported by internal practice-related performance analytics and information technology.

Practice and program transformation to this or similar models enables a new value proposition and participation in emerging alternate payment methodologies for cancer care that are now being promoted by commercial payers, as well as Medicaid and Medicare, including the recently designed CMS Oncology Care Model (OCM).

VALUE IN CANCER CARE

Health care reform is focused on value and the demonstration of results. Value is commonly defined as some variation of the equation quality/cost. Let's review the Institute of Medicine's (IOM) definition of quality in health care as it relates to cancer care (Fig. 5).

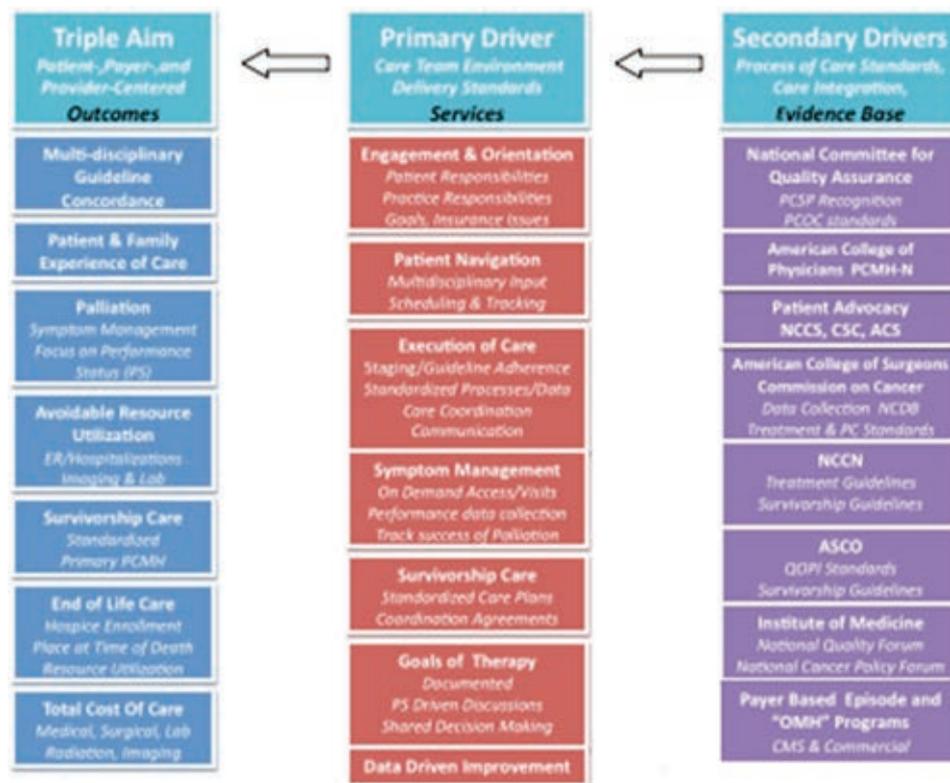
- Quality is: "The degree to which health services [center column on diagram] delivered to individuals or populations increase the likelihood of desired health outcomes [left column] and are consistent with current professional knowledge [right column]."
- Value can be defined using the IOM definition of quality care delivered with the proper allocation of resources (cost).

It has become recognized by patients and payers that the utilization of unnecessary resources— often, a result of the execution of even the most artfully constructed treatment plan—is poor quality care, no matter the degree of adherence to the evidence base. Transformation of a practice to a PCMH-related model is related to improving the consistency of the activities of a coordinated care team.

The effectiveness and efficiency of the physician-led care team's activities (primary driver, center column) drive the desired payer- and patient-centric outcomes (left column). In cancer care, the desired outcomes are self-evident: guideline-based multidisciplinary care, improved patient experience, prompt palliation of symptoms, reduction in unnecessary resources, coordinated survivorship care, rational care at the end of life, and control of cost by focusing on the reduction of unnecessary resource utilization.

There are well-recognized quality performance metrics in the domain of secondary drivers, the evidence base (right column). Oncology is rich in externally recommended treatment standards from which all cancer care providers benefit: National Comprehensive Cancer Network (NCCN), American Society of Clinical Oncology (ASCO), and Commission on Cancer (COC) all have created guidelines. In the OPCMH model, validated process standards (NCQA, American College of Physicians, National Coalition of Cancer Survivors) are equally important secondary drivers of quality, cost, service, and practice efficiency.

Value and quality metrics are embedded within all three columns of the driver diagram (Fig. 5). As we study and understand which specific process-related activities drive outcomes, we can better define future quality measures (i.e., turnaround time, content and dissemination of documentation). Quality measures (based on the IOM definition) will not be limited to well-recognized evidence-based standards or even outcomes; rather, the emergence of practice-level performance-based metrics that are proven to drive desired outcomes.

FIGURE 5. Oncology PCMH Quality and Value Driver Diagram


The real focus of oncology practice transformation is how efficiently the physician-led care team—the primary driver of quality and cost—actually delivers care while adhering to the secondary drivers of the evidence base and validated process standards.

PAYER SUPPORT

The last of the seven *Joint Principles of PCMH,* a collaborative effort to standardize the PCMH model for primary care, calls for "appropriate payment recognizing the added value of the model."[8] Payer recognition of the variability of cost and quality, and the willingness to align appropriately motivated changes in care delivery was critical to the adoption of the model by primary care providers. The same holds true for specialty care providers, most notably oncology. As outlined in the OPCMH payer-provider collaboration diagram (Fig. 6), several synergistic activities and commitments between providers (right column) and payers (left column) drive performance enhancement within the care team (center column).

By focusing on the essential demand for improved quality and value regardless of the payment model or organizational structure of the parties adopting it, transformed practices can become providers of choice by driving consistency of the execution of care and being flexible enough to accommodate whatever payment changes may come in the future:

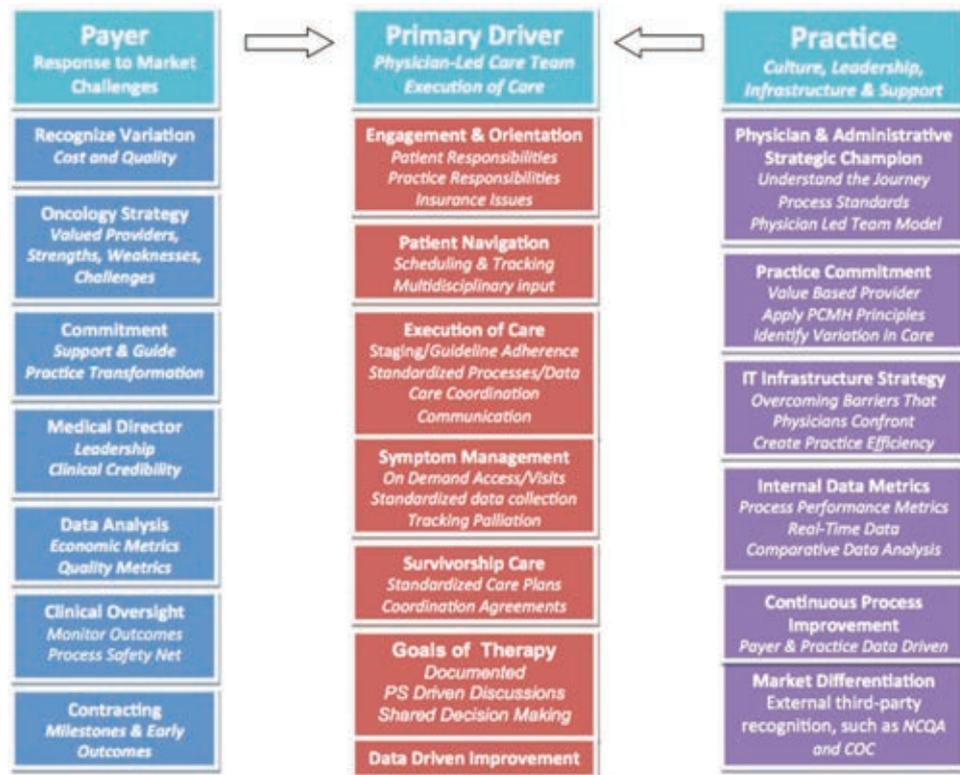
performance-based, budgeted (episodic or bundled), or progressive risk-assuming contractual models.

PROCESS AND POLICY STANDARDS

The NCQA has played a dominant role in defining standardized and validated processes of care delivery that provide direction for infrastructure development, enabling practices to focus intently on the way that primary care is delivered. Many of these standards are applicable to both primary and specialty care as they relate to patient access and communication, the identification and coordination of patient populations, the planning and management of care, the tracking and coordination of care, and measurement and improvement of practice performance.

In March 2013, the NCQA released the PCSP standards that are applicable to all specialty practices, especially those involved in longitudinal care of medically complex patients. Current NCQA PCSP standards serve as the foundation for transformation of the cancer care team activities. These activities include patient engagement and orientation, patient navigation, execution of care, symptom management, survivorship care, goals of therapy and end-of-life care.

Furthermore, the NCQA, in conjunction with ASCO, the RAND Corporation, OMS, National Coalition for Cancer Survivorship, and Independence Blue Cross, is refining oncology-specific patient-centered oncology care (PCOC)

FIGURE 6. Oncology PCMH Payer/Provider Collaboration


standards within a Patient-Centered Outcomes Research Institute–funded project in southeastern Pennsylvania. This project is studying practice transformation in five practices in community- and institutional-based settings. Process standardization is encouraged, with each practice having the freedom to develop specific processes most appropriate to their individual sites. The use and optimization of technology is encouraged, but not mandated, as one of the participating practices does not even use an EHR. It is anticipated that the NCQA PCOC standards will be finalized during the course of the project. The PCSP and PCOC standards are complementary to the CMS OCM, reinforcing the common processes and service components required for the creation and demonstration of value by the oncology care team.

It is anticipated that additional nongovernmental organizations will be providing certification or recognition of cancer programs and practices including ASCO, the COC, and The Joint Commission.

IS A PATIENT-CENTERED MEDICAL HOME IN ONCOLOGY SCALABLE?

Scalability is important to both payers and providers. Practices recognize that innovative care models provide them with a new value proposition and the option of participation in emerging payment methodologies. Broad scalability among practices requires a model that guides process standardization that is effective yet flexible to best suite each prac-

tice's existing environment and infrastructure. The goal is to streamline and standardize existing processes, not the disruption of effective services and workflow. Practice affordability is another issue; willingness to transform will, in part, depend on practices understanding the importance of process standardization, not only as a driver of value, but with optimal information technology support, as a major driver of practice and provider efficiency (refer to the section on CMOH results).

Payers desire uniformity of the outcome goals and cost control as well as broad adoptability throughout their provider networks. Payers also desire flexibility regarding the payment methodology. OMS is involved in several payer-provider transformation projects. There is common ground regarding the goals of every oncology-related payer-provider experiment underway— enhance quality and control cost. However, each of the projects involves innovative payment methods that vary considerably and are based primarily on the uniqueness of markets, sometimes the patient population, and in large measure, payer- and practice-related data reporting capabilities.

Scalability will require one more important step. During the last 90 years, a number of professional organizations and patient advocacy groups have provided invaluable leadership and direction regarding quality and service standards to the cancer care community. Many of these organizations, along with a growing number of payers, understand the importance of adopting specific PCMH-related standards to cancer

care and the value created. These important organizations could continue to provide leadership by collaborating to develop a core set of cancer care standards, elements, and features to enhance the focus, minimize the confusion, and shorten the timeline for adoption of new cancer care models within the payer and provider communities. Unification and working toward common patient and provider goals will enhance adoptability, and, therefore, scalability.

CONCLUDING REMARKS

Innovative payment models in cancer care are getting increased attention from all oncology stakeholders, including CMS, private payers, providers, drug manufacturers and distributors, hospitals, professional societies, and, importantly, the patients. Faced with spiraling costs, regulatory burdens, impaired access to treatment, and inefficiencies of care there has been a driven focus on delivering cancer care with greater value to all the stakeholders. The OPCMH concept has now been shown to be a viable foundation for carrying out quality-driven, cost-effective comprehensive management of patients with cancer. Much of the value gained from the OMH infrastructures comes through refinement of day-to-day patient care processes resulting in superior outcomes.

Practices should be held accountable to quality practice standards through established and developing accreditation standards through entities such as NCQA and COC, as well as adherence to recognized treatment guidelines and pathways. The further development of these quality metrics should be evidence-based, succinct (clinically relevant), advocate the patients' best interests, and with expert consensus from all stakeholders.

As it becomes acutely apparent that a major element of health care reform is to move away from FFS to varieties of bundled payment options, we believe that the PCMH models in oncology can provide the stable infrastructure required to mitigate the inherent financial risks of bundled payment, episodes of care, and share savings payment options. However, without payer support, further attrition of community-based practices can be anticipated, resulting in escalating costs and a decline in the value of cancer care. It is important for payers and policymakers to understand that for providers to implement substantive practice management changes that provide higher quality care at lower costs under a system other than FFS, it is mandatory that the financial value of uncompensated comprehensive services provided through an OMH program be recognized to be sustainable and scalable.

A Strategic Plan for Integrating ICD-10 in Your Practice and Workflow

Sue Bowman, MJ, RHIA, CCS, FAHIMA, Risë Marie Cleland, BS, and Stuart Staggs, MSIE

OVERVIEW

The adoption of the International Classification of Disease (ICD) 10th Revision (ICD-10) diagnosis code set in the United States has been legislatively delayed several times with the most recent date for implementation set for October 1, 2015. The transition from ICD-9 to ICD-10 will be a major undertaking that will require a substantial amount of planning. In the following article, we outline the steps to develop and implement a strategic plan for the transition to the new code set, identify training needs throughout the practice, and review the challenges and opportunities associated with the transition to ICD-10.

Unless there is another delay, the United States will transition from ICD-9 to ICD-10 in all health care settings on October 1, 2015. This will not be a gradual transition as there will be no grace period. Still, the replacement of ICD-9 with ICD-10 as the Health Insurance Portability and Accountability Act (HIPAA)-named code set did not come without plenty of notice. Before we get into the practical elements of ICD-10 implementation and the opportunities associated with the implementation of ICD-10, let us step back and take a brief look at the history of the ICD.

The first international classification edition was adopted in 1893 by the International Statistical Institute and was called the International List of Causes of Death. The ICD has been revised over the years and is now the standard diagnostic tool for epidemiology, health management, and clinical purposes. It is used globally as the foundation for the identification of health trends and statistics.[1]

The World Health Organization (WHO) has been maintaining and publishing the ICD since 1948, with periodic revisions. To date, there have been 10 revisions of the ICD; the most current edition is ICD-10. The United States has used ICD to classify the causes of death since 1900 and is currently using ICD-10 to report causes of death.

In 1979, the WHO adopted ICD-9, and, with the approval of WHO, the United States adopted a modified version of ICD-9, the International Classification of Diseases Clinical Modification (ICD-9-CM), to assign codes to diagnoses associated with inpatient, outpatient, and physician office utilization, and the International Classification of Diseases Procedure Coding System (ICD-9-PCS) to assign codes associated with inpatient procedures.[2]

WHO adopted ICD-10 in 1994, and, once again, the United States received approval from WHO, which owns and publishes the classification, to develop a revised ICD-10-CM for use in this country. However, although the developed ICD-10-CM codes are updated annually, we have yet to adopt them.

The U.S. Department of Health and Human Services first published a proposed rule to replace ICD-9-CM with ICD-10-CM in August 2008. At that time, it proposed an effective date of October 1, 2011, for the transition to ICD-10. Since then, the ICD-10 deadline has been postponed three times (Fig. 1).

The American Medical Association (AMA) has been very vocal in their opposition to the adoption of ICD-10. Still, in a letter to the Centers for Medicare & Medicaid Services (CMS) just before the most recent delay, the AMA acknowledged that there were other "well-intended" stakeholders in the health care industry that are advocating the move to ICD-10. In their letter, the AMA asked CMS to implement the following provisions if they were intent on adopting ICD-10:

1. A 2-year implementation period during which Medicare will not deny payment based on the specificity of the ICD-10 code, will provide feedback to the physician on any coding concerns, and will not recoup payment because of a lack of ICD-10 specificity.

2. When the most specific ICD-10 code is submitted no additional information will be required to adjudicate the claim, particularly in the absence of an attachment standard.

3. Physicians would be eligible for advance payments when the physician has submitted claims but is having problems getting the claim to reach the contractor because of problems on the contractor's end; a physician

Disclosures of potential conflicts of interest are found at the end of this article.

FIGURE 1. ICD-10 Legislative Timeline

Overview of ICD-10 Legislation

➤ **August 15, 2008** - Department of Health and Human Services (HHS) publishes proposed rule to replace ICD-9-CM with ICD-10-CM effective October 1, 2011.
➤ **January 2009** - HHS publishes the final rule for adoption of ICD-10-CM and ICD-10-PCS, setting a compliance date of October 1, 2013 (rather than the proposed date of October 1, 2011).
➤ **April 2012** - HHS releases a proposed rule calling for a 1-year delay for the ICD-10 compliance date from October 1, 2013 to October 1, 2014.
➤ **April 1, 2014** - President Obama signs the bill, Protecting *Access to Medicare Act of 2014* into law, which mandates that ICD-10 cannot be implemented before October 1, 2015.
➤ **May 1, 2014** - CMS announces new compliance date of October 1, 2015 and states that HIPAA covered entities are required to continue to use ICD-9 through September 30, 2015.

ICD-10-CM

(Clinical Modification)

The <u>diagnosis</u> code set that will replace ICD-9-CM Volumes 1 & 2:

- Will be used by all providers in every health care setting
- CPT/HCPCS will still be used for outpatient and physician office procedures

ICD-10-PCS

(Procedural Coding System)

The code set of hospital inpatient <u>procedures</u> that will replace ICD-9-CM Volume 3

Abbreviations: ICD, International Classification of Disease; CMS, Centers for Medicare & Medicaid Services; CM, clinical modification; CPT/HCPCS, Current Procedural Terminology/Healthcare Common Procedure Coding System; PCS, procedural coding system.

has not been paid for at least 90 days; at least 25% of their patients are on Medicare; or at least 25% of their reimbursements are from Medicare.

The Protecting Access to Medicare Act of 2014, implemented on April 1, 2014, includes a provision that the Secretary of the U.S. Department of Health and Human Services may not adopt ICD-10 before October 1, 2015.[3] Nevertheless, not everyone was in favor of another delay in ICD-10 implementation. The American Hospital Association, most of the national payers, and the American Academy of Professional Coders lobbied against another delay.

Absent another delay, effective October 1, 2015, ICD-10-CM will replace ICD-9 as a HIPAA-named code set to be used on electronic, paper, fax, and phone transactions by HIPAA-covered entities, which include providers, payers, health care clearinghouses, software vendors, and third-party billing services. Furthermore, ICD-9-CM will not be maintained after implementation of ICD-10-CM, thus non-covered entities will also likely transition to ICD-10.

CREATING AND MAINTAINING A HOLISTIC ICD-10 READINESS PROGRAM

No matter if a practice is a five-physician oncology clinic or a 100-plus multispecialty physician group, a holistic approach to ICD-10 preparation is essential. For example, if a health system is focused primarily on application readiness, then issues would occur with lack of staff knowledge, workflow, gaps in clinical documentation, mitigation of payer risk, and care team overall readiness.

Below are examples of work streams that would be part of a holistic remediation approach we will describe in the following sections:

- Communication and engagement
- Application remediation and testing

KEY POINTS

- The International Classification of Disease (ICD) is used globally to identify health trends and statistics.
- In 1994, the World Health Organization adopted the 10th revision of the ICD, ICD-10.
- Despite the advantage of more precise coding under ICD-10, the United States has delayed adoption of the code set several times.
- The transition from the current ICD-9 code set to ICD-10 is a major undertaking that will require significant resources.
- Careful systematic planning is necessary to minimize costly disruptions and errors during the transition.

SIDEBAR. ICD-10-CM versus ICD-10-PCS

ICD-10-CM (Clinical Modification)
- The diagnosis code set that will replace ICD-9-CM volumes 1 and 2 and will be used by all providers in every health care setting
- Current Procedural Terminology/Healthcare Common Procedure Coding System (CPT/HCPCS) will still be used for outpatient and physician office procedures

ICD-10-PCS (Procedural Coding System)
- The code set of hospital inpatient procedures that will replace ICD-9-CM volume 3.

- Training and clinical documentation improvement
- Payer engagement and readiness
- Denial management
- Data warehouse and reporting

Along with having a balanced approach to remediation, it is important to have the right people involved, especially since ICD-10 conversion will affect essentially every role in an organization. Every person in the practice needs to know how ICD-10 will affect their daily routines. Establishing an overall ICD-10 leader and leads for each of the work streams above is ideal, and for many leads this responsibility should fall under their current role in the practice as business office manager, coding lead, trainer, etc.

To gain the leadership and financial support needed to be ICD-10 ready, it is important to have a physician champion and involve practice leadership in planning, risk mitigation, and education events to be prepared for the effects of ICD-10. Engage physicians and clinicians to understand how improved documentation will be required as part of being ICD-10 ready. Creating awareness across departments on codependent readiness tasks is needed to ensure that the right people are working together on tasks like workflow readiness, claims edits/rules remediation, reduction of unspecified codes, end-to-end testing, etc.

When practices work together on large transformations like ICD-10, it is a great opportunity for practice staff to collaborate across functional areas and learn how they are all dependent on each other to provide care to patients and maintain a high-performing revenue cycle process. Because of the duration and complexity of migrating to ICD-10, having an integrated project plan, ongoing issue and risk management process, and change management plan have been essential to managing decision making and change over an extended timeline. Much of ICD-10 readiness is risk mitigation for assurance that after October 1, 2015, the effect is minimal and a steady-state can be achieved soon after.

ENGAGEMENT AND ONGOING COMMUNICATION

Awareness throughout a practice on ICD-10 conversion (i.e., why, when, and how) needs to be continuous and widespread. Conversations on ICD-10 need to be part of weekly meetings of all teams, and regular round table meetings with the ICD-10 work-stream leads need to occur to be able to follow through on an integrated plan with strong codependencies. Every practice's culture is different and effective communication methods will vary; always be sure ICD-10 conversion is part of the conversation and every planning session. Team with your physician champion to keep ICD-10 at the forefront of conversations with his or her colleagues.

APPLICATION AWARENESS AND TESTING TO VALIDATE READINESS

Every application that contains and utilizes diagnosis codes in a practice will be affected by ICD-10 and will need to be on an ICD-10–compliant version and tested before conversion. Practices need to target their electronic health record (EHR), practice management system, laboratory information system, radiation oncology information system, claim scrubber, and any other application that carry codes for remediation. Mapping out systems affected, along with interfaces and application version required, is a basic first step to know what will need to be remediated and ready for conversion. Spend the time to keep in regular contact with application vendors to know what is required and has changed as the vendor also prepares for ICD-10.

Preparedness for ICD-10 requires more than just having each application on an ICD-10–compliant version. Applications need to be tested end to end in a nonproduction (i.e., live) environment before activating ICD-10 codes on October 1, 2015. This testing is essential to identify major defects, issues, and workflow that need attention from the point of documentation in the her, to the practice management system through the claim scrubber, and then clearinghouse to the payers and back. Ideally, a practice would have a chance to participate in acknowledgment and end-to-end testing with Medicare by teaming with a Medicare Administrative Contractor (MAC). End-to-end testing MACs and private payers often only target select providers, which limits end-to-end testing opportunities for many practices. Practices need to test early and often to minimize the potential risk of activating ICD-10 code across all applications on October 1, 2015. The Nachimson Advisors Study on ICD-10 readiness estimates ambulatory practices will spend $4,300 to $9,600 per physician on application end-to-end testing efforts and guidance.[9]

TRAINING FOR ALL PERSPECTIVES AND CLINICAL DOCUMENTATION IMPROVEMENT

Because of the diverse effects of ICD-10, training needs to be widespread and encompassing to ensure all practice staff are clear on how ICD-10 will affect their work environment. When determining who needs training, consider targeting all physicians, advanced practice providers, nurses, medical assistants, radiation therapist, coders, all business office staff, front-office staff, and any other staff members that are dependent on diagnosis codes. The Nachimson Advisors Study estimates practices will spend $480 to $1,000 per physician on training of staff and themselves.[9] This cost varies by practice size and type of training and does not include the cost of physicians' and staff's time. The study also estimates a physician will need an hour of documentation training, which will likely be the minimum, and training for coding and other staff will be much more time consuming.

Utilize a mixture of training methods to help meet the different learning needs and challenging schedules of providers and staff. Consider attending boot camps to set aside dedicated time for those who will be affected the most. Providing access to eLearning, podcasts, and illustrations of common diagnoses can help make learning more on demand and accessible. Many coders are looking to become ICD-10

certified to help assist their practices in being ready for the conversion.

Providing coders the opportunity to become ICD-10 certified is a good idea to promote the sharing of knowledge among coders and throughout the practice as a whole. Coders should also be an essential part of establishing a closed-loop process for reducing the use of unspecified codes and increasing the specificity of documentation and coding. Teams need to focus on reducing the use of unspecified codes now to decrease the risk for increased denials with ICD-10 because of lack of documentation specificity. Increased specificity means documenting more details on location, laterality, severity, sequelae, duration, stage, cell type, etc. If documented in a structured manner, some EHRs can use documentation to assist providers in selecting a diagnosis. For example, some EHRs will reduce the list of diagnoses or problem codes to ease selection based on laterality, stage, etc., and also alert the clinician when there is not enough documentation to support a specific code.

Many practices are applying the concept of dual coding to help staff learn by practicing documenting and coding in ICD-10. A dual-coding regimen leading up to the conversion can also help practices prepare for the productivity effects of coding in ICD-10 compared with ICD-9 by measuring side-by-side productivity. Dual coding can also help identify areas for clinical documentation improvement.

PAYER ENGAGEMENT AND MONITORING READINESS

Teaming with payers is essential, but it is also a challenge. Many payers are only testing with select providers or recommending that providers only test with clearinghouses and vendors. Ideally, providers would be able to perform end-to-end testing with all of their high-volume payers and receive a full round-trip test and testing results from the payers. This provides the best representation of the actual process and eventual results of converting to ICD-10 on October 1, 2015. Take advantage of any opportunities to test with Medicare, whether it be acknowledgment or end-to-end testing. For end-to-end testing with Medicare, MACs target select clearinghouses and providers, therefore practices should register to have a chance of being selected.

Payer readiness is uncontrollable from a provider perspective. Project teams should work diligently to gauge the readiness of their high-volume payers. Identify any risk that can potentially be mitigated by asking payers how they plan to handle activation tasks and stabilization support after converting to ICD-10. For example, know when payers have updated their medical policies and how they plan to handle authorization before and after the conversion.

DENIAL MANAGEMENT FOCUS ON METRICS, WORKFLOW, AND PERFORMANCE

Proactive monitoring and elimination of denials is typically part of the daily fabric of a practice's business office. With ICD-10, practices need to actively work today to reduce the potential of new future denials by increasing the specificity of documentation. Care team education and awareness on required documentation and tracking unspecified code utilization to target areas for improvement are two attributes of a closed-loop approach to improve documentation.

Comprehensive and timely metrics are essential for practices to track denial trends leading up to and after the conversion to ICD-10. Tracking performance after conversion will let practices know when steady-state has been achieved or target areas to address to get back to steady-state. Refine denial and rejection metrics to target denial reasons that are driven by diagnoses and coding. This is a good way to target areas for improvement that would otherwise be exacerbated with the introduction of ICD-10.

ICD-10 workflow remediation is the perfect opportunity to look at your denial management workflow from start to finish. Reduction of current and potential future denials can be accomplished through collaboration across teams, targeting areas for improvement based on denial trends, education, and new policies and procedures to invoke and maintain change. This is a good opportunity to apply Lean Six Sigma principles with the team for long-term improvement.

NAVIGATING CHANGE THROUGHOUT ICD-10 CONVERSION

Change is inevitable during long-term programs like ICD-10 remediation and especially now with an extended timeline. Have mitigation plans in place to help prepare for and adjust to change. There are obvious substantial changes, like the delay of ICD-10, but again with the duration of this type of remediation, always prepare for other events such as staff turnover, new substantial projects, application migrations for meaningful use, etc.

Any controllable changes definitely need to be addressed before the 90 days leading up to the ICD-10 conversion date. Ideally, this 90-day period would be a freeze period with no change to prepare for activation of ICD-10.

Beyond the inherent benefits of converting to ICD-10, seize this opportunity to achieve as much long-term value as possible from remediating practice processes, improving performance, and creating a team-based approach to improvement. Always take advantage of large systemic changes like ICD-10 to take a renewed look at how the practice team collectively provides patients access to care.

DETERIORATING QUALITY OF HEALTH CARE DATA

The quality of health care data progressively deteriorates as long as the United States continues to rely on the outdated and imprecise ICD-9-CM code set. By continuing to use the outdated ICD-9-CM code set, the United States has limited ability to extract information that will optimize public health surveillance, exchange meaningful health care data for individual and population health improvement, and move to a

payment system based on quality and outcomes. Continued use of an outdated and broken coding system erodes data quality and, thus, has an adverse effect on the value of health care data, including an increased risk for inaccurate health care decisions based on faulty and imprecise data. The ability to accurately analyze health care services provided to patients and whether care is fairly reimbursed is compromised.

Continued use of ICD-9-CM results in costs associated with:

- Inaccurate decisions or conclusions based on faulty or imprecise data
- Administrative inefficiencies because of reliance on manual processes
- Coding errors related to code ambiguity and outdated terminology
- Worsening imprecision in the ICD-9-CM code set because of the inability of the code structure to adequately accommodate desired modifications[4]

OPPORTUNITIES FOR LEVERAGING ICD-10 TO IMPROVE CARE AND REDUCE COSTS

The transition to ICD-10-CM and ICD-10-PCS (collectively referred to as "ICD-10") presents an opportunity to greatly improve the capture of information about the increasingly complex delivery of health care, leading to improvements in health care delivery and operations, better patient outcomes, and reduced health care costs. ICD-10 is the next-generation coding system that will modernize and expand the capacity of health care organizations to keep pace with changes in medical practice and health care delivery by providing higher-quality information for measuring service quality, outcomes, safety, and efficiency. The granular level of detail in ICD-10 codes is expected to generate more precise and clinically accurate characterizations of patient diagnoses, which in turn will lead to a more accurate reflection of patient conditions. The improved structural flexibility will allow for the addition of new diseases or expanded detail in the future.

Measures of health care are only meaningful if the data used to define conditions and services accurately represent the reality of care.[5] Increased precision in ICD-10 will lead to better quality measures. Better and more effective quality measures will translate to better care that will ultimately benefit consumers. The additional detail in ICD-10 will affect analytic tools, reports, and comparative data used by all quality measurement systems, including quality indicators from The Joint Commission, CMS, and the Agency for Healthcare Research and Quality, as well as clinical registries and state reporting systems.

By allowing for greater coding accuracy and specificity, ICD-10 is key to collecting the information needed to implement health care delivery innovations such as patient-centered medical homes and value-based purchasing. The investments that are being made in accountable care organizations (ACOs), meaningful use EHRs, and value-based pur-chasing are all predicated on having a more precise and comprehensive code set that is up to date with the rapid changes in practices and technologies utilized in today's health care system. ICD-10 will enable better patient care through better understanding of the value of new procedures, improved disease management, and an improved ability to study and understand patient outcomes, yielding benefits to patients far beyond cost savings. Better understanding of diseases and injuries will lead to improved prevention or mitigation strategies. Clinically robust algorithms to treat chronic diseases and track outcomes of care can be designed.

New models of health care payment and patient management, such as ACOs, bundled payments for episodes of care, pay for outcomes, risk sharing for total costs of care, and patient-centered medical homes will create increased demand for detailed, high-quality data. Accurate, detailed health care data will be needed to construct risk analyses and predictive models that allow rational risk sharing. Patient populations need to be defined, care paths assessed, and care outcomes understood much more clearly and deeply than they are today if payers, employers, and providers are to negotiate as equals. Additionally, information that drives regional or national health care policies relies on intelligence derived from coded data. Decisions are only as good as the information those decisions are based on. Better data will translate to better decisions.[5]

EHRs and interoperability require a modern code set for summarizing and reporting data. Without ICD-10, the U.S. investments in EHRs is greatly diminished, as the value of more comprehensive and detailed health information is lost if it is aggregated into outdated, broad, ambiguous codes. The health care industry has struggled to define health information standards that will allow true interoperability and the ability to analyze "big data" across enterprises.[5] ICD-10 is needed to exchange meaningful data. Also, many public and national health information systems, reporting programs, and data sets rely on accurate and timely diagnosis codes to classify and track disease morbidity and mortality, quality of care, and health disparities, and monitor public health threats. Use of ICD-10 will standardize the reporting of public health data (including disease outbreaks and bioterrorism events) across the globe, achieve international health data comparability, and enable international comparisons of quality of care and sharing of best practices among countries.

Since ICD-10 has been used for mortality reporting in the United States since 1999, the implementation of ICD-10 for morbidity reporting would achieve comparability between mortality and morbidity data, resulting in enhanced data for improving community health and administrative cost savings. In many states, mortality data are cross-analyzed with hospital data to develop intervention strategies. Resources are being wasted to convert mortality data back to ICD-9-CM to correlate with hospital data.

Anticipated benefits of using more robust, up-to-date code sets can be identified in the following areas[6]:

Quality measurement

- Better data for evaluating and improving quality of care
- Reduction in complications and improved patient safety
- Improved patient outcomes
- Greater ability to measure outcomes, efficacy, and costs of new medical technology
- Greater ability to ascertain disease severity for risk and severity adjustment
- Greater ability to manage chronic diseases

Public health

- Enhanced public health surveillance
- Greater ability to track and respond to global health threats
- Facilitate international comparisons of quality of care and global sharing of best practices

Research

- Code analysis is essential to research when direct access to patient records is not possible
- Data could be used in more meaningful ways to enable better understanding of complications, better design of clinically robust algorithms, and better tracking of the outcomes of care
- Greater detail offers the ability to discover previously unrecognized relationships or uncover phenomenon such as an incipient epidemic early
- Expanded injury research and successful injury prevention strategies
- Organizational monitoring and performance
- Administrative efficiencies
- Cost containment
- More accurate trend and cost analysis
- Improved ability to analyze trend and cost data
- More effective monitoring of resource and service utilization
- Reduced submission of medical record documentation to support reimbursement claims
- Reduced reliance on manual medical review
- Improved coding accuracy and productivity

Reimbursement

- More accurate and fair reimbursement
- Better justification of medical necessity
- Fewer erroneous and rejected claims
- Increased sensitivity when making refinements in applications, such as grouping and reimbursement methodologies
- Reduced opportunities for fraud and improved fraud detection capabilities

Health information technology

- Realize benefits of SNOMED-Clinical Terms and interoperable health data exchange
- Facilitate electronic data retrieval
- Expanded computer-assisted coding technologies

Health policy and strategy

- Improved information for setting health policy
- Better data for operational and strategic planning

- Better data for designing health care delivery

ICD-10 can be viewed as the hub of a number of major health information technology initiatives (Fig. 2).[7]

ICD-10 BENEFITS FOR PATIENTS AND CONSUMERS

The higher-quality health information produced by ICD-10 will benefit patients and consumers. Although clinical research in controlled studies is invaluable, it is necessary to have standard and universally available data across all health care settings to assess health care delivery across providers, payers, populations, and regions. Today, that data primarily come from coded data reported on reimbursement claims.

Better information around metrics such as risk, complexity, comorbidities, complications, sequelae, severity, health care–associated conditions, safety, and effectiveness of treatment is essential for improving our health care delivery system, properly allocating resources, and ultimately improving patient care. The more specific the diagnostic information is, the easier it is to identify the best treatment and avoid potential complications. Greater detail also offers the ability to discover previously hidden relationships or uncover phenomena such as an incipient epidemic early. ICD-10 provides much more detail about adverse clinical events and medical device complications, allowing better identification and tracking of these occurrences so that more effective strategies can be developed to reduce the incidence and clinical consequences of these events. Not only will better data lead to improved care of the individual patient, but the health of populations locally, regionally, and nationally will also be improved.

Improved diagnostic data will permit improved identification of patients for disease management programs and more effective tailoring of these programs to meet individual patient needs, thus, improving patient outcomes, patient satisfaction, and lowering health care costs. ICD-9-CM codes describe many chronic diseases in general terms, whereas

FIGURE 2. ICD-10 and Health Information Technology Initiatives

Abbreviations: ICD, International Classification of Disease; ACO, accountable care organization.

ICD-10 recognizes distinctions in clinical conditions and severity that can help segment patient populations within a disease category. ICD-10 offers opportunities for improved, automated identification, stratification, and segmentation of patient populations. With greater code specificity, better algorithms can be developed to identify and target-specific patient populations and subpopulations for disease management programs and customize programs for patients with differences in severity or risk. Target groups' progress toward goals and effectiveness of treatment can be monitored through the clinical and severity distinctions in ICD-10 codes. As more ICD-10 data is collected and additional ICD-10 experience is gained, prediction models can be greatly enhanced to more accurately predict risk within populations by a number of refined parameters. Superior data will improve the ability to evaluate the effectiveness of disease management programs in improving patient outcomes, reducing the incidence of acute episodes, and decreasing health care costs.

Ultimately benefiting patients, better data will support:

- Improvements in patient outcomes and patient safety through better data for analysis and research
- Improved ability to manage chronic diseases by better capturing patient populations
- More accurate reflection of patients' clinical complexity and severity of illness
- Improved ability to identify high-risk patients who require more intensive resources
- Improved ability to manage population health
- Improved information sharing, which can enhance treatment accuracy and improve care coordination
- Improved ability to assess effectiveness and safety of new medical technology
- Improved diagnosis of chronic illness and identification of underlying causes, complications of diseases, and conditions that contribute to disease complexity
- More accurate reflection of clinical complexity and severity of illness
- Increased patient engagement

Complete and accurate data must be reported to put the most appropriate picture of the quality of care delivery in front of increasingly sophisticated and informed potential patients. With better data will come an expanded ability to educate consumers on costs and outcomes of treatment options. Increased patient understanding and involvement in their health care will improve the population's health and decrease the cost of health care.

ICD-10 BENEFITS FOR CLINICIANS

The transition to ICD-10 also benefits clinicians. Compared with ICD-9-CM, medical terminology and classification of diseases are more consistent with current clinical practice and medical knowledge (e.g., newly recognized conditions are identified and conditions with a recently discovered etiology have been reclassified). Many physician specialty societies have actively contributed to the clinical content of ICD-

10-CM/PCS and continue to be involved in the annual updating process to ensure the code sets represent current clinical knowledge. The increased specificity will provide better justification of medical necessity for treatment and diagnostic tests. Exchange of patients' clinical information will be more efficient. Better data on patients' clinical conditions will help to validate reported evaluation and management codes and result in less misinterpretation by auditors, attorneys, other third parties. More detailed data facilitates the informed use of both business intelligence and clinical dashboards. Business intelligence dashboards make performance and trend data more readily available and, thus, facilitate attainment of meaningful use criteria. Clinical dashboards have the potential to drive better care paths and achieve better clinical outcomes.

The increased granularity of ICD-10 will enable more directed clinical decision support. When a patient has multiple medical conditions or manifestations of a condition, the failure of clinical decision support to take into account all of the patient's clinical factors can result in: (1) lack of oversight or specific monitoring of manifestations and (2) medication protocols and their effect on the patient during and after treatment. The ability to fully leverage clinical decision support tools will help direct clinician monitoring to avoid complications or adverse drug events.

In an accountable care environment, providers need to assume an essential role in determining and prioritizing those services that offer the greatest benefit in the context of financial constraints. Models that allow providers who are part of integrated delivery systems to take on the risk of care delivery and share the rewards of high-quality, efficient care are continuing to evolve. The ability of ICD-10 to provide better detail to define risk, severity, anatomic detail, comorbidities, complications, disease phases, sequelae, and other key parameters of the patient's health state will be critically important in effectively managing patients and benefiting from efficient care delivery.[5]

The move to ICD-10 will also lead to increased administrative efficiencies and, thus, lower administrative costs. These reduced administrative costs come from improved coding accuracy and productivity, fewer pended or denied reimbursement claims because of more information provided by the submitted codes, and fewer payer requests for submission of supporting medical record documentation (because of more detailed information provided by the codes). The increased specificity, representation of current clinical knowledge, and use of more up-to-date medical terminology will make ICD-10 codes easier to assign than ICD-9-CM codes. In the long-term, after the learning curve has ended, it is expected that the use of ICD-10 will result in fewer coding errors than ICD-9-CM because ICD-10 is less ambiguous and more logically organized. The ambiguity in ICD-9-CM and use of outdated terminology that does not correspond to terms used in clinical documentation makes ICD-9-CM confusing, difficult to use, and open to misinterpretation. The increased specificity in ICD-10 will also facilitate the development of more sophisticated automated coding tools to as-

sist with proper code selection, thereby, improving coding accuracy and compliance with payment policies, increasing administrative efficiencies, and reducing manual labor involved in the coding process. For all of these reasons, coding productivity is expected to improve over time, once the learning curve to become familiar with the new codes has ended. In fact, computer-assisted coding technology may increase coder productivity by as much as 30% to 50%.[8]

umentation led to the inclusion of the expanded detail and specificity in ICD-10. Since precise medical record documentation is critical to support ICD-10 codes, the transition to ICD-10 can help to achieve high-quality documentation by advancing documentation assessment and improvement efforts. Ensuring high-quality documentation and thorough coder preparation minimizes the adverse effects of the ICD-10 transition on coding accuracy and productivity, which in turn reduces the potential for rejected claims and payment errors.

LEVERAGING TECHNOLOGY TO IMPROVE CLINICAL DOCUMENTATION

The transition to ICD-10 presents opportunities for innovations in improving the quality of clinical documentation while minimizing the burden of documentation capture on clinicians. For example, technology can be leveraged to facilitate documentation capture at the point of care (such as the use of prompts or templates in EHRs). Mobile devices can be used to provide physicians with customized lists of documentation tips.

High-quality documentation is increasingly in demand to support many emerging health care initiatives aimed at improving care and reducing costs. Growing demands for more detailed diagnostic data generated from medical record doc-

BENEFITS OF ICD-10 PREPARATION IN ADVANCE OF TRANSITION

Many ICD-10 preparation activities can provide value in advance of the transition to ICD-10. Clinical documentation is necessary for supporting many health care initiatives, including improving the quality of care, lowering health care costs, measuring mortality risk and severity of illness, analyzing readmission rates, and meeting meaningful use requirements. Also, high-quality documentation will help improve today's ICD-9-CM coding accuracy. Accurate and complete documentation is important for good patient care regardless of the code set in use. ICD-10 education has been shown to improve ICD-9-CM coding accuracy, as basic coding principles are reinforced and foundational knowledge in biomedical sciences is strengthened.[6]

Targeted and Immunotherapeutic Approaches in Brain Metastases

Manmeet S. Ahluwalia, MD, and Frank Winkler, MD

OVERVIEW

Brain metastases are a common and devastating complication of cancer. The approach to the management of brain metastases is often multidisciplinary and includes surgery, whole-brain radiation therapy (WBRT), stereotactic radiosurgery (SRS), and systemic therapeutic agents. Until recently, systemic therapy has had a limited role in the management of brain metastases because of a lack of activity, challenges of blood-brain barrier penetration, the heterogeneous patient population, and a heavily pretreated patient population. Advances in the understanding of the biology of brain metastases and molecularly defined disease subsets have facilitated an emerging role of novel therapeutic agents, including targeted therapies and immunotherapy, in the management of brain metastases.

Brain metastases are serious complications of systemic cancer that occur in 10% to 30% of adults with cancer.[1] The most common malignancies that metastasize to the brain are lung, breast, and melanoma.[2-5] Eighty percent of patients present with brain metastases within the cerebral hemispheres; 15% are within the cerebellar hemispheres and 5% are within the brainstem.[6] Key determinants in the management of brain metastases include the tumor histology, number, size, and site of lesions; the status of extracranial metastases; and the performance status of the patient. One of the challenges in the development of effective therapies for brain metastases is the presence of the blood-brain barrier, a highly selective permeability barrier made of capillary endothelial cells connected by tight junctions and astrocyte foot processes that limit entry of systemic therapies into the brain.[7,8] In addition, active transport mechanisms of drug efflux and high plasma protein binding of agents further lower the volume of distribution of agents in the brain parenchyma.[8] An additional challenge is that patients who develop brain metastases often are heavily pretreated with tumors that are more likely to be resistant to therapy at diagnosis of the brain metastases. The role of systemic therapy (chemotherapy, targeted agents, or immunotherapy) in brain metastases is not well defined, because there is no level-1 evidence favoring the use of systemic therapy compared with local approaches. However, in recent years, the development of novel cytotoxic agents and targeted therapies with better blood-brain barrier penetration have increased the interest in use of systemic therapies in brain metastases.

TARGETING BRAIN HOST CELLS

Another potential mechanism of resistance in metastatic tumor cells in the brain is their interaction with brain resident cells. The brain metastatic process depends on the perpetuation of a perivascular niche, at least during the early steps,[9] and this niche has been associated with promotion and/or maintenance of a stem-like and resistant cellular phenotype, per se, in brain tumors. The components of the blood-brain barrier (endothelial cells, pericytes, astrocytic foot processes, and/or the vascular basement membrane)[10] are likely candidates to provide this supportive niche for cancer cells. Conversely, the high inefficiency of the brain metastatic process (with 95% to 99% of brain-arrested cancer cells failing to successfully grow to a macrometastasis[9]) raises the question of whether some of these components are more foe than friend for extravasating cancer cells in the brain. A recent report suggested that the astrocyte-produced plasminogen activator forces brain metastatic cancer cells into apoptosis and that cancer cells need to inhibit this process to survive this brain protective mechanism.[11] In contrast, astrocytes might protect brain metastatic cancer cells from the adverse effects of chemotherapy by buffering intracellular calcium increases via gap junction coupling and other mechanisms.[12] Thus, the role of many brain resident cells appears to be complex, and further research is required to understand the potential to target them for brain metastasis prevention or treatment. The brain endothelial cell (the main cell type reacting to angiogenic growth factors produced by tumor cells) appears to be among the most promising cellular target that is emerging, as detailed in this review.

TARGETING ANGIOGENESIS

Preclinical data from multiple animal models support the potential role of antiangiogenic agents for the prevention and treatment of brain metastases. Elevated vascular endothelial growth factor (VEGF) expression has been linked to the development of brain metastasis in a murine model.[13] Kim et al[14] showed that treatment with a VEGF receptor tyrosine kinase inhibitor reduced angiogenesis and restricted the growth of brain metastasis in a murine breast cancer model.[14] In another mouse model, inhibition of VEGF signaling using bevacizumab efficiently inhibited angiogenesis-dependent macrometastases formation of brain-metastasizing lung adenocarcinoma cells, arresting micrometastases in a chronic dormant state.[9] However, the growth pattern of different tumor (sub-)types in the brain is highly different; for example, lung carcinoma is highly angiogenesis dependent, and melanoma is less dependent on angiogenesis (because of the ability to grow co-optively along pre-existing brain microvessels[9]). These preclinical observations support the clinical evaluation of antiangiogenic agents in brain metastases therapy and prevention. Antiangiogenic agents (e.g., those targeting the VEGF pathway) have to reach only the endothelial cell to inhibit ligand-receptor interactions and may not need to fully cross the blood-brain barrier. Initial experience with bevacizumab in six patients who had non–small cell lung cancer (NSCLC) with brain metastases was shown to be safe and resulted in a partial response in two patients,

stable disease in three patients, and disease progression in one patient.[15] Initial safety concerns about the risk of bleeding in the brain with such agents have not been supported by reported experience.[16] A phase II trial of bevacizumab in combination of carboplatin showed an overall response rate in the central nervous system (CNS) of 45% by RECIST.[17] An initial report of a phase II study of cisplatin, etoposide, and bevacizumab demonstrated a response rate of 60% in patients who have breast cancer with brain metastases.[18] These high response rates with bevacizumab may be a result of pseudoresponse (decrease in contrast enhancement on MRI because of the antipermeability effect of bevacizumab on the vasculature) and not necessarily an antitumor effect.[19]

TARGETING EPIDERMAL GROWTH FACTOR RECEPTOR AND ANAPLASTIC LYMPHOMA KINASE IN LUNG CANCER WITH BRAIN METASTASES

Approximately 40% to 50% of patients who have locally advanced NSCLC will develop brain metastases.[20] Activating mutations in the epidermal growth factor receptor (*EGFR*) occur in approximately 10% to 15% of NSCLC. Multiple small-molecule tyrosine kinase inhibitors, such as erlotinib, gefitinib, and afatinib, are U.S. Food and Drug Administration (FDA) approved for the treatment of lung cancer with *EGFR* mutations. An *EGFR* inhibitor, such as erlotinib, can serve as a potential radiation sensitizer to increase the efficacy of the radiation. In a phase II study of 40 patients who had NSCLC with brain metastases, the combination of whole-brain radiation therapy and erlotinib was reported to be safe (no reported increase in neurotoxicity).[21] The median survival time was 11.8 months for the whole cohort. The overall survival (OS) time was 19.1 months in the patients with mutant *EGFR* compared with an OS time of 9.3 months in the patients with wild-type *EGFR* (Table 1).[21] However, a phase III trial (RTOG 0320) failed to show any additional benefit of erlotinib in combination with WBRT and stereotactic radiosurgery (SRS) in patients who had brain metastases from NSCLC.[22] However, one limitation of the study was that patients were not stratified according to *EGFR* mutational status. In a large cohort of 110 patients who had *EGFR*-mutant lung cancer with newly diagnosed brain metastases, patients treated with WBRT (32 patients) had a longer median time to intracranial progression than the 63 patients who received erlotinib as up-front therapy (24 vs. 16 months).[23] Patients treated with erlotinib or SRS experienced intracranial failure as a component of first failure more often, whereas patients who received WBRT experienced failure outside the brain more often. The OS was similar between the WBRT and erlotinib groups; patients treated with SRS initially had a longer OS than those who received erlotinib. In a phase II study of 41 patients who had NSCLC (unselected for *EGFR* mutation), treatment with gefitinib resulted in an objective response rate of 10% in the brain.[24] Higher response rates with *EGFR* inhibitors have been reported in studies that are enriched with pa-

KEY POINTS

- A multidisciplinary approach involving the neurosurgeon, medical oncologist, neuro-oncologist, and radiation oncologist is recommended in the management of brain metastases.
- A number of agents that target epidermal growth factor receptor and anaplastic lymphoma kinase mutations have been effective in the treatment of brain metastases that harbor these mutations.
- The greatest advances in the systemic treatment of breast cancer brain metastases have been made in patients who have *HER2*-positive disease.
- Small-molecule tyrosine kinase *BRAF* inhibitors that target *BRAF*^V600-mutant melanoma have demonstrated activity in active melanoma brain metastases. Ipilimumab is an immunotherapeutic agent that has demonstrated activity in a prospective, phase II trial conducted in patients who have melanoma with asymptomatic brain metastases. (Patients who did not require corticosteroid therapy had a better response than those who needed corticosteroids because of brain edema.)
- There is a need for prospective clinical trials to test new combinations of targeted and immunotherapeutic agents with local therapies to address the optimal sequencing of local and systemic therapies in the management of brain metastases.

TABLE 1. Selected Clinical Trials with Targeted Agents and Immunotherapy in Brain Metastasis

Study	Year	Study Design	Patient Population	Therapeutic Intervention	No. of Patients	Median PFS (Months)	Intracranial RR (%)	Median OS (Months)
Ceresoli et al[24]	2004	Phase II	New and recurrent NSCLC- BM	Gefitinib	41	3	27	5
Wu et al[69]	2007	Single arm, phase II	New and recurrent NSCLC- BM	Gefitinib	40	9.0	32	15.0
Sperduto et al[22] (RTOG-0320)	2013	Three arm, phase III	New NSCLC-BM	WBRT + SRS	44	8.1	–	13.4
				WBRT+ SRS + temozolomide	40	4.6	–	6.3
				WBRT + SRS + erlotinib	41	4.8	–	6.1
Welsh J et al[21]	2013	Single arm, phase II	New NSCLC-BM	WBRT + erlotinib	40	8.0	86	11.8
Lee et al[70]	2014	Phase II, double blind, placebo controlled	New NSCLC-BM	WBRT	40	1.6	–	2.9
				WBRT + erlotinib	40	1.6	–	3.4
Long et al[48] (BREAK-MB)	2012	Open label, two cohort, phase II	New and recurrent *BRAF*-positive MBM	Dabrafenib	Cohort A, V600E (new): 74	4.0	39.2	8.2
					Cohort A, V600K (new): 15	2.0	6.7	4.0
					Cohort B, V600E (recurrent): 65	4.1	30.8	7.8
					Cohort B, V600K (recurrent): 18	4.0	22.2	5.4
Kefford et al[51]*	2015	Open label, two cohort, phase II	New and recurrent *BRAF*-positive MBM	Vemurafenib	Cohort 1 (recurrent): 90	4.0	18	7.0
					Cohort 2 (new): 56	4.3	20	6.9
Bachelot et al[40] (LANDSCAPE)	2013	Open label, phase II	HER2+ BCBM	Lapatinib + capecitabine	45	5.5 months (TTP)	66	17
Lin et al[71]	2009	Phase II	HER2+ BCBM	Lapatinib	242	2.4 months	6	6.4

Abbreviations: PFS, progression-free survival; RR, response rate; OS, overall survival; NSCLC-BM, non-small cell lung cancer brain metastases; WBRT, whole-brain radiation therapy; SRS, stereotactic radiotherapy; MBM, melanoma brain metastases; BCBM, breast cancer brain metastasis; TTP, time to tumor progression.
*Preliminary results.

tients who have known *EGFR* mutations.[25,26] In a phase II study, treatment with erlotinib or gefitinib resulted in partial response rate of 83% and a disease control rate of 93% in 28 patients who had *EGFR*-mutant NSCLC with brain metastases.[25] A recent pooled analyses also strongly suggests that EGFR tyrosine kinase inhibitors are an effective treatment for patients who have NSCLC with brain metastases.[27] Erlotinib appears to achieve higher cerebrospinal fluid concentrations than gefitinib.[28]

Approximately 2% to 7% of patients who have NSCLC harbor rearrangements in the anaplastic lymphoma kinase *(ALK)* gene that encodes a cytoplasmic chimeric protein with constitutive kinase activity.[29] Crizotinib is an oral kinase inhibitor approved for the treatment of *ALK*-rearranged NSCLC. An analysis of 275 patients with asymptomatic brain metastases who were randomly assigned to the crizotinib arm in the PROFILE 1005 or 1007 studies included 109 patients who were radiation naive and 166 patients who had received prior brain radiotherapy.[30] The systemic disease control rate (DCR) at 12 weeks was 63%, the intracranial DCR was 56%, and the median intracranial time to progression (TTP) was 7 months in the radiation-naive group. In the cohort of patients who had previous radiation therapy, the systemic DCR was

65%, the intracranial DCR was 62%, and the median intracranial TTP was 13.2 months.

TARGETING HER2 IN BREAST CANCER BRAIN METASTASES

An estimated 10% to 30% of all patients with breast cancer will eventually develop brain metastases.[31] The greatest advances in systemic treatment of brain metastases in patients with breast cancer have been made in patients with *HER2*-positive disease primarily because of the advent of efficacious *HER2*-directed agents. Approximately one-third of patients who have advanced *HER2*-positive breast cancer develop brain metastasis, which is responsible for death in half of these patients.[32,33] Large monoclonal antibody agents, such as trastuzumab, trastuzumab-emtansine (T-DM1), and pertuzumab, may not penetrate the blood-brain barrier. However, PET imaging data in a limited number of patients using [89]Zr-trastuzumab have demonstrated CNS uptake of trastuzumab into brain metastases, which suggests an ability of trastuzumab to cross a disrupted blood-brain barrier.[34] There is some evidence that these patients may derive additional benefit with the continuation of trastuzumab after development of breast

cancer brain metastasis.[35] There are multiple cases of *HER2*-positive breast cancer with brain metastasis that show a CNS response to T-DM1.[36,37]

Lapatinib, a small-molecule tyrosine kinase inhibitor of *HER1* and *HER2*, is FDA approved for metastatic HER2-positive breast cancer after progression occurs during treatment with trastuzumab in combination with capecitabine. There is preclinical evidence that lapatinib has activity in *HER2*-positive breast cancer with brain metastasis in mouse models that led to clinical trials of lapatinib in HER 2-positive breast cancer with brain metastasis (Table 1).[38] However, in a phase II study of 242 patients who had HER2-positive breast cancer and progressive brain metastases (after radiation), monotherapy with lapatinib resulted in an intracranial response rate of 6%.[39] During disease progression in the same study, 10 of the 50 patients (20%) who received a combination of lapatinib and capecitabine showed an objective response in the brain. In the LANDSCAPE study, a combination of lapatinib plus capecitabine in previously untreated patients with HER2-positive breast cancer with brain metastasis resulted in an objective CNS response in 29 of the 45 patients (66%) and a median time to CNS progression of 5.5 months.[40]

There are number of ongoing studies (Table 2) on HER2-positive breast cancer with brain metastasis that include the cooperative-group randomized, phase II study of WBRT with or without lapatinib in patients who have HER2-positive breast cancer with brain metastasis. This study (NCT01622868) evaluates lapatinib as a radiosensitizer in combination with WBRT.[41] Other HER2-directed therapies under active investigation in breast cancer with brain metastases include the irreversible HER2 inhibitors neratinib (NCT01494662)[42] and afatinib (NCT01441596).[43] ARRY-380, a HER2-selective inhibitor with some ability to cross the blood-brain barrier and activity in intracranial tumor mod-els, is undergoing evaluation in combination with trastuzumab (NCT01921335).[44]

TARGETING *BRAF* IN MELANOMA BRAIN METASTASES

Brain metastases are a substantial problem in melanoma and occur in up to 50% of patients with metastatic melanoma.[45] Activating *BRAF* mutations that result in constitutive activation of the mitogen-activated protein kinase pathway occur in 40% of patients with melanoma. More than 95% of *BRAF* mutations are the V600E mutation (substitution of valine by glutamic acid at the 600th amino acid position). Other mutations seen in melanoma include *NRAS* (20%) and *KIT* (2%). Patients who harbor these mutations may be at a higher risk for developing brain metastases, as demonstrated in a study in which 24% and 23% of patients who had stage IV melanoma and *BRAF* and *NRAS* mutations, respectively, had CNS involvement at the time of diagnosis, compared with 12% of patients who did not harbor these mutations.[46]

Promising initial activity was seen in 10 patients with untreated, asymptomatic brain metastases who were enrolled in the phase I study of dabrafenib, a BRAF inhibitor. There were four brain complete responses and four brain partial responses.[47] This led to the open-label phase II study, BREAK-MB (*BRAF*-mutant melanoma metastatic to the brain). In this trial, 172 patients who had V600E or V600K mutation–positive melanoma brain metastases received dabrafenib monotherapy.[48] Eighty-nine patients in cohort A were naive to local therapy (no prior local therapy), and 83% of patients in cohort A and 78% (65 of 83 patients) in cohort B had *BRAF*^{V600E}-mutant melanoma. This study demonstrated the activity of a *BRAF* inhibitor in patients who had *BRAF*^{V600E}-mutant melanoma metastatic to the brain, irrespective of prior local therapy. The response rates were lower

TABLE 2. Selected Ongoing Clinical Trials of Targeted and Immunotherapeutic Agents in Brain Metastasis

Intervention	Phase	Primary Malignancy	Target	Anticipated Enrollment (No. of Patients)	CT No.
WBRT vs. erlotinib + WBRT[72]	III	NSCLC	*EGFR*	224	NCT01887795
Veliparib + WBRT vs. WBRT[73]	II	NSCLC	PARP	307	NCT01657799
Pembrolizumab[63]	II	Melanoma and NSCLC	PD-1	64	NCT02085070
Radiation + ipilimumab[74]	II	Melanoma	CTLA-4	66	NCT02115139

Dabrafenib[49]	II	Melanoma	*BRAF*	39	NCT01721603
Nivolumab + ipilimumab[76]	II	Melanoma	PD-1/CTLA-4	148	NCT02320058
Everolimus + trastuzumab + vinorelbine[77]	II	Breast	*HER2*	35	NCT01305941
BKM 120 + trastuzumab[78]	II	Breast	*HER2*/PI3K	72	NCT01132664
WBRT ± lapatinib[41]	II	Breast	*HER2*	143	NCT01622868
HKI-272 (neratinib)[42]	II	Breast	*HER2*	105	NCT01494662
Afatinib[43]	II	Breast	*HER2*	121	NCT01441596
ARRY-380 + trastuzumab[44]	I	Breast	*HER2*	50	NCT01921335

Abbreviations: CT, clinical trials; WBRT, whole-brain radiation therapy; NSCLC, non-small cell lung cancer; PARP, poly(ADP-ribose) polymerase; PD-1, programmed cell death protein 1; CTLA-4, cytotoxic T-lymphocyte-associated antigen 4; PI3K, phosphatidylinositol 3-kinase.

in patients in cohort B who had progressive brain metastases after some initial local therapy (surgery, WBRT, and SRS). Dabrafenib therapy resulted in a 39% intracranial response rate (29 of 74 patients in those with V600K mutations); 7% (one of 15 patients) and 22% patients (four of 18 patients) in cohorts A and B, respectively, achieved intracranial response. There is an ongoing study of dabrafenib in combination with SRS in $BRAF^{V600E}$-mutated metastatic melanoma (NCT01721603).[49]

In an open-label pilot study, 24 patients who had $BRAF^{V600}$ mutation–positive melanoma with brain metastases were treated with vemurafenib, a $BRAF$ inhibitor. Three of 19 patients who had measurable brain disease achieved a partial response, and seven of 19 patients (37%) achieved at least 30% tumor regression.[50] A phase II trial of 146 patients who had $BRAF^{V600}$ mutation–positive melanoma with active brain metastases and who were treated with vemurafenib was recently reported.[51] Cohort 1 consisted of 90 patients without any prior local treatment for brain metastases, and cohort 2 included 56 patients who had progressive brain metastases after prior local therapy. Vemurafenib resulted in intracranial objective response rates of 18% (16 of 90 patients) and 20% (11 of 56 patients) in cohorts 1 and 2, respectively. The median progression-free survival and OS were similar in both cohorts (3.7 and 6.5 months, respectively, in cohort 1, and 4.0 and 6.4 months, respectively, in cohort 2).

IMMUNOTHERAPY IN MELANOMA BRAIN METASTASES

Traditionally, the CNS was considered an immunologically privileged site because of the restriction of the conventional circulation of lymphocytes and antibodies by the blood-brain barrier. Recently, though, the concept of immunologic privilege in the CNS has been refuted.[52] There is evidence that activated T cells can patrol the CNS in an antigen-independent and unrestricted manner and then return to the systemic circulation.[53] Several studies have confirmed that T cells can cross the blood-brain barrier,[54] thereby supporting the strategy of T-cell responses as an antitumor approach.[55]

Cytotoxic T-lymphocyte–associated antigen 4 (CTLA-4) is an inhibitory immune checkpoint that downregulates T-cell proliferation. Blockage of CTLA-4 results in T-cell proliferation and an associated immunologic response, leading to interleukin-2 production and cytotoxic activity.[56] Ipilimumab is a monoclonal antibody against CTLA-4 that has showed activity in patients who have melanoma with brain metastases. Eighty-two patients with stable brain metastases off corticosteroids were enrolled in MDX-020, a randomized, double-blind, and placebo-controlled trial of ipilimumab plus gp100 versus ipilimumab alone versus gp100 glycoprotein vaccine.[56] The toxicity profile of ipilimumab in these patients was similar to that seen with other studies, and there were no additional safety concerns.

This led a phase II study of 72 patients who had melanoma with brain metastases and who were treated with ipilimumab.[57] The patients were divided in two cohorts depending on corticosteroid use and age: cohort A included 51 patients who had asymptomatic brain metastases, and cohort B included 21 patients who were neurologically symptomatic and receiving corticosteroids. Some patients had received prior brain radiotherapy. Global disease control (defined as complete response or partial response or stable disease) after 12 weeks as assessed by modified World Health Organization criteria was seen in 18% (nine of 51 patients) in cohort A and in 5% (one of 21 patients) in cohort B. Using the immune-related response criteria, the response rates were 24% (13 of 51 patients) and 10% (two of 21 patients) in cohorts A and B, respectively. Eight of 51 patients in cohort A had a partial response, and four had stable disease, which provided a disease control rate in the brain of 23.5%. The response rate in cohort B was lower, with one patient each having a partial response or stable disease in brain. The median OS and the 24-month survival rate were 7.0 months and 26%, respectively, in cohort A and 3.7 months and 10%, respectively, in cohort B.

A phase II study of ipilimumab in combination with fotemustine included 20 patients who had asymptomatic brain metastases. This study showed intracranial disease control in 50% of patients who had melanoma with brain metastases (10 patients). Five patients had stable disease or a partial response, and five patients had a complete response.[58]

Anti-programmed cell death protein 1 (PD-1) antibodies are checkpoint inhibitors that block the interaction between the PD-1 receptor, expressed on T cells, and a ligand, programmed death ligand 1 (PD-L1), expressed on tumor cells and resulting in inactivation of T cells at the tumoral level and augmenting the antitumor immune response. Two agents in this class, nivolumab and pembrolizumab, have shown promising activity and some durable responses in metastatic melanoma.[59-62] There is an ongoing phase II study of pembrolizumab in patients who have brain metastases from NSCLC and melanoma (NCT02085070).[63]

OUTLOOK: FROM TREATMENT TO PREVENTION

The advent of targeted therapies has facilitated the transition from the previous practice of treating brain metastasis according to a rather crude algorithm,[64] which at times did not take into consideration the histologic tumor type, to a more rational treatment approach based on individual tumor characteristics. Patients with brain metastases have long been systematically excluded from clinical trials, although there is a growing recognition in the physician community that there is no rationale to continue to do so.[65] We expect the development of more trials that focus on systemic targeted therapies in brain metastases in the future. Such studies should implement molecular stratification factors whenever possible. Basic and translational investigations are needed to identify novel molecular targets and also to understand secondary resistance mechanisms that are likely to limit lasting effects of many targeted drugs. The use of RECIST to measure the tumor response of molecularly targeted agents may underestimate their effectiveness, because prolonged tumor stabilization is a common finding with some of these agents.

However, the potential of targeted agents (like classical chemotherapy) to prevent metastases, including brain metastases, has rarely been systemically addressed.[66,67] In general, clinical trials are not (yet) designed to prospectively investigate the rate of metastasis formation. Given that the vast majority of patients with cancer die from metastatic disease and not from the primary tumor, and given that brain metastases constitute a most serious neurologic complication of cancer, brain metastasis is an important area for future preclinical and clinical cancer research.[68] Targeted therapies are excellent candidates for such brain metastases prevention studies; they often can be given to patients over prolonged periods of time with good tolerability.

CONCLUSION

A multidisciplinary strategy is recommended for the individualized management of brain metastases for every patient. An approach that includes surgery, WBRT, SRS, or systemic therapy, or a combination of these modalities, often is advocated on the basis of the performance status, age, tumor type, number of metastases, and extracranial disease status of patient. There is emerging data that targeted agents and immunotherapeutic approaches have activity in the brain, which is likely to develop a significant impact on the intracranial disease. The optimal timing of systemic therapies (therapeutic or prophylactic) remains to be determined.

Whole-Brain Radiotherapy and Stereotactic Radiosurgery in Brain Metastases: What Is the Evidence?

Minesh P. Mehta, MD, and Manmeet S. Ahluwalia, MD

OVERVIEW

The overall local treatment paradigm of brain metastases, which includes whole-brain radiotherapy (WBRT) and stereotactic radiosurgery (SRS), continues to evolve. Local therapies play an important role in the management of brain metastases. The choice of local therapy depends on factors that involve the patient (performance status, expected survival, and age), the prior treatment history, and the tumor (type and subtype, number, size, location of metastases, and extracranial disease status). Multidisciplinary collaboration is required to facilitate an individualized plan to improve the outcome of disease in patients with this life-limiting complication. There has been concern about the neurocognitive effects of WBRT. A number of approaches that mitigate cognitive dysfunction, such as pharmacologic intervention (memantine) or a hippocampal-sparing strategy, have been studied in a prospective manner with WBRT. Although there has been an increase in the use of SRS in the management of brain metastases in recent years, WBRT retains an important therapeutic role.

One of the first descriptions of WBRT is from Chao et al,[1] who demonstrated a high rate of short-duration palliation. Several subsequent large trials established a significant palliative role for this modality. Borgelt et al[2] demonstrated equivalency between various dose-fractionation schema by reviewing the Radiation Therapy Oncology Group (RTOG) trial outcomes; currently, 30 Gy in 10 fractions and 37.5 Gy in 15 fractions are considered standard doses for WBRT.[2] For almost 5 decades, WBRT has remained the primary modality for the treatment of the vast majority of patients with brain metastases, but, starting in the 1990s, several new treatment refinements have led to the redefinition of its role.

THE PARAMOUNTCY OF LOCAL CONTROL CHANGES THE PARADIGM

After the 1990 study by Patchell, which established a survival benefit from resection of a single metastatic lesion to the brain beyond that of WBRT alone, the next logical question was whether or not WBRT is necessary after resection at all. In 1998, in a randomized study, the addition of WBRT after complete tumor resection decreased intracranial failure from 70% to 18% (p < 0.001) and decreased local recurrence from 46% to 10% (p < 0.001).[3] Although there was improved survival with the use of WBRT, this was not significant, which is an observation worth noting, with the caveat that this study was not powered to assess a survival benefit. Three major di-

rectional thrusts emerged as a consequence of this work: First, in several quarters, WBRT became a routine and accepted standard of care after resection to dramatically and convincingly lower intracranial relapse; second, SRS became widespread as a modality for the local control of at-first limited number of brain metastatic lesions but more recently of multiple lesions; third, the role of WBRT in terms of enhancing local control came under intense scrutiny because of concerns regarding its potential for neurotoxicity and a perceived lack of a survival benefit. The bidirectional evolutionary ramifications of the latter trend were to better understand the mechanisms underlying some of these neurotoxicities and efforts to modulate these through the conduct of innovative clinical trials, as well as to become more selective regarding the application of WBRT primarily for patients who had multiple (with a flexible definition of this concept) brain metastases. This selection often has been in the context of a combined approach with systemic therapeutics, a direction that recently has experienced an upsurge because of the emergence of blood-brain barrier–penetrating agents, primarily in malignancies with driver mutations.

THE EMERGENCE OF RADIOSURGERY AS AN EFFECTIVE LOCAL CONTROL THERAPY

SRS now has become the most widely used focal treatment modality for patients who have brain metastasis. The efficacy

of SRS for brain metastases was first reported in multiple retrospective studies. Sanghavi et al[4] showed in a retrospective, multi-institutional analysis of 502 patients who were stratified by recursive partitioning analysis (RPA) classes I, II, and III that patients treated with WBRT and SRS compared with WBRT alone had a significant increase in median survival times.[4] The survival times in classes I, II, and III with the combination versus alone were 16.1 versus 7.1 months, 10.3 versus 4.3 months, and 8.7 versus 2.1 months, respectively ($p < 0.05$).[4] RTOG 9508 was a randomized, controlled, phase III trial of 333 patients with one to three brain metastases and a Karnofsky performance score (KPS) of 70 or greater who were treated with WBRT and SRS or WBRT alone.[5] In patients who had a single brain metastasis, treatment with WBRT and SRS compared with only WBRT resulted in a decreased rate of local recurrence at 1 year (18% vs. 29%; $p = 0.01$) and superior median survival times (6.5 vs. 4.9 months; $p = 0.039$). In patients who had two or three brain metastases, local control was significantly improved in the combination arm, but there was no difference in survival time between the two groups. There was an additional benefit in outcomes (maintenance or improvement of KPS and corticosteroid use) in patients who received SRS and WBRT compared with WBRT alone.

The role of SRS alone, without WBRT, was evaluated in subsequent studies. Aoyama et al[6] published a prospective, phase III trial, JROSG 99-1, that randomly assigned 132 patients (mostly with lung cancer) who had a KPS score of 70 or greater and four or fewer metastases to SRS with or without WBRT. The results showed no survival difference (8.0 months for SRS vs. 7.5 months for SRS with WBRT; $p = 0.42$); however, the trial was not powered to detect a significant difference in overall survival and, relative to longer-term survival, there was a nonsignificant survival trend in favor of the WBRT arm (1-year survival rates of 38.5% in the group treated with WBRT plus SRS vs. 28.4% for SRS alone).[6] As anticipated, the study demonstrated that local control rates were improved with the addition of

WBRT to SRS, with a 1-year failure rate of 23.6% for SRS and WBRT compared with 53.2% for SRS only ($p < 0.001$). Two additional randomized trials boosted this data set. The EORTC 22952-26001 study randomly assigned 359 patients to either 30 Gy of WBRT or observation after either surgery or SRS that was performed at the individual discretion of the physicians for patients who had one to three brain metastases. After either surgery or SRS, WBRT was associated with improved local and distant brain control ($p < 0.001$). More robust intracranial control led to less use of salvage therapies and a slightly longer progression-free survival but had no impact on overall survival or survival with functional independence (the primary endpoint of the study). It is important to note that part of the eligibility for the trial required stable systemic disease or asymptomatic primary tumors, thereby attempting to mitigate the dilution effects of extracranial disease progression on the translation of central nervous system (CNS) control to overall survival, but did not mandate this through systematic restaging. Even so, approximately one-third of patients had extracranial progression, which raises the issue of extracranial death as a competing risk.[7]

Chang et al[8] performed a phase III study in patients who had one to three brain metastases that compared the approach of combination of SRS and WBRT versus SRS alone (MDACC NCT00460395).[8] The primary endpoint of this study was neurocognitive function, as measured by the Hopkins Verbal Learning Test-Revised (HVLT-R).[8] The trial was stopped early after 58 patients were accrued because of a high probability that the SRS-plus-WBRT arm would show a significant decline in learning and memory function (total recall) at 4 months compared with SRS alone. Similar to the previous two studies, there were more CNS recurrences in the group treated with SRS alone; 73% of patients in the SRS-and-WBRT group were free from CNS recurrence at 1 year, compared with 27% of patients who received SRS alone ($p = 0.0003$). In this trial, the WBRT arm was associated with inferior survival, an issue that has become rather controversial but is most likely explained by maldistribution of patients on this small trial relative to the extent of extracranial disease, a factor that would categorically drive mortality.

EXPANDING THE HORIZONS OF STEREOTACTIC RADIOSURGERY

Although SRS typically is offered for patients with four or fewer brain metastases, it is increasingly utilized for patients with five or more lesions. A retrospective study showed that the median overall survival in patients with five or more brain metastases was 7.5 months after treatment with SRS.[9] Interestingly, the number of brain metastases was not a significant predictor of survival, but higher intracranial burden (higher volume of brain metastases within the brain) predicted for poorer outcomes.[10] In a prospective, observational study for one to 10 brain me-

---

KEY POINTS

- Selection of local therapy for brain metastases requires a multidisciplinary approach that includes neurosurgery, radiation oncology, medical oncology, and neuro-oncology.
- Treatment with whole-brain radiotherapy (WBRT) after surgery or radiosurgery improves local and distant brain failure but does not improve survival.
- Stereotactic radiosurgery (SRS) increasingly is employed in the management of these metastases in combination with surgery, WBRT, and medical systemic therapies.
- Prospective, randomized trials are needed to define the role and applications of WBRT and SRS.
- Areas of active investigation include techniques (e.g., pharmacologic, hippocampal sparing) to preserve neurocognitive function with radiotherapy.

tastases performed in 23 hospitals in Japan, no difference in overall survival was demonstrated in patients who had two to four brain metastases versus five or more brain metastases when treated with SRS alone.[11] The median overall survival after SRS was 13.9 months in patients who had a single brain metastasis, 10.8 months in patients who had two to four brain metastases, and 10.8 months in patients who had five to 10 brain metastases. This suggests that SRS may be a reasonable approach in selected patients with up to 10 brain metastases, further broadening the horizon of use of SRS in these patients. This also supports the hypothesis that the volume, and not the number, of metastases may be the driver in determining the outcomes in brain metastases.[12] An ongoing prospective trial, NAGKC 12-01, is comparing the neurocognitive outcomes and survival in patients with five or more brain metastases treated either with SRS or WBRT (NCT01731704); this trial will further define the role of SRS in this patient population.

Another active area of interest is utilization of SRS in lieu of WBRT to prevent local recurrence after resection. Resection bed SRS targeting is more complex because of uncertainties about the interpretation of postoperative MRI. Soltys et al[13] showed a 1-year local control rate of 94% with the addition of a 2-mm margin around the defined tumor bed versus 78% when there was no margin.[13] The median overall survival time was 17 months, and 72% of patients were able to avoid WBRT, although intracranial relapse and salvage with other therapies (such as SRS) was required in a substantial proportion of patients. Concerns with this approach include the possibility of leptomeningeal spread secondary to the resection, especially for patients who have breast cancer and those who have posterior fossa disease.[14] The North Central Cancer Treatment Group (NCCTG) study N107C is an ongoing intergroup study of patients who have one to four brain metastases that compares WBRT versus SRS after resection (NCT01372774).

An approach to potentially minimize leptomeningeal spread is to perform neoadjuvant SRS before surgery to sterilize the tumor cells before surgical resection. Neoadjuvant SRS in 47 patients, who were undergoing preoperative SRS with a median dose of 14 Gy (range, 11.8 to 18 Gy), was reported by Asher et al.[15] Surgical resection performed after SRS resulted in control in 86% at 1 year, and only 15% of the patients eventually required WBRT. Significantly, no leptomeningeal failures were observed in this study.

There is no level-1 evidence to support use of SRS in lieu of surgery. More than one randomized effort to answer this question has failed because of poor accrual. In a retrospectively matched series of 75 patients treated by surgery and SRS, a median survival time of 7.5 months with SRS versus 16.4 months in the surgical group was reported.[16] However, the dosing regimen for SRS in this study resulted in the use of lower prescriptions to the tumor margin than would be considered standard according to the widely accepted RTOG dosing schema.[5,17] Auchter et al[18] reported a multi-institutional data set of SRS in 122 highly selected patients who had one resectable brain metastasis. The median survival was 56

weeks in this retrospective series, which was comparable to the results of most surgical series.[18] Schoggl et al[19] performed a retrospective case-control analysis with 133 patients who were treated with either SRS (67 patients) or surgery (66 patients) along with WBRT. There was no difference in median survival (SRS vs. surgery, 12 vs. 9 months; p = 0.19), but the local control rate was superior with SRS.[19] In a retrospective study that compared surgery and SRS for the treatment of a solitary brain metastasis, no significant difference was found in patient survival. However, the difference in the local tumor control rate was significant (100% after SRS vs. 58% after surgery).[20] Muacevic et al[21] compared surgery and WBRT with SRS in patients who had single brain metastases.[21] The approaches— of surgery and WBRT, or of SRS—resulted in similar 1-year survival rates (53% vs. 43%; p = 0.19), 1-year local control rates (75% vs. 83%; p = 0.49), and 1-year neurologic death rates (37% vs. 39%; p = 0.8).

THE ABANDONMENT OF WHOLE-BRAIN RADIOTHERAPY

The randomized studies discussed above demonstrate that postoperative WBRT clearly improves intracranial control of brain metastases, but they also demonstrate that this benefit has not categorically translated into an overall survival benefit. Further, there are concerns regarding the potential for cognitive decline in patients receiving WBRT. More importantly, there are emerging data presented by Sahgal et al[22] showing an overall survival advantage of SRS alone over WBRT (10 vs. 8.2 months) for patients age 50 or younger who have one to four brain metastases, on the basis of a meta-analysis of three phase III studies.[22] Collectively, these factors, as well as the ability to salvage intracranial relapses with further application of SRS (an opportunity afforded in abundance by withholding WBRT), recently have led to the wholesale abandonment of WBRT, with its use reserved largely for patients who have multiple brain metastases and are not deemed favorable SRS candidates.

This approach requires thoughtful scrutiny. The analysis by Sahgal et al[22] was conducted by merging the EORTC 22952-26001, JROSG99-1, and MDACC NCT00460395 data sets. Collectively, these three trials included patients who had one to four brain metastases, who were treated with SRS with or without WBRT, and who had variable entry criteria for each trial and considerable variability in terms of systemic therapies, enrollment eras, SRS dose, follow-up imaging, and re-treatment considerations. Further, the EORTC trial also included patients undergoing resection at physician discretion. A total of 364 patients is available in this collated data set, of whom 51% (185 patients) were treated with SRS alone and only 19% (69 patients) were younger than age 50. The results demonstrate a curious blend of outcomes; for the post hoc–defined subset of these patients younger than age 50, the overall survival was superior with the SRS-alone arm (10 vs. 8.2 months), but the time to distant brain failure was shorter

for patients older than age 55 who were treated with SRS alone (4.5 vs. 6.5 months). The time to local failure was superior with the use of WBRT (7.4 vs. 6.6 months). Crucially, it is important to recognize that the recommendation regarding the survival gain in the younger patient category with SRS alone is based on approximately 35 patients per arm and on a post hoc analysis of a cohort in which the pre-enrollment balance regarding the extent of systemic disease could not be assured, because structured pre-SRS staging—a necessary element for assessing overall survival as an endpoint to avoid systemic burden as a confounder—was not performed.

Therefore, it is reasonable to hypothesize that, in reality, the survival benefit from WBRT is likely limited primarily to patients who do not experience extracranial disease progression. Unless this question is studied in such an enriched cohort, most other studies would likely remain significantly underpowered to demonstrate a survival advantage. In fact, as early as 1998, Pirzkall et al[23] reported on a 236-patient retrospective cohort and found a trend toward improved longer-term survival in favor of SRS plus WBRT (actuarial 1- and 2-year survival rates: 30% and 14% vs. 19% and 8%). More importantly, for patients without extracranial disease, the median survival was impressively (but not significantly) different at 15.4 vs 8.3 months (p = 0.08) in favor of WBRT.[23] More recently, Wang et al[24] retrospectively reviewed a 528-patient database (lung cancer, 257 patients; breast cancer, 102 patients; melanoma, 62 patients; renal cell carcinoma, 40 patients) from Columbia University; patients were treated between 1998 and 2013 with SRS alone (206 patients), with SRS and WBRT (111 patients), with resection followed by SRS (109 patients), or with all three modalities (102 patients). The overall median survival was 16.6 months; for patients who had a single brain metastasis, the median survival times after SRS, SRS plus WBRT, SRS plus resection, and all three modalities were 9.0, 19.1, 25.5, and 25.0 months, respectively. Even for patients who had more than one metastasis, the corresponding median survival times were 8.6, 20.4, 20.7, and 24.5 months, respectively, which demonstrated the survival inferiority of SRS alone as a modality in this cohort. This inferiority associated with the use of SRS alone as a modality was validated in a multivariate analysis.[24]

The data that call the meta-analysis by Sahgal et al[22] most into question, however, come from one of the key sources used within that analysis, JROSG 99-1. At the JASTRO 2014 annual meeting, Aoyama et al (personal communication, March 2015, quoted with permission) presented their own reanalysis of this study, using the now widely accepted disease-specific Graded Prognostic Assessment (ds-GPA), a prognostic stratification tool.[25] Because the ds-GPA relies on molecular variables for stratifying patients who have breast cancer, information that was not collected on JROSG 99-1, these patients could not be adequately categorized and were excluded; 88 (of the 132 total enrolled patients) patients who had non–small cell lung cancer were grouped into favorable (ds-GPA of 2.5 to 4; 47 patients) and unfavorable (ds-GPA of 0.5 to 2; 41 patients) categories. The median survival time was 16.7 versus 10.6 months in favor of the WBRT arm over SRS alone (p = 0.03) for the favorable group, but a similar survival improvement was not observed in the unfavorable group (personal communication, March 2015, quoted with permission). This lends credence to the hypothesis that in patients with a high ds-GPA category, improved brain control translates to a survival advantage because these patients do not die as rapidly from extracranial progression. Therefore, the beneficial effects of improved brain control from WBRT actually affect overall survival. This is quite contrary to the current wisdom of reserving WBRT only for the prognostically least-favorable group of patients. This issue, therefore, remains unresolved.

THE ELEPHANT IN THE ROOM: NEUROCOGNITIVE ISSUES

Diffuse radiographic periventricular white matter changes (leukoencephalopathy) after cranial radiation have been well described and occur at a far higher frequency with WBRT than with SRS.[26] The pathogenesis and clinical relevance of this difference, however, is not well established. In contrast, neurocognitive dysfunction after cranial radiation is multifactorial and is typically mild to moderate in most people; however, this remains one of the most distressing side effects of WBRT and often is the rationale for not utilizing it. However, the clinical results with and without WBRT, in the context of SRS, remain mixed. As mentioned previously, Chang et al[8] demonstrated a decline in HVLT-DR associated with WBRT. Aoyama et al,[6] in contrast, demonstrated that progressive disease has a greater impact than WBRT in terms of cognitive decline, with patients who receive SRS alone experiencing a faster decline in scores of the mini mental status examination.[6,8] The NCCTG, in concert with NRG Oncology, recently has completed accrual to a phase III trial (N0574) comparing SRS versus SRS followed by WBRT for patients who have one to three brain metastases, with built-in early cognitive change as an endpoint. Results are pending.

Mitigation of cognitive dysfunction, therefore, has become an important research direction. The RTOG performed two studies to try to modulate this side effect. In the study RTOG 0614, patients were randomly assigned to receive memantine, an NMDA receptor agonist, versus placebo.[27] The patients in the memantine arm had a significantly longer time to cognitive decline (p = 0.02). The median decline on HVLT-R scale was 0 in the memantine arm compared with −2 in the placebo arm (p = 0.059). Fewer patients treated with memantine had a decline in the Controlled Oral Word Association test at 16 weeks (p = 0.004) or in the Trail-Making test part A at 24 weeks (p = 0.014).

Hippocampal neural stem cell injury from irradiation during WBRT may play a role in memory decline, primarily by shifting the stem cell maturation cycle from neurogenesis to gliogenesis, a phenomenon that is well established in preclin-

ical models.[28,29] In a prospective human study, a strong association with increasing hippocampal radiation dose and neurocognitive dysfunction was demonstrated.[30] Intensity-modulated radiotherapy can be used to conformally avoid the hippocampal neural stem cell compartment during WBRT (HA-WBRT). This hypothesis was tested in a single-arm phase II study of HA-WBRT for brain metastases that used a prespecified comparison with a historic control of patients treated with WBRT without hippocampal avoidance (RTOG 0933).[31] The primary endpoint was change in HVLT-DR measured at 4 months. The historic control (without hippocampal avoidance) resulted in a 30% mean relative loss in HVLT-DR from baseline to 4 months. The actual observed mean relative decline in HVLT-DR from baseline to 4 months was, in fact, only 7.0%, which was significantly lower than the historic control of 30% (p = 0.0003). No decline in quality-of-life scores up to 6 months was

seen.[31] These observations now form the basis of two newer phase III trials, NRG CC 001 and CC 002.

CONCLUSION

The management of brain metastases has evolved over the years from palliation to an era of exciting active research. Local therapies (WBRT, SRS) are important modalities in the management of brain metastases. Areas of active investigation include techniques to preserve neurocognitive function with radiotherapy. The optimal management strategy for these patients involves a multidisciplinary approach that accounts for individual characteristics of both the patient and the tumor. A number of ongoing prospective clinical trials will help further define the role and application of WBRT and SRS in the management of brain metastases.

Biology and Clinical Management Challenges in Meningioma

Christian Mawrin, MD, Caroline Chung, MD, FRCPC, and Matthias Preusser, MD

OVERVIEW

Meningiomas are the most frequently occurring intracranial tumors. They are characterized by a broad spectrum of histopathologic appearance. Molecular alterations driving meningioma development, which affect the *NF2* gene, are found in roughly 50% of patients. Rare genetic events in benign meningiomas are mutations in *TRAF7*, *KLF4*, *AKT1*, and *SMO*; all of these mutations are exclusive of *NF2* alterations. Progression to a clinically aggressive meningioma is linked to inactivation of *CDKN2A/B* genes, and a plethora of signaling molecules have been described as activated in meningiomas, which supports the concept of successful clinical use of specific inhibitors. Established treatments include surgical resection with or without radiotherapy delivered in a single fraction, a few large fractions (radiosurgery), or multiple fractions (fractionated radiotherapy). For recurrent and aggressive tumors, inhibitors of the vascular endothelial growth factor (VEGF) pathway, such as vatalinib, bevacizumab, and sunitinib, showed signs of activity in small, uncontrolled studies, and prospective clinical studies will test the efficacy of the tetrahydroisoquinoline trabectedin and of *SMO* and *AKT1* inhibitors.

Meningiomas are tumors that arise from meningeal coverings of the brain and spinal cord. According to current epidemiologic data, they are the most common intracranial tumors, with an incidence of 7.7 per 100,000. Meningiomas are tumors of older populations, with a clear increase in incidence after the age of 65.[1] They preferentially affect women, with a female:male ratio of 3.5:1.[2] Meningiomas in children are exceptionally rare. Risk factors other than age include exposure to ionizing radiation,[3] the presence of diabetes mellitus or arterial hypertension, and, possibly, smoking; the use of mobile phones does not seem associated with an increased tumor risk.[4-6]

CLINICAL PRESENTATION AND RISK FACTORS

Approximately 90% of meningiomas develop from the cranial meninges, although 10% occur in the spinal meninges. The clinical presenting symptoms reflect the anatomic region that is involved and compressed by tumor or peritumoral edema. In many cases, patients with small meningiomas are asymptomatic, and the tumors are found incidentally as a result of imaging for other purposes.

Some patients may present with multiple meningiomas. Among these cases, approximately 1% of multiple occurrences is associated with *NF2*, and 4% of these cases are unrelated to *NF2*.[7] Hereditary meningiomas in adults are highly associated with *NF2* alterations (see below), and 50% to 75% of patients with neurofibromatosis type 2 (NF2) develop me-

ningiomas during their lifetime.[8] Meningioma development in other familial tumor syndromes is uncommon.

PATHOLOGY AND DIFFERENTIAL DIAGNOSES

Meningiomas originate from arachnoidal cap cells, which form the outer layer of the arachnoid mater and the arachnoid villi; the villi are responsible for cerebrospinal fluid (CSF) drainage into the dural sinuses and veins. Arachnoidal cap cells can appear either as a single fibroblast-like cell layer or as epitheloid nests that form several layers. Embryonically, the meninges at the skull base are derived from the mesoderm, and the telencephalic meninges are derived from the neural crest.[9] With age, arachnoidal cap cell clusters become increasingly prominent, forming whorls and psammoma bodies identical to those found in meningiomas. On the basis of cytologic and functional similarities to meningioma cells, arachnoidal cap cells are favored as the most likely cell of origin.[10]

As the neoplastic counterpart of cap cells, meningiomas can have both mesenchymal and epithelial features, reflected by the histopathologic appearance of the most frequent meningioma subtypes (Table 1). Approximately 80% are World Health Organization (WHO) grade 1 meningiomas, which consist mainly of meningothelial, fibrous, or mixed (transitional) tumors. There is a preponderance of specific intracranial sites affected by meningiomas in association with certain histopathologic subtypes. Meningothelial (epithelial) meningiomas are frequently found at the skull base, whereas fi-

TABLE 1. Meningioma Subtypes, Grading, and Associated Molecular Alterations

Histologic Subtype	WHO Grade	Molecular Alteration*
Meningothelial meningioma	1	NF2
Fibroblastic meningioma	1	NF2
Transitional (mixed) meningioma	l	NF2
Psammomatous meningioma	1	
Angiomatous meningioma	1	
Microcystic meningioma	1	
Secretory meningioma	1	KLF4/TRAF7
Lymphoplasmacyte-rich meningioma	1	
Metaplastic meningioma	1	
Chordoid meningioma	2	
Clear cell meningioma	2	SMARCB1
Atypical meningioma	2	NF2
Brain invasive meningioma	2	
Papillary meningioma	3	
Rhabdoid meningioma	3	
Anaplastic meningioma	3	NF2

*Includes only molecular changes with high frequency and/or association with a specific tumor location.

broblastic meningiomas are more likely to develop at the convexity of the brain.[11,12] If the location is related to the grade of malignancy, the proportion of grade 2 or grade 3 meningiomas at the convexity or with a parasagittal location is much higher than at the skull base.[13] In addition to the three main grade 1 tumor types, other rare variants might be seen, and some of them are associated with specific genetic alterations.

Approximately 20% of meningiomas fall into the group of atypical WHO grade 2 tumors. Interestingly, these tumors have been increasingly recognized in the last few years, mainly as a result of a diagnostic shift from grade 1 to grade 2 meningiomas that is based on a better definition of histopathologic criteria.[14] Atypical meningiomas are characterized by aggressive histologic features, such as increased mitotic activity, nuclear atypia, and necroses. The aggressive biology is reflected by the roughly eight-fold increased risk of recurrence experienced by patients with grade 2 meningio-

---

KEY POINTS

- Meningiomas are the most frequent types of intracranial tumors.
- Surgery and radiotherapy are established treatments.
- No standard treatments exist for recurrent/progressive meningiomas.
- Vascular endothelial growth factor pathway inhibitors sunitinib, vatalinib, and bevacizumab showed potential activity in small, uncontrolled studies that require confirmation.

---

mas compared with benign WHO grade 1 tumors, and by the considerably increased risk of mortality associated with grade 2 versus grade 1 in with age- and sex-matched controls. Meningiomas with proven brain invasion also are considered grade 2 tumors, and patients with these tumors are prone to an increased risk of tumor recurrence. However, the molecular mechanisms driving brain invasion are not well understood so far. Malignant meningiomas (WHO grade 3) are rare, accounting for only 1% to 2% of all meningiomas, but are associated with a considerable risk of death from disease and an average survival of less than 2 years.[15-17] Although the characteristic histopathologic features of meningiomas are at least focally found in atypical meningiomas, malignant WHO grade 3 meningiomas may completely lack any morphologic hint that points toward a meningeal origin, thus requiring extensive pathologic investigations to confirm the true nature of the tumor.

For differential diagnoses, meningiomas can present with a wide spectrum of histopathologic patterns, and coexistence of various morphologic features within one tumor may occur. Using immunohistochemistry, meningiomas usually express epithelial membrane antigen (EMA) and vimentin. Cytokeratins are usually not expressed, which helps to rule out metastatic carcinoma. Exceptions include secretory meningiomas and some anaplastic meningiomas. Highly vascularized meningiomas must be separated from hemangiopericytoma and solitary fibrous tumor (SFT). There typically is diffuse CD34 positivity in SFT. Extensive staining for CD99 and B-cell lymphoma 2 is common to both SFT and hemangiopericytoma, but it is missing in meningiomas. In contrast, EMA expression is much more typical of meningioma.[10]

MOLECULAR GENETIC ALTERATIONS IN MENINGIOMAS

The first genetic alteration described was the loss of chromosome 22, and chromosome 22 alterations are still the most frequent findings in meningiomas. Subsequently, a gene on chromosome 22 responsible for the hereditary tumor syndrome NF2 was identified.[18,19] Although bilateral vestibular schwannomas are the hallmark of the disorder, the majority of patients with NF2 develop multiple meningiomas, which suggests a role for the NF2 gene in meningioma development.[20] Indeed, allelic losses of chromosome 22, including the NF2 region, occur in more than 50% of sporadic meningiomas.[21-24] In meningiomas with allelic losses (loss of heterozygosity [LOH]) at the NF2 locus, point mutations in the remaining allele can be found in sporadic meningiomas, which suggests complete gene inactivation.[25,26] Merlin, the gene product of NF2, has significant sequence homology to members of the ezrin/radixin/moesin (ERM) family of proteins, which link various cell-adhesion receptors to the cortical actin cytoskeleton.[27] The frequency of NF2 inactivation is roughly equal among different WHO grades, which suggests that NF2 loss is an initiating rather than progression-associated alteration.[16,28-30] With variant histology, differences in the frequency of NF2 alterations have been reported.

Fibroblastic, transitional, and psammomatous have higher frequencies of *NF2* alterations than meningothelial or secretory meningiomas.[28,31-33] Accordingly, patients with non-*NF2* familial multiple meningiomas are more likely to develop meningothelial tumors.[34] An association between the *NF2* gene and location has also been reported, and tumors of the convexity are more likely than anterior cranial-based tumors to harbor *NF2* alterations.[11] In contrast, patients with neurofibromatosis type 1 (NF1) only rarely present with meningiomas,[35] and *NF1* gene mutations are absent in anaplastic meningiomas, which suggests that *NF1* alterations are not involved in meningioma development and/or progression.[30]

Based on the clearly established role of *NF2*, it could be demonstrated that *NF2* inactivation in leptomeningeal cells of conditional *NF2* knockout mice (*NF2*^*flox/flox*) by Cre recombinase injection induces meningiomas.[36] Most of these mouse tumors recapitulate the meningothelial, fibroblastic, or transitional subtype of human meningiomas and are characterized by reduced merlin expression. The knowledge concerning the mechanisms driving the development of the main histopathologic subtypes among grade 1 meningiomas has been expanded recently by generating a mouse model with inactivation of meningeal *NF2* by using the prostaglandin D2 synthase (PGDS) gene promoter. PGDS is a specific marker of arachnoidal cells.[37] *NF2* inactivation in PDGS-positive meningeal progenitor cells resulted in both meningothelial and fibroblastic meningiomas.[38] Of note, *NF2* inactivation in mice led to meningioma development only during a critical prenatal and perinatal time frame.

On the basis of recent whole genome-sequencing approaches, few other recurrent genetic alterations have been identified recently in benign meningiomas. In 2013, four genes altered in a small fraction of meningiomas—*TRAF7*, *KLF4*, *AKT1*, and *SMO*—were identified.[29,39,40] Probably the most important new mutation identified is related to the v-akt murine thymoma viral oncogene homolog 1 gene (*AKT1*), with a hotspot mutation (p.Glu17Lys) named *AKT1*^E17K. This somatic mutation occurs in breast, ovarian, and colorectal cancers.[41,42] In meningioma, this mutation was found nearly exclusively in 7% to 12% of WHO grade 1 meningiomas but was (exceptionally) rare in grade 2 and was absent in grade 3 tumors.[39,40] The *AKT1*^E17K mutation was found predominantly in the meningothelial/transitional subtypes, and tumors that harbored the *AKT1*^E17K mutation were *NF2* wild type. Another gene found mutated in grade 1 meningiomas was the receptor-associated factor 7 gene (*TRAF7*).[39] *TRAF7* is located on chromosome 16p13 and encodes a proapoptotic protein that interacts with multiple signaling pathways. *TRAF7* mutations are mutually exclusive of *NF2* mutations and occur in approximately 24% of meningiomas.[39] They are present in 93% to 100% of secretory meningiomas.[43] In addition, meningiomas with *TRAF7* mutations are almost always characterized by the mutation K409Q in the gene for the transcription factor Kruppel-like factor 4 (*KLF4*). *KLF4*, located on chromosome 9q, is involved in transcriptional activation and repression.[44] The combined

TRAF7/KLF4 mutation characterizes secretory meningiomas[39,43] and provides a molecular marker for this grade 1 subtype. Meningiomas with *TRAF7/KLF4* mutations are predominantly located at the medial/lateral skull base.

Another non–*NF2*-associated mutation of skull base meningiomas affects the Smoothened gene, *SMO*. *SMO* mutations occur in 4% to 5% of grade 1 meningiomas and are restricted to the medial anterior skull base near the midline. *SMO* mutations are exclusive of *NF2* and of *AKT1* or *TRAF7/KLF4*.[29,39]

Although all of these mutations are mutually exclusive of *NF2* alterations, other genetic alterations occur in association with chromosome 22 in meningiomas. One gene located on chromosome is *SMARCB1*, and alterations are frequently found in *SMARCB1* in pediatric malignant rhabdoid tumors. Screening a large group of sporadic meningiomas revealed that *SMARCB1* mutations occur with low frequency and might be cooperating with *NF2* mutations, because tumors showing both *SMACRB1* and *NF2* mutations were reported.[45,46] *SMARCB1*-mutated meningiomas are preferentially found at the falx cerebri.[47]

In families with multiple spinal meningiomas and without *NF2* mutations, a loss-of-function mutation in the *SMARCE1* gene was recently identified.[48] *SMARCE1* is located on chromosome 17q21 and encodes for a 57-kDa subunit of the SWI/SNF complex, which is involved in the regulation of chromatin structure by nucleosome remodeling. The mutation occurs selectively in spinal meningiomas with histologic features of clear cell meningioma, so it providing a potential molecular hallmark for this rare meningioma subtype.

The merlin protein belongs to the protein 4.1 family, with members linking the membrane protein to the cytoskeleton. One gene of the protein 4.1 family relevant for meningioma biology is *DAL1*. Reduced expression of the *DAL1* gene product protein 4.1B was found in approximately 60% of meningiomas regardless of histologic grade, which suggests that protein 4.1B loss is another early event in meningioma pathogenesis.[49,50] Nearly all tumors with *DAL1* LOH have simultaneous *NF2* LOH.[51] Mice lacking *DAL1* do not develop tumors,[52] which suggests that *DAL1* alterations are early progression–associated steps. In patients with multiple meningiomas, *DAL1* mutations were found in both tumor and paired blood samples, which suggests substantial differences between patients with sporadic single and multiple meningioma with respect to *DAL1*.[34]

MALIGNANT PROGRESSION IN MENINGIOMA

Meningiomas are generally thought to progress from low-grade to high-grade tumors. Histologically, progression from grade 1 to grade 2 can be confirmed in 17% to 38% and from grade 1/2 to grade 3 in 54% to 70%.[53,54] At the cytogenetic level, a stepwise acquisition of chromosomal gains and losses during meningioma progression has been proven.

Losses of 1p, 6q, 10q, 14q, and 18q, as well as gains of 1q, 9q, 12q, 15q, 17q, and 20q have been proposed as important events in meningioma progression and recurrence,[29,55-59]

and 1p and 14q loss especially are associated with meningioma progression.[60-62] Interestingly, 1p loss commonly is found in tumors located at the convexity but is rare in skull base or spinal meningiomas.[13] Moreover, 1p loss is associated with faster meningioma recurrence.[63] Losses of 6q, 9p, 13, and 14 are found exclusively in highly proliferating meningiomas.[64] Radiation-induced aggressive meningiomas show cytogenetic aberrations on chromosome 1p, 6q, and 22.[65]

Few specific genes associated with chromosomal alterations have been identified. Besides *NF2*, the tissue inhibitor of metalloproteinase 3 gene (*TIMP3*), location on 22q12, is another gene associated with meningioma progression . Hypermethylation of the *TIMP3* promoter occurs in 17% of benign, 22% of atypical, and 67% of anaplastic meningiomas and is associated with allelic loss on 22q12.[66] The TIMP3 protein inhibits matrix metalloproteinases, which suggests that epigenetic inactivation of *TIMP3* by promoter hypermethylation might favor aggressive invasive tumor growth. *TIMP3* has additional tumor suppressor activity, and in vitro overexpression of *TIMP3* reduces tumor growth and induces apoptosis.[67] However, *TIMP3* hypermethylation does not seem associated with tumor recurrence or overall survival.[63]

Alterations on 9p21 have been found to represent losses of the tumor suppressor genes *CDKN2A* ($p16^{INK4a}$), $p14^{ARF}$, and *CDKN2B* ($p15^{INK4b}$).[30,68] In anaplastic grade 3 meningiomas, deletions of *CDKN2A*/*CDKN2B* are associated with poorer survival.[69] In mouse models, deletion of *CDKN2A*, together with *NF2* inactivation, results in increased meningioma frequency and the development of grade 2 or 3 meningiomas, which proves that loss of *CDKN2A* and *CDKN2B* is a feature for aggressive meningioma development.[70]

Amplification of the S6 kinase gene region on chromosome 17q23 is present in malignant meningiomas,[71,72] which suggests that mammalian target of rapamycin (mTOR) signaling pathway inhibition might be a therapeutic target.[73] The 14q32 region has been implicated in meningioma progression because of the maternally expressed gene 3 (*MEG3*), which has antiproliferative activity in meningiomas. Aggressive meningiomas show allelic losses, promoter hypermethylation, and reduced expression of *MEG3* compared with normal arachnoidal cells.[74,75] The important role of chromosome 14q loss was supported by findings that showed *NDRG2* as a gene commonly inactivated in meningioma progression. *NDRG2* is downregulated in anaplastic meningiomas and in a small subset of lower-grade meningiomas and atypical meningiomas with aggressive clinical behavior. The reduced expression of *NDRG2* is associated with promoter hypermethylation.[76,77]

MOLECULAR FACTORS AFFECTING MENINGIOMA PROGNOSIS

The histologic tumor grading is one of the strongest factors influencing tumor recurrence and overall prognosis.[17] A high MIB-1 labeling index is associated with poor prognosis.[78] Losses of 1p and 14q have a poor prognostic implication.[60-63,79-81] Patients who have tumors greater than 50

mm and a combined loss of 1p and 14q represent a subgroup at high risk for early relapse.[82] Relapse-free survival is negatively associated with male sex, presence of brain edema, intraventricular and anterior cranial base tumor location, age younger than 55, and tumor size larger than 50 mm.[83]

MOLECULAR SIGNALING PATHWAYS

Molecular signaling pathways, including those involved in mitogenic signal transduction, have been studied intensively in meningiomas. Nearly all of the growth factor receptors/kinases known to be involved in tumor growth (epidermal growth factor receptor [EGFR], platelet-derived growth factor receptor [PDGFR] beta, vascular endothelial growth factor receptor [VEGFR], insulin-like growth factor receptor [IGFR]) have been expressed in meningiomas.[84-87] Mitogenic signals of EGFR and PDGFR are mediated by the Ras-Raf-Mek-MAPK pathway. Indeed, these pathways are activated in meningiomas.[88,89] The phosphoinositide 3-kinase–AKT/protein kinase B p70 signaling pathway is another important mediator of growth-favoring signals in meningiomas.[73,89,90] The mTOR signaling pathway is of relevance for both *NF2* mutant meningiomas and for meningiomas with other mechanisms of mTOR pathway activation, such as *S6K* gene amplification.[71,72] Merlin (*NF2*) is a negative regulator of the mTOR complex 1 (mTORC1) kinase complex, and constitutive activation of mTORC1 signaling is present in meningioma cells from patients with NF2.[91,92] Other signaling pathways activated in meningiomas include the phospholipase A2-arachadonic acid-cyclooxygenase pathway[93,94] and the PLC-gamma1-PKC pathway.[89,95] The transforming growth factor-beta (TGF-beta)-SMAD signaling pathway represents an inhibitory mechanism, and TGF-beta, and the TGF-beta receptor, are expressed in meningiomas.[96-98] All of these activated signaling pathways represent potential therapeutic targets.

MANAGEMENT OF MENINGIOMAS

The overall management approach for newly diagnosed meningiomas is usually dependent on a number of factors including the patient's age, comorbidities, and clinical symptoms as well as the tumor location (proximity to critical structures or regions of brain), size, and mass effect. For patients who are symptomatic as a result of the mass effect from the tumor, surgery is typically recommended. For other patients, discussion with the patient and interdisciplinary discussion of all management options, including observation, surgical resection, and radiotherapy (including radiosurgery and fractionated radiotherapy) are considered.

OBSERVATION

For patients who have asymptomatic meningiomas that are not in close proximity to critical structures, an observational approach may be considered. Most meningiomas are low

grade and have annual growth rates of 1 to 3 mm per year.[99] If an observational approach is taken, close follow-up with serial imaging and clinical neurologic assessment is required to avoid overlooking the development of symptoms that suggest more rapid tumor growth. If tumor growth is documented or if clinical symptoms develop or progress, discussion about treatment should be revisited.

SURGERY

The usual initial treatment is surgical excision of the tumor and its dural base, particularly for tumors located on the outer brain surface and surgically easily accessible. After gross total resection (i.e., complete excision of the tumor and its dural attachments) of a benign meningioma, the risk of tumor recurrences are 5%, 10%, and 30% at 5, 10, and 15 years, respectively.[100] The extent of surgery is reported by Simpson grade. Sughrue et al[101] reported that, for patients who have grade 1 meningioma, the extent of resection impacts the risk of recurrence and progression-free survival. After Simpson grade 1, 2, 3, and 4 resections, the respective 5-year progression-free survival rates were 95%, 85%, 88%, and 81%.[101]

Not all meningiomas can be totally resected without an unacceptable risk of postoperative neurologic deficits. For skull-based meningiomas, a particular surgical risk is cranial nerve palsy.[102-104] Newer microsurgical and endoscopic techniques in combination with advances in neuroimaging have improved the outcomes of surgical resection of meningiomas.[105,106] Finally, there has been a move toward optimizing functional preservation by utilizing a combination of the currently available surgical and radiotherapy techniques personalized to the patient and particular clinical situation over achieving radical resections that results in functional loss.

RADIOTHERAPY

The role of radiotherapy in the management of meningiomas depends on patient factors, such as their comorbidities and preference, and on tumor factors, including tumor size, resectability, and—particularly— grade. Radiotherapy also is usually recommended for recurrent meningiomas after initial surgical resection, either as monotherapy or as adjuvant therapy after reresection.[107]

In general, radiotherapy is recommended after surgical resection of malignant (WHO grade 3) meningiomas because of the considerably better 5-year progression-free survival seen with surgery followed by adjuvant radiotherapy (80%) compared with surgery alone (15%).[108] Radiotherapy was shown to shrink any remaining tumor burden in addition to preventing tumor recurrence.[109,110]

For atypical (WHO grade 2) meningiomas, the optimal timing of radiotherapy is less clear, particularly after a complete resection. Retrospective studies have demonstrated that early adjuvant radiotherapy for nonbenign meningiomas improves progression-free survival, but the majority of these studies have evaluated grade 2 and 3 meningiomas together, and the benefit may reflect selection bias of higher risk cases to receive adjuvant radiotherapy versus those that did not receive radiotherapy postoperatively.[108,111-113] As the goals of treatment shift toward optimizing functional outcome and minimizing treatment-related toxicity, close observation is typically preferred after a gross total resection of a grade 2 meningioma. After an incomplete resection or at the time of tumor recurrence, radiotherapy options, including potential radiosurgery or fractionated radiotherapy, are offered, depending on the volume and location of the tumor.[114]

For WHO grade 1 meningiomas, there is even greater controversy about the optimal management, because there are a greater number of management options, including observation, radiosurgery alone, fractionated radiotherapy alone, surgical resection alone, or a combination of surgery with postoperative radiosurgery or fractionated radiotherapy. After surgical resection, there is controversy about early postoperative radiotherapy versus delayed radiotherapy at the time of tumor recurrence. Data support the improved local control of early adjuvant radiotherapy compared with surgery, particularly after partial resection.[115] In contrast, a delay in radiotherapy until tumor recurrence can help spare radiotherapy and its associated toxicities in a proportion of patients who do not experience tumor recurrence.[116]

Radiosurgery

Radiosurgery can be delivered with a variety of devices, including the Gamma Knife, Cyberknife, and a linear accelerator (LINAC). A single fraction to a marginal dose of 10 to 15 Gy is usually given.[117,118] Because treatment of a larger target volume results in greater treatment-related toxicity, radiosurgery typically is offered to tumors that are smaller volume and not in very close proximity to critical structures, such as the optic chiasm.[119] In a multicenter study of 254 patients treated up front for petroclival meningioma with radiosurgery (140 patients) or with radiosurgery after surgery (144 patients), the actuarial progression-free survival rates were 93% and 84% at 5 and 10 years, respectively.[120] Similar tumor control, with actuarial 5- and 10-year progression-free survival rates of 95% and 92%, respectively, has been reported for sellar and parasellar meningiomas treated with a single-fraction radiosurgery treatment to a median prescription dose of 13 Gy (range, 5 to 30 Gy).[121]

Fractionated Radiotherapy

Fractionated radiotherapy is often delivered with stereotactic radiotherapy (SRT) or image-guided radiotherapy approaches to optimize the precision of radiotherapy delivery in combination with intensity-modulated radiotherapy techniques to improve the dose shaping around complex targets in close vicinity to critical normal structures. For benign meningiomas, fractionated radiotherapy is offered for large volume tumors or those in very close proximity to critical structures, such as the optic chiasm. The volume that is targeted for benign tumors is typically the enhancing tumor, with a minimal margin for set-up error. The radiation dose

generally ranges between 50 and 56 Gy and is delivered in fractions of 1.8 to 2.0 Gy. After a median follow-up of 43 months (range, 2 to 144 months), Soldà et al[122] reported similar local control rates for fractionated radiotherapy as reported for radiosurgery; 5- and 10- year local control rates were 93% and 86%, respectively. For higher-grade meningiomas, there is greater concern for brain invasion and, therefore, the target volume includes an additional margin for microscopic spread, typically 1 to 2 cm. Because of the more aggressive biology, higher doses of radiation are generally used for higher-grade meningiomas, ranging between 60 66 Gy.[108,112,123]

Proton Therapy

Proton therapy provides the potential benefit of a more conformal dose distribution that can cover the tumor with a higher dose of radiation while minimizing entry, exit, and overall integral radiation dose. At the present time, the ability to generate a highly conformal proton radiotherapy plan is user and center dependent. Using standard fraction sizes of 1.8 Gy and total doses of 50.4 to 66.6 Gy for grade 1 meningiomas and doses of 54.0 to 72.0 Gy for grade 2 meningiomas, the results from Loma Linda show a 5-year actuarial control rate of 96%, with better control for grade 1 meningiomas (99% at 5 years) compared with grade 2 meningiomas (50% at 5 years). No associations with local control and total dose were seen in this retrospective review, but increased optic neuropathy was seen with higher doses delivered to tumors in close proximity to the optic apparatus.[124] Gudjonsson et al[125] reported their outcomes of stereotactic hypofractionated proton radiotherapy using doses between 14 Gy in three fractions to 24 Gy in four fractions. They reported no signs of tumor progression after 36 months of follow-up of 19 patients with partially resected grade 1 (15 patients) or unresectable (4 patients) meningiomas. However, two patients developed clinical signs and radiologic evidence of a radiation reaction with this hypofractionated approach.[125]

SYSTEMIC THERAPIES

Systemic therapies are usually considered in patients who experience progression after exhaustion of all local treatment options (surgical resection, radiotherapy) and in the rare cases of metastatic meningiomas. Unfortunately, the lack of adequately designed and powered clinical trials on systemic therapeutics in meningiomas prohibits treatment planning on a high level of evidence. On the basis of documented low response rates and progression-free survival times, a number of drugs, including hydroxyurea, interferon alfa, octreotide analogs (sandostatin, pasireotide), mifepristone, megestrol acetate, imatinib, erlotinib, and gefitinib are not considered beneficial agents.[126] However, some agents have shown promising signs of efficacy in preclinical investigations and small clinical studies that may translate into clinically relevant activity if confirmed in larger, prospective clinical trials.

Evidence from several studies indicates that antiangiogenic agents may have some therapeutic value in meningiomas. Indeed, pathologic neoangiogenesis and upregulation of angiogenic pathways, such as the vascular endothelial growth factor axis, repeatedly have been shown in meningiomas, thus providing a pathobiologic rationale for such agents.[86,127,128] Some case reports and small retrospective patient series have shown relatively high 6-month progression-free survival rates for recurrent/progressive meningiomas treated with the VEGF-A-binding monoclonal antibody bevacizumab.[129-134] Further data on the efficacy of bevacizumab is awaited from ongoing single-arm phase II trials enrolling patients with recurrent, progressive WHO grade 1, 2, and 3 meningiomas (NCT01125046, NCT00972335). So far, no unexpected toxicities of bevacizumab were seen in this patient population. Of note, bevacizumab has a marked antiedematous effect that may lead to clinical improvements and reduced corticosteroid need.[135]

Vatalinib (PTK787/ZK22584), a tyrosine kinase inhibitor of VEGFR1 to VEGFR3, was tested in a series of 24 patients with meningiomas of all grades. Toxicities were manageable and included fatigue (60%), hypertension (24%), and elevated transaminases. Favorable 6-month progression-free survival rates of 64.3% and 37.5% were seen in grade 2 and 3 tumors, respectively.[136]

A recent publication reported the results of a prospective, multicenter, phase II trial that enrolled patients with surgery and radiation-refractory recurrent grade 2 to 3 meningioma in a primary cohort and patients with WHO grade 1 meningioma, hemangiopericytoma, or hemangioblastoma in an exploratory cohort.[126] Patients were treated with the tyrosine kinase inhibitor sunitinib, which targets VEGF, platelet-derived growth factor (PDGF), c-KIT, FLT, macrophage colony-stimulating factor (CSF-1R), and RET. Thirty-six patients were enrolled in the primary cohort and 13 patients in the exploratory cohort. In the primary cohort, the 6-month progression-free survival rate was 42%, which met the primary endpoint. Toxicity, however, was substantial with one grade 5 intratumoral hemorrhage, two grade 3 and one grade 4 CNS/intratumoral hemorrhages, one grade 3 and one grade 4 thrombotic microangiopathy, and one grade 3 gastrointestinal perforation. Interestingly, tumoral VEGFR2 expression correlated with favorable outcome, thus introducing a potential biomarker for response to sunitinib therapy.

Several upcoming clinical trials have been designed according to preclinical data and may introduce novel medical options for the therapy of meningiomas. The EORTC-1320 trial will evaluate in a randomized fashion the effect of trabectedin on progression-free survival versus local standard-of-care therapy. Trabectedin is a tetrahydroisoquinoline originally isolated from the sea squirt *Ecteinascidia turbinate* and is approved for the treatment of advanced sarcoma and recurrent ovarian cancer. Trabectedin binds to the minor groove of the DNA, induces apoptosis in tumor cells as well as depletion of tumor-associated macrophages, and has antiangiogenic properties.[137,138] Another multicentric clinical trial will prospectively evaluate the efficacy of *SMO* and *AKT1* inhibitors in mutation-bearing meningiomas.

What Can We Learn about Antibody-Drug Conjugates from the T-DM1 Experience?

Francisco J. Esteva, MD, PhD, Kathy D. Miller, MD, and Beverly A. Teicher, PhD

OVERVIEW

Antibody conjugates are a diverse class of therapeutics that consist of a cytotoxic agent linked covalently to an antibody or antibody fragment directed toward a specific cell surface target expressed by tumor cells. The notion that antibodies directed toward targets on the surface of malignant cells could be used for drug delivery is not new. The history of antibody conjugates has been marked by hurdles identified and overcome. Early conjugates used mouse antibodies, drugs that either were not sufficiently potent, were immunogenic (proteins), or were too toxic, and linkers that were not sufficiently stable in circulation. Four main avenues have been explored using antibodies to target cytotoxic agents to malignant cells: antibody-protein toxin (or antibody fragment−protein toxin fusion) conjugates, antibody-chelated radionuclide conjugates, antibody-small molecule conjugates, and antibody-enzyme conjugates administered along with small molecule prodrugs that require metabolism by the conjugated enzyme to release the activated species. Technology is continuing to evolve regarding the protein and small molecule components, and it is likely that single chemical entities soon will be the norm for antibody-drug conjugates. Only antibody-radionuclide conjugates and antibody-drug conjugates have reached the regulatory approval stage, and there are more than 40 antibody conjugates in clinical trials. The time may have come for this technology to become a major contributor to improving treatment for patients with cancer.

The challenges posed by the development of therapeutic antibody-drug conjugates (ADCs) are formidable. Over the past 30 years, many cell surface proteins that have selective aberrant expression on malignant cells or are aberrantly highly expressed on the surface of malignant cells have been identified. In many cases, specific antibodies that bind tightly to malignant cell surface proteins were developed. However, these antibodies often were not active antitumor agents. ADCs provide an opportunity to make use of antibodies that are specific to cell surface proteins.[1] Successful ADCs have improved tumor specificity and potency compared with traditional drugs.[2,3] Heterogeneity of antibody target expression on the tumor surface, and expression of the antigen by normal tissues, can limit the effectiveness of ADCs. For some hematologic malignancies, antigen expression is specific and homogeneous.

Early ADCs were composed of tumor-specific murine monoclonal antibodies covalently linked to anticancer drugs, such as doxorubicin, vinblastine, and methotrexate. These early conjugates were evaluated in human clinical trials but had limited success because of immunogenicity, lack of potency, and insufficient selectivity for tumor versus normal tissue. The lessons learned from these early explorations led to improvements in all aspects of antibody conjugate therapeutics and, hence, to renewed interest in ADC technology.[4] Immunogenicity was overcome by replacing murine antibodies with humanized or fully human antibodies. Potency was improved by using drugs that were 100- to 1,000-fold more potent than previously used drugs. Selectivity was addressed by performing more careful target and antibody selection. As a result of such improvements, gemtuzumab ozogamicin (Mylotarg; Pfizer, New York, NY) was granted accelerated U.S. Food and Drug Administration (FDA) approval for the treatment of acute myelogenous leukemia in 2000, becoming the first commercially available ADC. However, gemtuzumab ozogamicin was withdrawn from the market in 2010 because, in postmarketing follow-up clinical trials, it failed to meet the prospective efficacy targets. Two ADCs, trastuzumab emtansine (T-DM1, Kadcyla; Genentech/Roche, South San Francisco, CA) and brentuximab vedotin (SGN-35; Adcetris, Seattle Genetics, Seattle, WA; Millennium/Takeda, Boston, MA), reached FDA approval in 2014 and 2011, respectively, for treatment of metastatic breast cancer and refractory Hodgkin lymphoma and systemic anaplastic large cell lymphoma, respectively. More than 40 ADCs are in clinical trials (Table 1).

From the Laura and Isaac Perlmutter Cancer Center, NYU Langone Medical Center, New York, NY; Indiana University Melvin and Bren Simon Cancer Center, Indianapolis, IN; National Cancer Institute at the National Institutes of Health, Bethesda, MD.

Disclosures of potential conflicts of interest are found at the end of this article.

TARGETS AND ANTIBODIES

In selecting cell surface protein targets, whether on malignant cells, on malignant disease–associated cells (e.g., tumor endothelial cells), or in the tumor microenvironment, it is important that the antigen expression is abundant on the target cells or in the tumor region and is very limited on all other cells and normal tissues.[5-9] The patient whose tumor expresses high levels of the target antigen is most likely to benefit from treatment. ADCs are targeted, potent cytotoxic agents. Most of the proteins being targeted with antibody conjugates are normal proteins, as opposed to mutant proteins; therefore, some antigen expression on normal cells is possible and even likely. Technologies for antibody discovery, development, and engineering are well established. Phage display libraries and humanized mice can produce fully human antibodies, and mouse antibody humanization can result in highly specific nonimmunogenic antibodies (Fig. 1). In most cases, the most appropriate antibody for ADC therapeutics requires that the antibody-target complex internalize into the target cells where the drug is released.

DRUGS

The drugs most widely conjugated to form ADCs target tubulin or DNA and are uniformly highly potent cytotoxic agents with 50% inhibitory concentration (IC_{50}) values in the picomolar range in cell culture.

Though ADCs are among the most tumor-selective anticancer therapeutics developed to date, only a small fraction of the drug reaches the intracellular target. The maytansinoids and dolastatin analogs target tubulin, and both suppress microtubule dynamics.[10] The duocarmycins and calicheamicins target the minor groove of DNA. The amatoxin analogs inhibit RNA polymerase II and III, and SN-38 targets toposiosmerase I, which results in DNA double-strand breaks.[11] These molecules have in

KEY POINTS

- Most antibody-drug conjugate (ADC) targets are cell surface proteins that are much more abundant on tumor cells than on normal cells/tissues.
- ADCs selectively deliver targeted chemotherapy and could be important components of combination treatment regimens.
- ADCs are being targeted to solid tumors and to hematologic malignances.
- The three components of ADCs, antibody, linker, and drug, must be stable in circulation for days or weeks.
- T-DM1 and brentuximab vedotin are the first two ADCs to gain regulatory approval for HER2-positive metastatic breast cancer and Hodgkin lymphoma, respectively. Patient selection and understanding about the toxicity profiles of these agents are critical for integration of ADCs into inpatient care.

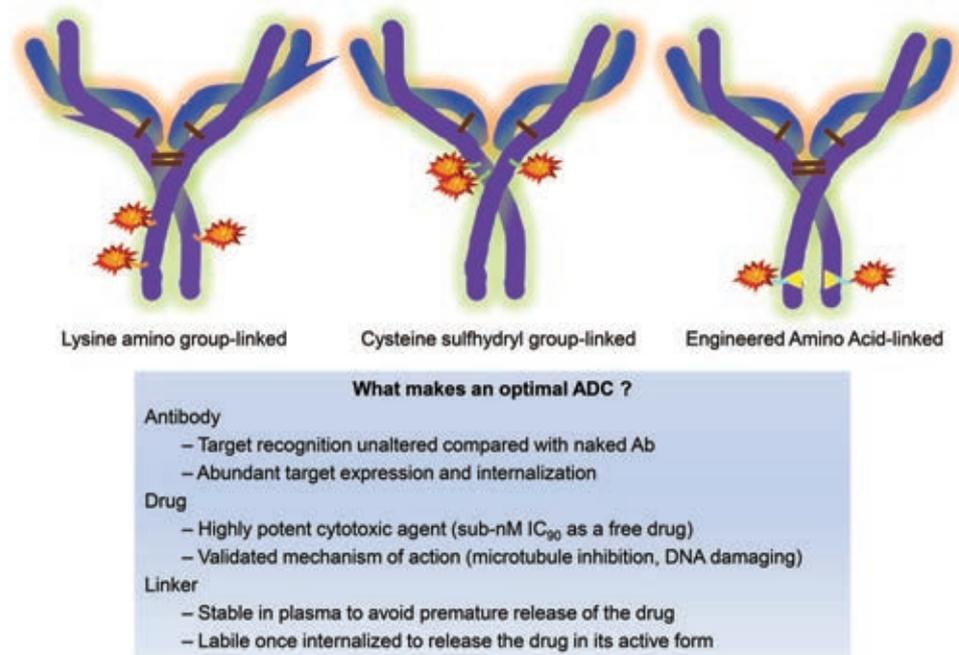
Abbreviations: ADC, antibody-drug conjugate; DOX, doxorubicin; EGFR, epidermal growth factor receptor.

FIGURE 1. Antibody-Drug Conjugate Schematic


The drug is linked through the epsilon amino groups of lysine, through the intrastrand sulfhydryl linkages, and through genetically engineered unnatural amino acids to provide specific binding sites and, thus, a single chemical species.

common an extreme potency and a lack of tumor selectivity, which limits the use of the parent compounds. Dolastatin 10, the parent molecule of the auristatins, was explored in clinical trials in the 1990s, but exploration was terminated in 1995 when the drug failed in a phase II trial in patients with prostate cancer.[12] The maytansinoids are exquisitely potent cytotoxic agents. Maytansine was assessed in early clinical trials in the early 1980s. The phase II clinical trials were disappointing, with very little evidence of response.[13] Duocarmycins are antibiotics that alkylate DNA in the A-T–rich regions of the double-helix minor groove. Several duocarmycins were evaluated in clinical trials, and dose-limiting toxicities occurred at doses too low to achieve antitumor activity.[14,15] Calicheamicins bind in the DNA minor grove and induce double-strand breaks, but they have narrow therapeutic indices and serious late toxicities.[16,17] SN-38, the active metabolite of irinotecan, is poorly bioavailable and has a narrow therapeutic index.[18] Amatoxins, cytotoxic cyclopeptides that target RNA polymerases, are produced by poison mushrooms. Normal tissue toxicities of the amantins precluded their clinical exploration.[19]

ADCs are an effective method to increase the therapeutic index of these highly potent cytotoxic agents. The drugs used in ADCs must have sufficient water solubility and prolonged stability in aqueous formulations and in plasma, and they must have a functional group that is suitable for conjugation with a linker and that must not be readily susceptible to lysosomal enzyme degradation. Consistent with the potent nature of the drug, ADCs are often scheduled like cytotoxic chemotherapy in clinical regimens, with dosing once every 3 weeks.[20-22]

LINKERS

Linkers are short spacers that covalently couple the drug to the antibody protein and must be stable in circulation (Fig. 1). Inside the cell, most linkers are labile; however, some are stable, requiring degradation of the antibody and linker to release the cytotoxic agent.[23,24] Many linkers react with lysine side chains throughout the antibody or with the sulfhydryls in the hinge regions of the antibody. Linkers in clinical use include acid-labile hydrazone linkers that are degraded under the low pH conditions found in lysosomes. Disulfide-based linkers are selectively cleaved in the cytosol in the reductive intracellular milieu. Noncleavable thioether linkers release the drug after degradation of the antibody in the lysosome, and peptide linkers, such as citrulline-valine, are degraded by lysosomal proteases in cells. Linkers using L- and D-alanine and beta-glucuronide linkers are being explored. Linkers with polyethylene glycol spacers have been developed to increase the solubility of the conjugate.[25,26]

Linkers can influence the circulating half-life and safety of conjugates by minimizing the release of the drug molecule in circulation and optimizing the delivery of the conjugate to the target tissue. Often, during drug development, investigators will test several linkers in safety and efficacy assays to select the best candidate conjugate.

ADCs

Drug-loading stoichiometry and molecular homogeneity are important determinants of the safety and efficacy of antibody conjugates (Fig. 1). The goal is to develop ADCs that are sin-

gle chemical species or nearly single chemical species. Under-conjugated antibody decreases ADC potency, and highly-conjugated antibody markedly decreases circulating half-life and impairs binding to the target protein, thus decreasing ADC potency and efficacy.[27] For most ADCs, linkage of three to four drug molecules per antibody molecule is optimal to maintain the circulating half-life to near that of the naked antibody, preserving antibody binding to the target protein, and delivering a lethal number of drug molecules to the target cell. Several site-specific conjugation approaches are being explored to achieve ADCs that are single chemical species. Antibodies with site-specific incorporation of non-native amino acid linker sites can be efficiently produced.[28]

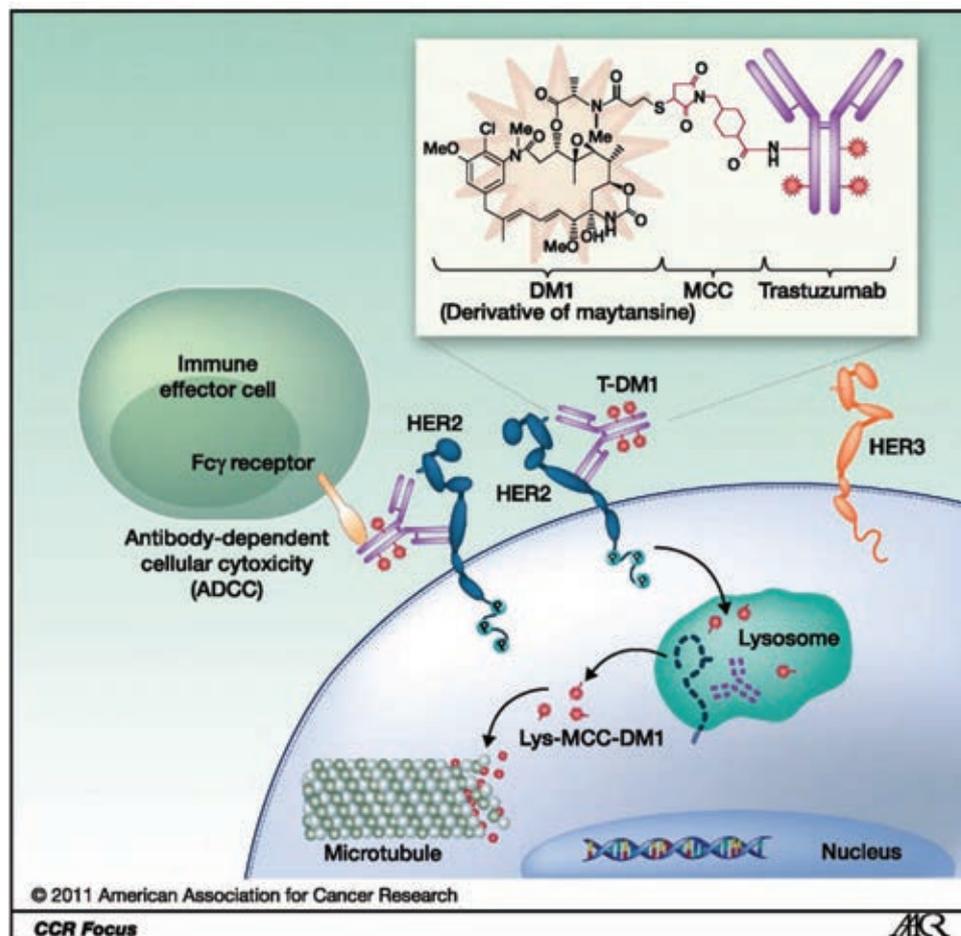
FROM THEORY TO PRACTICE: T-DM1 CASE STUDY

Mechanisms of ADC action for T-DM1 include all of the effects of trastuzumab plus the effects of the conjugated maytansine derivative. T-DM1 binds HER2, and the HER2/T-DM1 complex undergoes internalization, followed by lysosomal degradation. This process results in the intracellular release of DM1-containing catabolites that bind to tubulin

and prevent microtubule polymerization as well as suppress microtubule dynamic instability. T-DM1 also has been shown to retain the mechanisms of action of trastuzumab, including disruption of the HER3/phosphoinositide 3-kinase (PI3K)/AKT signaling pathway and Fcγ receptor–mediated engagement of immune effector cells, which leads to antibody-dependent cellular cytotoxicity (Fig. 2).[29]

INTEGRATION OF T-DM1 IN CLINICAL PRACTICE

The experience with trastuzumab over the past 2 decades has facilitated the rapid integration of T-DM1 for the treatment of HER2-positive metastatic breast cancer (HER2+ MBC). HER2 testing must be performed at the time of diagnosis or recurrence for all invasive breast cancers. HER2 positivity is defined as protein expression using immunohistochemistry (score, 3+), or as *HER2* gene amplification using fluorescence in situ hybridization.[30] Unless there is a contraindication, trastuzumab-based chemotherapy is recommended for the treatment of HER2+ breast cancer in the adjuvant, neoadjuvant, and metastatic settings.[31] Pertuzumab has been shown to be effective as part of neoadjuvant taxane/trastuzumab-based

FIGURE 2. Structure of T-DM1 and Mechanisms of Action


T-DM1 binds HER2; the complex is internalized and degraded in lysosomes, releasing DM1. T-DM1 retains the mechanisms of action of trastuzumab, including antibody-dependent cellular cytotoxicity and HER pathway signaling disruption.

regimens[32] and as first-line therapy for HER2+ MBC.[33-35] Lapatinib is approved in combination with capecitabine for patients whose tumors have progressed on trastuzumab-based therapy.[36] A combination of lapatinib and trastuzumab has been shown to improve overall survival rates in patients with HER2+ MBC who have experienced progression after multiple regimens.[37] For details regarding the management of HER2+ MBC, please refer to the American Society of Clinical Oncology (ASCO) clinical practice guideline.[38] On the basis of the results of the EMILIA randomized trial described below,[39] the FDA-approved T-DM1 (Kadcyla, Genentech, South San Francisco) in February 2013 for the treatment of patients with HER2-overexpressing MBC who have received prior treatment with trastuzumab and a taxane.

T-DM1: PATIENT SELECTION

All clinical trials of T-DM1 used HER2 protein overexpression and/or *HER2* gene amplification as one of the key inclusion criteria. As with all other HER2-directed therapies, T-DM1 appears to be effective only against HER2+ tumors. Ongoing clinical trials are evaluating the role of T-DM1 in other solid tumors that either overexpress HER2 protein and/or amplify the *HER2* oncogene (e.g., gastric cancer) or carry *HER2* mutations (e.g., NCI-MATCH trial).

Phase I and phase II trials of T-DM1 showed objective responses in patients with HER2+ MBC with an acceptable toxicity profile, leading to the design of pivotal phase III, randomized trial (EMILIA). In this study, patients with HER2-positive MBC were randomly assigned to T-DM1 or to capecitabine in combination with lapatinib. One of the key inclusion criteria was prior trastuzumab- and taxane-based chemotherapy. In this study, T-DM1 therapy improved response rate, time to progression, and overall survival rate compared with the combination of capecitabine and lapatinib.[39] In addition, T-DM1 was better tolerated than capecitabine plus lapatinib.

The TH3RESA global trial was launched to determine the effectiveness of T-DM1 in heavily pretreated patients (beyond second line) who had HER2+ MBC. In this study, more than 600 patients with progressive MBC who had been previously treated with trastuzumab and lapatinib were randomly assigned to either T-DM1 or to a standard treatment of the physician's choice. The final results showed a 3-month improvement in the median progression-free survival time in the T-DM1 group. Response rates were improved in the T-DM1 group (31% in T-DM1 vs. 9% in control group).[40] There was a suggestion of an improved overall survival rate for patients treated with T-DM1, although the data are not mature. Importantly, T-DM1 was better tolerated than other standard chemotherapies. On the basis of these results, T-DM1 is now considered a new standard treatment after multiple lines of therapy for patients who have HER2+ MBC.

After obtaining regulatory approval for T-DM1 when progression develops after trastuzumab treatment, the next logical step was to evaluate the efficacy of this novel ADC in the first-line setting. The MARIANNE trial recruited more than 1,000 patients with HER2+ MBC who had not received any chemotherapy in the metastatic setting. In this study, patients were randomly assigned to receive a taxane/trastuzumab, T-DM1, or T-DM1 plus pertuzumab (Perjeta; Genentech/Roche, South San Francisco, CA). However, this trial did not include a comparator arm with taxane, trastuzumab, and pertuzumab, which is the standard first-line therapy for HER2+ MBC.[33] Though detailed data have not yet been shared, the sponsor recently announced that the MARIANNE trial did not reach its primary endpoint.[41]

On the basis of the encouraging results reported in patients with metastatic disease, there is great interest in testing the efficacy of T-DM1 for early-stage breast cancer. An ongoing, single-arm, phase II trial (NCT01196052) is evaluating the efficacy of T-DM1 in the adjuvant or neoadjuvant setting. After completion of an anthracycline-based adjuvant/neoadjuvant chemotherapy regimen (doxorubicin/cyclophosphamide [AC] or 5-fluorouracil/epirubicin/cyclophosphamide [FEC]), 153 patients will be treated with T-DM1 instead of the conventional taxane/trastuzumab combination for 17 cycles. In the ATEMPT trial (NCT01853748), 500 patients with stage I breast cancer will be randomly assigned to T-DM1 versus paclitaxel plus trastuzumab. In the KAITLIN trial (NCT01966471), 2,500 patients will be randomly assigned after adjuvant AC/FEC to either a taxane, trastuzumab plus pertuzumab, or T-DM1 plus pertuzumab. A randomized, phase III trial (KATHERINE; NCT01772472) will evaluate the efficacy of T-DM1 in patients who have residual disease after neoadjuvant, trastuzumab-containing regimens. In this study, patients are randomly assigned to continuation of trastuzumab (standard treatment) or to T-DM1. This study has a planned enrollment of more than 1,400 patients. The KRISTINE trial will examine the combination of docetaxel, carboplatin, trastuzumab, and pertuzumab (one of the FDA-approved neoadjuvant pertuzumab-containing regimens) versus T-DM1 plus pertuzumab. All of these trials will provide key data to integrate T-DM1 in the treatment of HER2+ early-stage breast cancer.

MANAGEMENT OF T-DM1 OFF-TARGET TOXICITIES

It is important to understand common off-target toxicities caused by T-DM1 and to manage them appropriately (Table 2).

Thrombocytopenia was reported in phase I and phase II clinical trials of T-DM1. In the EMILIA trial, the incidence of grade 3 or worse thrombocytopenia was 12.9% in the T-DM1–treated group and was 0.2% in the lapatinib/capecitabine group (overall incidence, 28% and 2.5%, respectively). The mechanism of T-DM1–induced thrombocytopenia is puzzling, because platelets do not overexpress HER2. Recent data indicate that thrombocytopenia may be mediated in part by DM1-induced impairment of megakaryocytic differentiation, with a less-pronounced effect on mature megakaryocytes.[42] For most patients receiving T-DM1, thrombocytopenia is asymptomatic and can be monitored without any changes in treatment. Platelet counts should be monitored before ini-

TABLE 2. Management of T-DM1 Off-Target Toxicity

Toxicity	Management
IRRs	T-DM1 treatment should be interrupted in patients with severe IRRs and permanently discontinued in the event of a life-threatening IRR. Patients should be closely monitored for IRRs, especially during the first infusion.
Thrombocytopenia	Platelet counts should be monitored prior to initiation of T-DM1 and prior to each T-DM1 dose. Dose modifications should be instituted as appropriate.
Hemorrhage	Consider additional monitoring when concomitant use of anticoagulants or antiplatelet therapy is medically necessary.
Hepatotoxicity	Reduce the dose of T-DM1 if serum transaminases or total bilirubin are elevated. Discontinue the drug if abnormal liver function tests persist.
Left Ventricular Dysfunction	Hold T-DM1 if LVEF drops below normal (usually 50%) or is a >15% decrease from a prior level. Discontinue the drug if LVEF does not recover to normal levels.
Pneumonitis	Discontinue the drug.
Neurotoxicity	Monitor for signs or symptoms of neurotoxicity. T-DM1 should be temporarily discontinued in patients experiencing grade 3 or 4 peripheral neuropathy until it resolves to grade ≤2.

Adapted from the Kadcyla package insert.[58]
Abbreviations: T-DM1, trastuzumab emtansine; IRR, infusion-related reaction; LVEF, left ventricular ejection fraction.

tiation of T-DM1 and before each T-DM1 dose. Dose modifications should be instituted as appropriate.

T-DM1 can cause serious hepatotoxicity, including liver failure and death. Serum transaminases and bilirubin must be monitored before initiation of T-DM1 treatment and before each T-DM1 dose. If serum transaminases or total bilirubin are increased, the dose of T-DM1 should be reduced or discontinued.

T-DM1 administration may lead to reductions in left ventricular ejection fraction (LVEF). All patients should undergo evaluation of LVEF before and during treatment with T-DM1. If a patient develops a clinically meaningful decrease in left ventricular function, the treatment should be held.

T-DM1 FOR THE TREATMENT OF BRAIN METASTASES

Involvement of the central nervous system remains one of the major challenges for patients with HER2+ MBC.[43] ASCO has recently published a clinical practice guideline for patients with HER2+ breast cancer and brain metastases.[44] Despite all efforts, prognoses remains poor for these patients, and novel approaches are needed. Anecdotal reports suggest that T-DM1 can be effective for the treatment of HER2+ brain metastases.[45,46] A retrospective analysis of the EMILIA trial showed a low incidence of brain metastasis in patients treated with T-DM1 (1.8%) and in patients treated with lapatinib and capecitabine (0.6%). A total of 95 patients had controlled brain metastases at study entry. Only 2% of patients treated with T-DM1 and 1.6% of patients assigned to lapatinib

and capecitabine developed progressive disease in the central nervous system during the study. Although progression-free survival was similar for all patients with brain metastasis at baseline, the median overall survival was significantly longer in patients treated with T-DM1 compared with lapatinib and capecitabine (26.8 vs. 12.9 months; hazard ratio [HR], 0.382; p = 0.0081).[47] These data provide a rationale to study the safety and efficacy of T-DM1 in combination with stereotactic radiosurgery and other radiation therapy modalities.

NOVEL ADCs AND RATIONAL COMBINATIONS

The ability of ADCs to deliver chemotherapy neatly to the tumor not only offers the potential for greater efficacy and reduced toxicity as monotherapy but also expands the potential of combination regimens. In the case of T-DM1, virtually any agent that one would consider adding to a trastuzumab/chemotherapy backbone could be considered for addition to T-DM1. Conceptually, one could group the potential combinations into several broad categories including (1) anti-HER2 agents, (2) cytotoxics, (3) inhibitors of parallel growth factor pathways, and (4) inhibitors of downstream signaling molecules. Though a large number of clinical trials are ongoing, few trials have reported results thus far.

In vitro, T-DM1 and pertuzumab act synergistically; xenograft models confirm enhanced tumor inhibition with the combination compared with either agent alone.[48] T-DM1 and pertuzumab can be combined at full doses with no unexpected toxicities. In previously treated patients, T-DM1 plus pertuzumab had similar activity (objective response rate, 33%; progression-free survival, 5.5 months) to that observed with single-agent T-DM1 (objective response rate, 26% to 35%; progression-free survival, 4.6 to 6.9 months)[22,49,50] and with pertuzumab plus trastuzumab (objective response rate, 24%; progression-free survival, 5.5 months).[51] In previously untreated patients, the objective response rate was 57% and the median progression-free survival time was 7.7 months (95% confidence interval [CI], 3.71 to 15.87 months).[52] The order of treatment may be important; in preclinical models, pretreatment with pertuzumab appeared to blunt the efficacy of T-DM1.[53]

At first thought, the combination of T-DM1 and an unconjugated cytotoxic seems an anathema—why add the toxicity of another chemotherapy agent to one designed partly to minimize toxicity? In patients with low-risk disease, that argument may be persuasive, but the goal of increased efficacy predominates in patients with aggressive, high-risk disease. Ongoing trials explore the potential to combine T-DM1 with a variety of chemotherapy agents, including paclitaxel, docetaxel, and capecitabine, among others. Alternatively, T-DM1 has been substituted for the taxane/trastuzumab portion of adjuvant therapy for high-risk patients in the ongoing KAITLIN trial.

HER2+, hormone receptor–positive (HR+) breast cancer is a distinct subtype associated with a good prognosis but a lower response to standard chemotherapy plus anti-HER2 agents. Concurrent blockade of the HER2 and estrogen receptor pathways has been a successful strategy, increasing

objective response rates and progression-free survival in patients with advanced disease.[54,55] The ADAPT HER2+/HR+ trial compared T-DM1 monotherapy to T-DM1 plus endocrine therapy (premenopausal patients: tamoxifen; postmenopausal patients: aromatase inhibitor or trastuzumab plus endocrine therapy as neoadjuvant therapy). The treatment with T-DM1 plus endocrine therapy resulted in a greater median fractional decrease in proliferation (Ki67) after 3 weeks of therapy (40% in the T-DM1/endocrine therapy arm vs. 14% and 25% in the T-DM1 monotherapy and trastuzumab/endocrine therapy arms, respectively).[56]

T-DM1 is an ideal candidate to combine with agents that have been difficult to combine with chemotherapy because of overlapping toxicities. Ongoing trials combine T-DM1 with a variety of downstream signaling inhibitors and other molecular pathways, including inhibitors of heat shock proteins, cyclin-dependent kinases, PI3K/AKT, and mammalian target of rapamycin (mTOR).

Importantly, T-DM1 may be considered a prototype and is almost certainly just the first ADC for the treatment of HER2-expressing breast cancer. The potential to use HER2 as a molecular address also may increase the proportion of patients who could benefit from HER2-targeted agents. For example, SYD985 is an HER2-targeting ADC that combines trastuzumab and a duocarmycin payload with a cleavable linker. In cell lines with low HER2 expression (i.e., HER2 2+ and 1+), SYD985 had both in vitro and in vivo activity.[57] If confirmed in the clinic, this could extend the target population of patients with breast and gastric cancers who may respond to this treatment modality to include those with fluorescence in situ–negative or immunohistochemistry-negative HER2 2+ and 1+ disease.

Geriatric Oncology and Clinical Trials

Stuart M. Lichtman, MD

OVERVIEW

The overall aging of the population has resulted in a marked increase in the number of older patients with cancer. These patients have specific needs that are different from those of the younger population. Cancer clinical trials have included an inadequate number of older patients, resulting in lack of meaningful data to make evidence-based decisions for this population. As a result, clinicians have to extrapolate data from younger and healthier patients. There are a number of reasons for this under-representation, including a design and implementation structure for clinical trials that does not meet the needs of this vulnerable population. Issues that need to be addressed include alterations in eligibility criteria to make them less restrictive by accounting for multiple comorbidities and prior malignancy and endpoints specific for older patients, such as quality of life, changes in function, and maintenance of independence. Other issues specific to the older population include alterations in dose-limiting toxicity, measures of treatment-related toxicity, and polypharmacy. Phase I trials can be appropriate for older patients but need to be tailored to their needs. Some form of geriatric assessment needs to be included to help with eligibility, assessment, and stratification. For future clinical trials to be truly meaningful they need to appropriately assess and incorporate the needs of the majority of the cancer population.

The demographic shift and the resultant increase in the number of older patients with cancer, which was predicted by the founders of geriatric oncology (Dr. B.J. Kennedy, Dr. Rosemary Yancik, and others), has now arrived. It has long been recognized that the most significant risk factor for the development of cancer is aging. Cancer and its treatment can affect the overall life expectancy, as well as the active life expectancy and function, of older individuals. The traditional study approach to cancer, with its focus on younger, healthier patients, has resulted in a lack of high-quality data to adequately guide care for older patients. In 1983, Dr. Yancik organized a symposium sponsored by the National Cancer Institute and the National Institute on Aging and published a monograph, "Perspectives on Prevention and Treatment of Cancer in the Elderly," highlighting the importance of research in cancer and aging.[1] In the 1988 American Society of Clinical Oncology (ASCO) Presidential Address, Dr. Kennedy encouraged the study of aging and cancer.[2] He stated, "Our society need not ration how we will treat our disadvantaged members, but should continue to seek those preventive and positive measures that can shorten our later period of morbidity. A very major cancer load will persist well into the 21st century, even if the attempts at prevention are eventually a total success. There is a developing knowledge on aging. Care of the older person needs to be part of medical education and oncology education. Research will help attain a desirable quality of life with aging and a reduced morbidity."

The goals set forth by Drs. Yancik and Kennedy are yet to be fully achieved; however, many strides have been made toward that end. There has been increased recognition of the importance of the relationship between aging and cancer, as well as an increase in evidence-based research to guide the care of older adults with cancer. In addition, this research is being performed by a growing number of investigators at institutions across the nation, as well as internationally. The International Society of Geriatric Oncology, founded in the year 2000, fosters the mission of developing health professionals in the field of geriatric oncology to optimize treatment of older adults with cancer, through education, clinical practice, and research. The Society's publication, the *Journal of Geriatric Oncology*, is the first journal devoted solely to the field. The Cancer in the Elderly Committee of the Cancer and Leukemia Group B (now the Alliance for Clinical Trials in Oncology) has supported furthering research in geriatric oncology through clinical trials and secondary data analyses. The Cancer and Aging Research Group has developed an instrument to predict chemotherapy toxicity, initiated and supported trials to validate this methodology in different clinical settings, and, most importantly, mentored junior investigators in geriatric oncology. The Gynecologic Oncology Group Elderly Taskforce is supporting the first prospective trial in older women with ovarian cancer and planning further studies in other diseases and modalities. The American Society of Clinical Oncology has also fostered a number of initiatives in geriatric oncology. These

include a Geriatric Oncology Issue Exploration Team, educational materials including ASCO University, sessions at the Annual Meeting including a Geriatric Oncology track, the BJ Kennedy Award for Excellence in Geriatric Oncology, and a Geriatric Oncology component of the Cancer Education Committee.

Older patients have long been under-represented in clinical trials.[3,4] There are many reasons for this, including fear of toxicity, restrictive trial eligibility, and ageism, which includes physician barriers.[5-8] When older patients do participate, they are usually a disproportionately small representation of the patients and their data are under-reported.[9] The Institute of Medicine has issued a report describing the crisis in cancer care for an aging population.[10]

TRIALS SPECIFIC FOR OLDER PATIENTS

Older patients have often been undertreated.[11] In addition, because of the lack of objective data they have been subject to increased toxicity and poor outcomes. Clinical trial eligibility criteria have typically excluded these patients and been unable to meet their needs. Clinicians need objective, age-specific data to make appropriate treatment decisions for these vulnerable patients. The current accrual methods have been inadequate to accrue adequate numbers of older patients into studies. The need for such clinical trials was recognized in 1980 when Begg et al evaluated the studies from the Eastern Cooperative Oncology Group.[12] They showed that the patients in clinical trials did not experience excessive toxicity, compliance was good, and efficacy was equivalent. In 1983, Dr. Yancik organized a symposium sponsored by the National Cancer Institute and the National Institute on Aging and published a monograph, "Perspectives on Prevention and Treatment of Cancer in the Elderly," highlighting the importance of research in cancer and aging.[1] The participants noted a number of pervasive issues, including discrepancies between physiologic and calendar age and changes in the age structure of the nation's population. They recommended analyses of existing databases, prospective clinical trials, epidemiologic and longitudinal studies, pharmacokinetics and drug sensitivity trials, and quality-of-life issues. These recommendations are still relevant. In his ASCO Presidential Address of 1988 and Journal of Clinical Oncology editorial of 1991,[2,13] BJ Kennedy discussed the need to emphasize study of older patients and included physician education as a key factor. In 1994, Trimble et al demonstrated the discrepancy between the incidence of certain cancers and the under-representation of older patients.[14] In 1999, Hutchins et al reviewed participation of Southwest Oncology Group trials and found similar results.[3] Analysis of National Cancer Institute (NCI)-sponsored clinical trials also revealed a need to increase participation of older patients.[15] Despite this, in a subsequent review of cancer drug registration studies, under-representation of older people was again noted.[4] Even 8 years later, a follow-up analysis did not show any substantial improvement.[16] The clinical trial development process has been inadequate to meet the needs of the older population and there is a need to develop a new process and new thoughts on this issue.[17] Trials specific for older patients can incorporate functional and cognitive assessment instruments to help assess the patients. They can also include age-specific pharmacokinetic analyses, evaluation of polypharmacy, and other geriatric syndromes, which would not be possible in studies not specific for this population. Issues regarding barriers to trials and study design are summarized in Sidebars 1 and 2. Following is a discussion of problems related to clinical trial design and possible alternatives.

ELIGIBILITY ISSUES

Restrictive eligibility issues are an important reason why older patients are not accrued to clinical trials. Standard performance status measurements such as Karnofsky Performance Status or Eastern Cooperative Oncology Group (ECOG) are inadequate to define function in older patients.[18] Populations need to be defined more specifically to encompass the broad range of older patients (i.e., frail, vulnerable, or well). This can best be determined by some form of geriatric assessment, which could help in defining the patient population, aid in stratification, and improve analysis of the results.[19,20] The typical end-organ requirements for eligibility need to be made more flexible. For example, renal function requirements can be relaxed when the drug being studied

KEY POINTS

- Aging of the general population will result in a large increase in the number of older patients with cancer.
- Older patients with cancer are under-represented in clinical trials.
- There are a number of barriers that prevent older patients from participating in clinical trials.
- Current clinical trial design is inadequate to appropriately assess the value of newer therapies.
- Components of clinical trials such as eligibility, endpoints, survivorship, and dose-limiting toxicity need to be re-evaluated.

SIDEBAR 1. Barriers to Participation in Clinical Trials[17]

- Physician recommendation
- Social: transportation, caregiver issues
- Financial: not all study drugs covered, multiple visits not covered
- Trial design
  - Restrictive eligibility
  - "Excessive" visits
- Perception of aggressive therapy
- Limited expectation of benefit from patient or family

does not have a renal mechanism of clearance. Limiting office visits and testing will facilitate compliance by allowing patients with limited social supports to participate and minimizing caregiver burden. Many older patients have had previous cancer treatment; therefore, prohibition of a prior diagnosis of malignancy and treatment needs to be reconsidered. For diseases in which survival is relatively short, such as metastatic pancreatic cancer, treatment with localized radiation 5 or 10 years earlier for a localized disease is not relevant. Less restrictive eligibly criteria will allow a broader range of patients to participate in trials. These carefully assessed and monitored patients will yield data that will be applicable to the general population of older patients and will provide a degree of safety in terms of dosing and supportive care. It is fair to state that the doses obtained from phase I trials may not be broadly applied to the geriatric population without further exploration in that population, as we currently do in pediatric populations. A phase I dose should be studied in older patients with varying degrees of function impairment and comorbidity.

ENDPOINTS OF CLINICAL TRIALS

The traditional endpoint of survival may not be appropriate for the older patient and particular care must be must be taken when overall survival is a study endpoint. A number of studies determined that cause of death might differ in older versus younger patient populations. In lymphoma trials, deaths attributed to tumor or treatment-related toxicity were similar for patients older than and younger than 60. The observed differences in survival rate—22% of patients greater than or equal to 60 years of age but only 2% of patients less than 60 years—were instead associated with other causes of death not obviously related to the lymphoma or its therapy. The inclusion of older patients in clinical trials may decrease the overall survival secondary to deaths from ap-

parently unrelated causes.[21,22] Patients with early-stage breast cancer and comorbidity had a 4-fold higher rate of all-cause mortality compared with patients who had no comorbid conditions.[23] This phenomenon is particularly important in cancers that can have a relatively indolent course. In prostate cancer studies, it has been shown that competing causes of death are substantive contributors to mortality.[24,25] Progression-free survival, time without symptoms, measuring treatment-free intervals, or maintenance of independence (or prevention of dependency) may be more meaningful endpoints.

QUALITY OF LIFE IN CLINICAL TRIALS

Patient quality of life is affected by a number of factors related to the cancer and treatment, as well as its interaction with other diseases. Assessment of quality of life is an important endpoint in clinical trials for older adults; however, the traditional view of quality of life may be broadened in an older patient population. For example, the compression of morbidity and disability to maximize the preservation of "active" life expectancy is also a potential quality of life endpoint, particularly in a palliative care setting.[26,27] There are many parallels between geriatric assessment and quality of life assessment in that both are multidimensional and broad. They share many dimensions and focus on issues that are important to older people, particularly the ability to function fully in social roles and participate in daily activities. Quality of life studies have been performed as a predictive marker in non–small lung cancer and have been analyzed in the context of the effect of therapy.[28-30]

FUNCTION AND CLINICAL BENEFIT

Response rate is one of the standard endpoints of phase II studies, whereas survival and disease-free survival are endpoints of phase III studies. Assessment of clinical benefit has become an important endpoint, especially in the management of metastatic disease, and some agents, including gemcitabine for pancreatic cancer[31] and mitoxantrone for prostate cancer,[32,33] have been approved for use because of demonstrated clinical benefits. In the older population, impaired functional status is a risk factor for cancer treatment toxicity and overall survival. Longitudinal changes in functional status are a potential endpoint of clinical trials. This was explored in a clinical investigation of infectious syndromes in older people in which function was used as a risk factor for infectious syndromes as well as an outcome measure.[34] In older individuals with limited life expectancies, improvement in survival may be difficult to demonstrate and clinical benefits may become paramount. In addition to improvement in pain and other symptoms, the benefits of chemotherapy may include prevention of functional dependence and functional deterioration. As this is one of the most common complications of diseases in older individuals, it is surprising that it has not been more commonly explored as

an outcome of cancer treatment. Chemotherapy might not only affect functional status in metastatic incurable cancer, but might also result in changes of functional status in patients whose cancer may be curable, such as patients with breast or colorectal cancer receiving adjuvant chemotherapy and patients with lymphoma.

SURVIVORSHIP

Although not usually part of standard clinical trial design, the issues of survivorship in older survivors of cancer need to be explored.[35-37] As a result of increased utilization of screening and earlier detection of common cancers (i.e., breast, colorectal, and prostate), coupled with incremental improvements in cancer treatment and supportive care, the number of cancer survivors in the United States has increased from approximately 3 million in 1970 to almost 14 million in 2014. Patients age 70 and older account for 46% of all survivors.[38] Survivorship has become a separate, but related, discipline of oncology that requires both expertise and the infrastructure to provide optimal care for cancer survivors. Cancer survivors have unique problems. Pre-existing comorbid issues are often compounded by the residual toxicity of cancer treatment and the possibility of late adverse effects. There are also emotional issues regarding survivorship. The Institute of Medicine has issued recommendations regarding cancer survivorship programs and a number of centers of excellence have been developed to evaluate different survivorship clinical models. These are focusing on many different areas, including behavioral interventions, nutritional interventions, cancer screening, studies of morbidity, physical activity, sexual function, and fatigue.[39-41]

DOSE-LIMITING TOXICITY

Schedule changes may alter the toxicity profile of chemotherapy in an older population. For example, weekly paclitaxel versus paclitaxel and bolus 5-fluorouracil every 3 weeks versus infusional 5-fluorouracil may show differences in toxicity. The commonly used toxicity criteria may not be adequate to assess adverse events in older patients. Neuropathy assessment should include evaluation of functional decline or falls. The reports of studies should be age-specific. Most trials only report grade 3 or 4 toxicity, even though grade 2 toxicity often has clinical relevance. Reporting the full spectrum of toxicity for a clinical trial will help clinicians make treatment decisions. Studies of new agents in predetermined stages of aging (i.e., frail or vulnerable) or in patients with specific common comorbidities or functional impairments would be invaluable. Common Terminology Criteria for Adverse Events (CTCAE) version 4 does incorporate functionality in the grading and could be applied to geriatric patients.

PHASE I STUDIES

Only a limited number of phase I trials have involved older patients, despite the fact that the heterogeneity of this population limits the applicability of results from phase I studies performed in fit, younger patients.[42] Traditionally, during the phase I investigation, acute toxicities are identified and the potential duration and reversibility of the toxicities are defined. Selecting appropriate patients to accurately evaluate toxicity in a phase I clinical investigation is extremely important. Typically, patients included in phase I trials have a good performance status and normal organ function. As a result, entry criteria often exclude older patients from dose-finding trials. However, studies in the older person could be defined differently from what has been done historically. For example, after a phase I dose is determined, older patients with varying degrees of functional impairment or comorbidities can be treated to determine whether the dose is appropriate. ASCO has published a position paper on the importance of phase I studies with suggestions to enhance accrual. They mention the critical role that Medicare has in supporting these trials and by inference, increasing the participation of older patients. Although the position paper specifically cites issues regarding pediatric patients, there is no specificity with respect to older people.[43]

The Global Conduct of Cancer Clinical Trials: Challenges and Opportunities

Carlos H. Barrios, MD, Gustavo Werutsky, MD, and Jeovany Martinez-Mesa, MD, PhD

OVERVIEW

The nature of clinical research has changed substantially over the last 2 decades, evolving from being centered almost exclusively in developed countries to a more global scenario that is increasingly involving less developed regions of the world. Pharmaceutical companies and some academic cooperative groups have been conducting challenging, large pivotal registration studies with multinational participation. The much more needed globalization of academic research demands particular attention and represents a worthwhile subject for a more profound discussion. The requirement of large sample sizes and the potential for fast recruitment leading to a speedy completion of clinical studies are probably the most important factors that have fueled globalization of studies. Reduced operational costs and the ability to expedite the regulatory approval of drugs in various countries or regions are also important drivers. Globalization of research should be seen as having a much wider effect in the societies involved, in particular, when we consider public health, economic, social, and ethical implications. Most importantly, the process of expanding the network of clinical research sites also fosters the integration and the development of closer relationships among investigators at a global level. We consider this an essential element that should remain a prominent element in the discussion. In this article, we address the underlying reasons for globalization and we highlight some of the scientific and ethical concerns arising as a consequence. Finally, some strategies to address and mitigate the challenges of conducting multinational clinical research are proposed.

Globalization can be defined as the integration of economies, industries, markets, cultures, and policy-making processes around the world.[1] Even though the concept is not new, the current wave of globalization has been heavily driven and influenced by fantastic and unprecedented advances in the information technology that will likely have a long lasting effect in the process. Even though globalization is frequently approached with a focus in economy, the concept has been increasingly broadened to include a diverse range of areas such as culture, media and technology, socioculture, and the political arena, among others. Proponents of globalization argue that the ultimate result of this international interaction should be economic development and improvement of the standards of living.

Until not so long ago, drug development and cancer clinical research were conducted almost exclusively in wealthy developed regions of the world. However, over the last 2 or 3 decades, clinical trials have been progressively incorporated in a challenging globalization process. As such, the conduct of trials in a global scale represents a major aspect to be taken into account when analyzing the future development of the area. The globalization of clinical trials, as well as multinational and multi-institutional research collaboration, represents a scenario that requires permanent and concentrated efforts by all involved if we are to achieve the fundamental objective of generating the appropriate answers to the health problems we face around the world.

Large pharmaceutical companies have been conducting large pivotal registration studies increasingly with multinational participation, and much has been discussed on the globalization of clinical research addressing the subject from the pharmaceutical industry perspective. However, the much more needed globalization of academic research is at least as challenging, demands particular attention, and represents a worthwhile subject for a more profound discussion as well.

The requirement of large sample sizes and the potential for fast recruitment leading to a speedy completion of clinical studies are probably the most important factors that have fueled globalization of studies, particularly of large registration phase III trials. Other factors may include the reduced operational costs and the ability to expedite the regulatory approval of drugs in various countries or regions. However, globalization of research should be seen as having a much wider effect in the societies involved, in particular when we consider the public health, economic, social, and ethical implications.

The process of expanding the network of clinical research sites also fosters the integration and the development of

closer relationships among investigators at a global level. We consider this an essential element that should remain a prominent driver in this process.

In this article, we discuss recent trends in the globalization of clinical research in general and try to focus on some aspects particularly related to cancer research. As we address the underlying reasons for the phenomenon, we highlight some of the scientific and ethical concerns that have arisen as a consequence. Finally, some strategies to address and mitigate the challenges of conducting multinational clinical research are proposed.

GLOBALIZATION OF CANCER CLINICAL TRIALS

Cancer clinical research has historically been carried out in developed regions, particularly North America and Western Europe. Up to the 1980s, North American and European cooperative groups mostly sponsored by the National Cancer Institute (NCI) conducted most of the pivotal practice-changing trials. At that time, a progressive shift in the funding of research toward pharmaceutical companies was seen. In parallel, an increasing participation of research sites from countries outside North America and Western Europe was identified and has since transformed the development of new medications to what is now an increasingly globalized process.

Data from 15 global trial registries including more than 205,000 clinical trials conducted in 163 countries helps us to understand the dramatic changes in this area over the last few

KEY POINTS

- The nature of clinical research has changed substantially over the last 2 decades, evolving from being centered almost exclusively in developed countries to involve less developed regions of the world.
- Although early phase trials remain largely concentrated in the United States and Western Europe, confirmatory phase III studies have become increasingly global, sometimes with the largest proportion of patients being recruited in developing countries.
- Although the process of globalization should be considered largely unavoidable, we need to recognize both the advantages and the challenges associated with multiregional clinical trials.
- Both logistical and ethical implications of globalization of clinical research are important aspects to this discussion. In low- and middle-income countries, less people are dying from avoidable infectious diseases, and chronic noncommunicable illnesses are playing an increasing role in the mortality patterns justifying the inclusion of developing countries in global cancer studies.
- Although most of the discussion around globalization has been focused in pharmaceutical industry–sponsored research, efforts to integrate academic research at a global level are vital if we are going to succeed in advancing the science of medicine and improve health for all.

decades.[2] A 66% increase in the number of annually registered trials was identified comparing 2005 (introduction of International Committee of Medical Journal Editors registration requirements) and 2012. From 2005 through 2012, approximately 67% of the registered clinical trials were conducted in North America or Western Europe. The United States was the country with the single largest activity, conducting approximately 30% of the studies. However, the number of registered clinical trials has increased in all geographic regions during this time period, with the average annual growth greatest in the Asian (30%) and Latin American/Caribbean (12%) regions. During the same period, the average yearly increase was only 2% in North America.[2] These data indicate a large and unrealized potential for growth; the average clinical trial density (number of trials/population) of low-income countries averaged one clinical trial for every 3 million people, whereas Denmark demonstrated the highest density, with 107 trials for per 1 million individuals.[2]

Over the last decade, the number of U.S. Food and Drug Administration (FDA)–regulated clinical investigators has declined by 5.5% every year, whereas the percentage of investigators based outside the United States has grown yearly by an overall percentage of 15%. The annual growth has been 29% in Asia, 13% in Latin America, and 16% in Central and Eastern Europe.[3] A recent estimate indicates that one-third of all phase III trials sponsored by the 20 largest pharmaceutical companies are being conducted solely outside the United States.[4] Early trials seem to be conducted more frequently in North America (62%), whereas confirmatory trials are more frequent in Eastern Europe, Latin America, and Asia.[5] Data from ClinicalTrials.gov shows that over 70% of the registered cancer phase I trials are conducted in the United States, whereas less than 1% are conducted in Latin America. In larger registered phase III studies, 40% are conducted in the United States, 43% in Western Europe, and 17% in Latin America.[6]

Although pharmaceutical companies are sponsoring most of these multinational trials, we also have examples of increasing international cooperation in the academic research arena. The European Organization for Research and Treatment of Cancer (EORTC) has fostered clinical trials that bring together investigators and research groups from many different countries. The NCI and its cooperative groups have established guidelines for international collaboration.[7] The Breast International Group (BIG) has conducted large pivotal practice-changing studies that involved global participation and has recently launched an initiative addressing clinical research in Latin America organizing a retreat with the Latin American Cooperative Oncology Group (LACOG) and other research groups in the region (Argentine Group for Clinical Research in Oncology [GAICO], Uruguayan Oncology Cooperative Group [GOCUR], Peruvian Oncology Clinical Studies Group [GECOPERU], Brazilian Group of Breast Cancer Studies [GBECAM], Chilean Cooperative Group for Oncologic Research [GOCCHI]). The discussion identified major areas with need for improvement and gen-

erated a number of projects that will facilitate global integration and development of local expertise.[8] Although these are initiatives signaling a positive direction, they still fall short of what is really needed and a wider and more consistent international integration of academic research remains a challenge that should be addressed with much more emphasis in the future.

ASPECTS OF GLOBALIZATION OF CANCER CLINICAL TRIALS

Why Is Globalization Unavoidable?

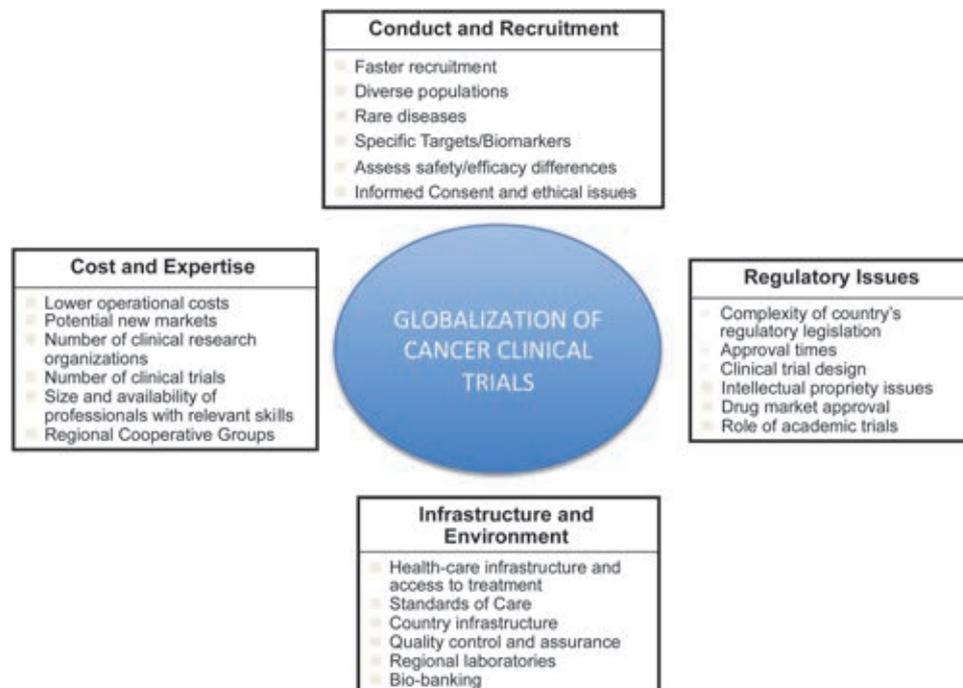
In our opinion, a number of factors do contribute for this globalization trend to continue and increase in the foreseeable future. In Fig. 1, we attempt to didactically address the large number of issues that are part of this complex process. First, among many other factors, we need to consider the large number of patients required for confirmatory trials in the drug development process. Recruitment issues are undoubtedly one of the most important elements to take into consideration explaining the need for multinational trials. This has an important effect in shortening timelines in the drug development process. Recent statistics indicate that less than 5% of U.S patients actually participate in clinical trials.[9] In the United Kingdom, from 2001 through 2011 the National Cancer Research Network was able to boost recruitment in cancer trials with a substantial increase in participation from 3.7% to 17%.[10] Costly delays in recruitment are seen in 86% of trials, and in 94% of the studies the delay is more than 1 month.[11] Low accrual rates have a negative effect in the development of new therapies, as trials take

longer to achieve endpoints with consequent delays in the interpretation of the results and sometimes leading to early closure of studies with substantial waste of precious resources. Since accrual in developing countries can be 5 to 10 times faster than in the United States or Europe, globalization is no longer an option, but a dear necessity for sponsors.[12]

As an added and very important characteristic, patients enrolled in developing countries are more frequently treatment-naive and have less, or many times, no competing trials as alternatives.[13] Although this certainly represents a central and positive factor for certain studies, regional treatment availability has a number of other possible consequences that need particular attention and are discussed later in this article.

Another important driving aspect is the fact that the cost of running clinical trials in developing countries is lower than in developed countries. The cost of conducting clinical research in Brazil, Russia, India or China (BRIC countries) can be a fraction of what it would be in the United States or most Western European nations.[14] With the increased need for larger trials, lower operational costs are a crucial consideration. With the substantial savings obtained conducting trials in developing countries, increasingly, more phase II and phase III trials are being conducted in India and South America.[11]

Finally, in this era of personalized or precision medicine the need for small specific populations with a defined targetable marker will be a vital element to consider in the drug development process. The issue of variability in the frequency of a specific tumor subtypes in different populations or regions of the world is another important consideration.

FIGURE 1. Globalization of Cancer Clinical Trials


To appropriately address some tumor subtypes, we will need trials that will screen very large populations to identify specific patients. Globalization not only addresses this challenging point, but also allows for subgroup comparisons and other inferences.

What Are Some of the Advantages of Globalization of Clinical Trials?

Conducting clinical trials in developing countries may facilitate local product approval, thereby generating local drug prescription more quickly.[11] At the same time, it is very important to consider that globalization of clinical trials not only benefits the sponsor, but also global health. Expansion of clinical trials into developing countries brings new medical care options to subjects who may not even have the current standard of therapy available. In parallel, there are clear benefits to the local medical community that has earlier access and exposure to new drugs and therapeutic advances. Involvement of investigators from developing countries in the planning phases of the trial is essential as they may provide valuable contribution while being exposed to an experience that will have long lasting effects in the future development of regional studies. Other than addressing a question that interests a pharmaceutical company, developing a reliable research infrastructure and local expertise allows us to expect the development of locally coordinated research addressing pertinent regional health questions benefiting the local community.

What Are Some of the Challenges of Globalization of Clinical Trials?

The globalization of clinical trials raises logistical challenges that need particular attention. In Table 1, we present a few general suggestions to address some of the issues and help in the conduct of global trials; only some of them are addressed in the discussion. As a first consideration, we need to take into account the wide cultural differences among regions participating in international clinical trials. Although this can be seen as a positive consequence that will certainly enrich the process making results more widely applicable, cultural characteristics remain a very particular aspect that needs to be addressed from the inception of the trial. The perception of what clinical research is varies substantially across regions and populations, and may influence the willingness of subjects to participate in a study. Interpretation of placebo arms, local dietary habits, use of herbal medications or alternative treatment methods, adherence to treatment and other protocol procedures, and reporting of adverse events all can be perceived differently in different regions of the world. The patient-doctor relationship also varies across cultures and may have an effect in different aspects of care that can affect the results of a clinical trial.

One of the most central challenges of globalization relates to the regulatory aspect of running trials across borders with different legislations. Even though there are initiatives to harmonize regulatory legislation across regions and countries, it remains a very difficult objective to reach. Good clinical practice (GCP) harmonization has gone a long way and has been

TABLE 1. Addressing Some of the Challenges of Globalization of Clinical Trials

Problem	Solution
Regulatory Standards	Harmonize regulatory standards, processes, and procedures for the pharmaceutical industry (e.g., ICH, ICH Global Cooperation Group Members)
	Share science-based goals and standards for product safety, quality, and efficacy
Leveraging Knowledge and Resources	Use finite resources strategically and more efficiently, sharing knowledge and information, leveraging inspection resources (share inspection data, plan joint inspections, provide parallel advice to sponsors, organize regular discussions that increase communication)
Advancing Regulatory Science	Actively engage global partners to harness scientific development, resources, and brainpower to support science-based regulatory decision making and pursue the best possible public health solutions
Risk-Based Monitoring and Inspection	Use innovative strategies and tools to identify sites for clinical inspection (e.g., GCP risk-based site selection tool for clinical inspection)
Build Quality During the Planning Stages of Clinical Trials	Incorporate prevention strategies to avoid critical errors, and monitor for those errors
	In the planning stages of the protocol, consider potential regional variations in standards of care and the impact they may have in trial results
Central Laboratories and Bio-Banking	Decentralize laboratories developing regional expertise that will have significant "carry-over" benefits once the trial is completed
	Advance, harmonize, and simplify bio-bank regulatory issues
Invest in Research and Evidence-Based Cancer Care Relevant to Each Region	Characterize the epidemiology of disease in specific regions
	Create and strengthen national cancer registries
	Monitor local cancer outcomes and study the regional cost-effectiveness of specific interventions
	Build a clinical trials infrastructure that is sustainable and will support local/regional innovative research and educational opportunities
	Promote translational research initiatives

Abbreviations: ICH, International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use; GCP, good clinical practices.

extremely successful in making possible the conduct of clinical research in different countries and health care scenarios. Although local regulatory standards may still vary, most respect the basic principles of GCP for clinical trials.

As quality is a fundamental principle in the conduct of clinical research, we need to address monitoring, auditing, and inspections as a basic element in the process of globalization. The mandatory requirement for GCP inspections in different parts of the world is costly, logistically challenging, and results in the need for qualified human resources. Barriers in communication (languages, dialects, and translation requirements), different qualification, interaction with national regulatory authorities, and confidentiality agreement issues are all very important considerations that can be difficult to address. As results are usually used to file for registration of new drugs, foreign data should be in accordance with FDA regulations.[15] Greater cooperation between national regulatory bodies and all involved in clinical research, including patient representatives, ethics committee, sponsors, and investigators needs to be stimulated to guarantee transparency in the whole process.

One other important aspect of globalization is the fact that the inclusion of geographically distinct populations with different lifestyles, ethnicities, and genetic profiles can influence the safety and efficacy of drugs. Global trials need to consider this genetic diversity, both when designing the study and at the time of interpreting or reporting the results. Safety concerns need to be taken into consideration, as several studies have shown that Asians metabolize drugs differently from other patients. As an example, for 31.2% of the new drugs approved in Japan between 2003 and 2005, the recommended standard doses were different from those in the Western population. In part as a result of this diversity, some countries like China and Japan require phase I trials to be performed in national subjects for all new drugs not already registered in another country.[16] As a consequence, early phase trials (usually performed in developed regions) are relatively more frequent there than in other countries. Another telling example comes from a study looking at the genetic makeup of the very heterogeneous Brazilian population, which demonstrated that well beyond self-characterization as white, brown or black, a large proportion of the population has substantial degrees of genetically defined African, Amerindian, and European ancestry with obviously important pharmacogenetic implications.[17] In our opinion, the explanation for this complex issue should widely link not only the genetic make-up of a population, but also take into account cultural and social differences in diet, way of life, education, physical activity, nutritional status, and religion, as they all could be contributing factors. Global studies should consider these important aspects that, in parallel, may represent a great opportunity to advance the investigation in this area.

Finally, a few words about the methodology and statistics of multiregional clinical studies. Global studies can answer global scientific questions and address global objectives, but at the same time they allow us to analyze regional aspects that could be extremely important. The ability of a study to reach a correct and robust conclusion depends heavily on a strong methodologic design and a careful sample size calculation, as well as planning a sampling strategy that could allow us to make inferences from specific populations.[18] The sample size calculation in a multiregional trial needs to take into account not only the overall sample size, but the influence that imbalances in regional recruitment may have in the interpretation of the results. In this sense, global trials, by expanding the population, can have both an extremely positive perspective of making inferences to a wider population, but at the same time, the danger of compromising the results because of problems with estimating the number of patients coming from a specific region.

A number of other issues should be considered when thinking about study design. The appropriateness of a global development strategy should be addressed or questioned if substantial regional variations in the results are to be expected. Different standards of treatment as well as differences in available supportive care could potentially have an effect in the results of a trial. Balancing enrollment or stratification according to region mitigates some of these potential imbalances; however, particular attention to these issues during trial design is mandatory. One issue that has been intensely discussed is the interpretation of the long-term survival results of some global trials. Regional variations in access to medications define different standards of care after progression in a study. This can and does have an important effect in survival estimations, as in many situations up to two-thirds or more of the survival of a certain population occurs after the patient has completed the trial and it can be expected that available treatments will be different depending on where the patient is from.[19]

Ethical Aspects of the Globalization of Clinical Trials

A number of ethical concerns have been appropriately raised in the process of globalization of clinical research. One of the main reasons to expand this debate is the fundamental need to protect subjects, regardless of where the clinical experiment is being conducted. Harmonization of ethical principles governing research, although different from the more standard and operational national regulatory legislation, still remains a challenge. Requirements for very specific, consistent, and clear documentation of the informed consent process are essential. Issues of language, cultural differences, illiteracy, and education should be constantly address.

The epidemiologic transition theory has focused in developing countries.[20] In low- and middle-income countries, less people are dying from avoidable infectious diseases as chronic noncommunicable illnesses are playing an increasing role in the mortality patterns. At the same time, we can identify changes in lifestyle behaviors and nutritional status with less nutrient deprivation and more obesity among the poorest populations. In addition, increases in life expectancy result in a higher proportion of older patients in these developing countries. All these epidemiologic conditions explain cancer as a global health care problem and justify the inclusion of patients from developing regions in global cancer studies.

One particular aspect that applies to most medium- and low-income developing countries is that participation in a clinical trial may represent the best therapeutic alternative for a specific patient, as the available standard of care or access to the health care system may be suboptimal. Although signing the informed consent can be interpreted as a reasonable attitude in this situation, the issue is the considerable difference this represents as we compare this situation with patients in other parts of the world where the standard of care is available outside a clinical trial. Recent research suggests that in a developing country like Brazil, financial gains and therapeutic alternative are the most frequent motivations explaining subject participation in clinical research.[21] The degree to which these elements represent nonperceived pressure that interferes with the consent process must be carefully considered while conducting research in less developed health care systems.

One particularly and very sensitive aspect of globalization of clinical research relates to what happens after the long and extremely expensive process of development, when a drug is proven as the better treatment alternative for a specific indication and is released into the market. Data presented by the European Federation of Pharmaceutical Industries and Associations breaking down sales of new medicines launched from 2009 through 2013 indicated that 55% were consumed exclusively in the United States, 23% in Western Europe, and 10% in Japan. This leaves 12% for the 6 billion people living in the rest of the world.[22] This fantastic heterogeneity in access has many implications and has not been appropriately addressed. Although the need to pay back the estimated more than 1 billion U.S. dollars it costs to develop a new medication is perfectly understandable, we should discuss how to make these pharmaceutical advances available to everybody who can benefit from it. Many of the institutions that participate in clinical research and generate data that helped with drug approval are not able to treat patients with the same medication after the trial is over and the drug is approved. These discrepancies in access are particularly striking when we look at a drug like imatinib that has changed the lives of patients with chronic myeloid leukemia and unquestionably can be characterized as the most successful targeted therapy to date. A recent publication suggests that less than 30% of the estimated 1.2 to 1.5 million patients with chronic myeloid leukemia had access to the drug 13 years after it was launched in 2001.[23] Whereas there are many other issues other than drug cost to explain this specific discrepancy, addressing the real value of a drug, much more than its price, is an urgent and inescapable debate.

The perception patients may have of what clinical research is also varies across different regions and is associated with educational and cultural characteristics that should be taken into account. Although the altruistic principles of participating in a phase I trial exist, data indicate that most patients do not have a clear understanding of the objective of the trial and accept entering the trial mainly expecting a therapeutic benefit. Analyses of predominantly early-stage cancer trials indicate that subjects are often motivated to participate in research by the expectation of a direct medical benefit, and when asked, blur the distinction between research and treatment. This therapeutic misconception has the clear potential of compromising the consent process. The subject knows it is research, but has an unrealistic expectation of being helped by the trial. For example, the investigator may think the chances of a subject benefiting from a phase I trial are remote (< 2%), but the patient thinks it may be as high as 50%. According to Kahneman, this may be an example where intuition (system 1) overwhelms logical thinking (system 2).[24] In one recently published report, 65 of 95 participants in phase I oncology trials did not know they were enrolled in a research study and 93% of them substantially underestimated their risk while overestimating their chances of benefit. Although the concerns of compromising consent have been heavily directed to developing countries where access to care, illiteracy, and language issues are substantial barriers, it is worth noting that these results refer to studies conducted in the United States.[25,26]

Looking from a wider perspective, the globalization of clinical research is an unavoidable process where the benefits do certainly exceed the potential challenges. Recent examples of trials with global participation have led to the development of fundamental advances in oncology. Among those, it is worth mentioning the development of anti-HER2 treatments that have improved the curability and survival of patients with the HER2-positive subgroup of breast cancer.[27-31] Another particular example is the fast development of crizotinib for the treatment of patients with ALK-positive non-small–cell lung cancer, in which global participation was instrumental to screen a large number of patients to identify the specific subgroup that benefits from crizotinib treatment.[32]

CONCLUSION

Globalization of clinical research is vital to speed up availability of life-saving medicines throughout the world. Challenges of conducting multiregional clinical trials can be successfully addressed through strategic and tactical planning as part of a global drug development program. Implementations of International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use guidelines, particularly GCPs, do help standardize procedures and are instrumental to conduct trials at a global level.

Although some global initiatives have addressed biomedical education and suggested strategies to strengthen health care systems, we still need much more emphasis in the discussion of improving clinical research capacity with a worldwide perspective. Clinical trials are needed in low-income and middle-income countries to answer questions on prevalent conditions. At the same time, they improve local clinical research training and infrastructure, as well as facilitate early access to technology. The positive and lasting effects of global trials in less developed regions are certainly unquestionable but unfortunately yet to be realized. As more trials are conducted in resource-limited settings, good clinical practices

and ethical assurances must be secured. Human participation in clinical research is essential to advance medicine and public health, and expanding clinical trials mandates constant oversight to ensure research quality and protection of study subjects. Some decades ago, the development of global clinical research could have been considered a dream; it is now a pressing need that should be considered unavoidable in the future.

Improving Clinical Trial Efficiency: Thinking outside the Box

Sumithra J. Mandrekar, PhD, Suzanne E. Dahlberg, PhD, and Richard Simon, DSc

OVERVIEW

Clinical trial design strategies have evolved over the past few years as a means to accelerate the drug development process so that the right therapies can be delivered to the right patients. Basket, umbrella, and adaptive enrichment strategies represent a class of novel designs for testing targeted therapeutics in oncology. Umbrella trials include a central infrastructure for screening and identification of patients, and focus on a single tumor type or histology with multiple subtrials, each testing a targeted therapy within a molecularly defined subset. Basket trial designs offer the possibility to include multiple molecularly defined subpopulations, often across histology or tumor types, but included in one cohesive design to evaluate the targeted therapy in question. Adaptive enrichment designs offer the potential to enrich for patients with a particular molecular feature that is predictive of benefit for the test treatment based on accumulating evidence from the trial. This review will aim to discuss the fundamentals of these design strategies, the underlying statistical framework, the logistical barriers of implementation, and, ultimately, the interpretation of the trial results. New statistical approaches, extensive multidisciplinary collaboration, and state of the art data capture technologies are needed to implement these strategies in practice. Logistical challenges to implementation arising from centralized assay testing, requirement of multiple specimens, multidisciplinary collaboration, and infrastructure requirements will also be discussed. This review will present these concepts in the context of the National Cancer Institute's precision medicine initiative trials: MATCH, ALCHEMIST, Lung MAP, as well as other trials such as FOCUS4.

The traditional drug development paradigm of phase I for establishing the safety profile, followed by phase II for efficacy signal, followed by phase III for establishing definitive clinical benefit is challenged by the use of targeted therapeutics and incorporation of biomarker assessment for medical treatment.[1] Biomarkers are a critical component of targeted therapies as they can be used to identify patients who are more likely to benefit from a particular treatment. In this context of personalized medicine, a phase I study tests the methods of assessment of marker alteration in normal and tumor tissue samples and guides in the determination of cut points, and preliminary assessment of efficacy within molecularly defined subsets, a phase II study includes careful retrospective assessment of the marker to establish clinical value, and phase III trials are confirmatory in nature that validate the marker (and companion diagnostic) through large prospective, randomized, controlled trials (RCT) in a multicenter setting.[2] The fundamental challenge for development of new cancer therapeutics is therefore to be able to identify and assess activity in molecularly defined patient subsets starting from early phase trials to predict which patients will respond to a new agent/regimen.

Design strategies have evolved in the past few years as a means to accelerate this new drug development process so that the right therapies can be delivered to the right patients. Basket, umbrella, and adaptive enrichment strategies represent a class of novel designs for testing targeted therapeutics in oncology.[3] This review will aim to address the following, using examples of ongoing or completed trials to present the concepts: (1) when it is appropriate to use enrichment or targeted trial design strategies, (2) use of umbrella trials in improving clinical trial efficiency to assess the effect of different drugs on different mutations (molecular subtypes) within a single tumor type, and (3) the role of basket trials in screening agents efficiently to identify the "exceptional" responders, such as the effect of a single drug across multiple tumor types and/or histologic subtypes harboring the same mutation (molecular profile).

These design strategies challenge the historic paradigm of drug development. New statistical approaches, extensive multidisciplinary collaboration, and state of the art data capture technologies are needed to implement these strategies in practice. Logistical challenges to implementation arising from centralized assay testing, requirement of multiple specimens, multidisciplinary collaboration, and infrastructure requirements will also be discussed using illustrative examples where appropriate.

ENRICHMENT TRIAL DESIGNS

The enrichment design, also called targeted design, has become the most commonly used phase III design for codevel-

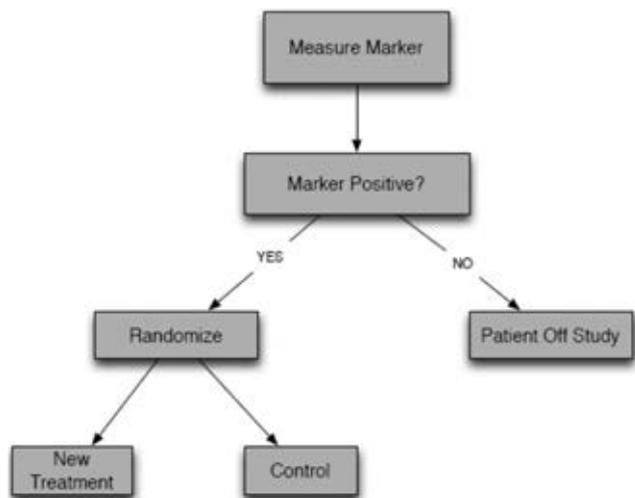
FIGURE 1. Schematic Representation of the Enrichment Trial Design Strategy


opment of a new cancer drug and a companion diagnostic. Patients are screened with the diagnostic test and those who are considered "test-positive" are eligible for the clinical trial. Eligible patients are randomized to receive either the test drug or an appropriate control regimen. In some cases, the randomization may be between the test drug and standard chemotherapy, or between standard chemotherapy alone versus standard chemotherapy plus the test drug. When there is no standard chemotherapy, the randomization may be

KEY POINTS

- Oncology is increasingly understood at the molecular level; therapeutic research has largely shifted from a focus of cytotoxic agents to newer targeted drugs that inhibit specific cancer cell growth and survival mechanisms.
- Novel clinical trial design strategies that challenge the historic paradigm of drug development are needed to accelerate the drug development process so that the right therapies can be delivered to the right patients.
- Patient selection and enrichment approaches are becoming increasingly relevant; however, sufficient biologic rationale, understanding of the mechanism of action of the drug, assay characteristics, and validated cut points are needed to support the enrichment strategy.
- Umbrella trials incorporate a central infrastructure for screening and identification of patients with a focus on a single tumor type or histology; multiple subtrials that test targeted therapeutics within molecularly defined subsets are embedded within the umbrella framework.
- Basket trial designs offer the possibility to include multiple molecularly defined subpopulations, across histologic subtypes or tumor types, in one cohesive design to evaluate the targeted therapy in question.

between the test drug and best supportive care. See Fig. 1 for a schematic of the enrichment trial design strategy.

Patients who are not marker-positive are not eligible for the study. Consequently, the design is best suited to settings where there is a strong biologic rationale or phase II data indicating that marker-negative patients are unlikely to benefit from the test drug. This was the case for the pivotal trials of vemurafenib for melanoma, in which the companion diagnostic was a sequencing test for a point mutation in the kinase domain of the *BRAF* gene.[4] It was also the case for crizotinib, in which the companion diagnostic was an assay for a translocation that activates the *ALK* gene.[5] One of the first uses of the enrichment design in oncology was for the pivotal trial of trastuzumab in women with metastatic breast cancer.[6] The companion diagnostic in that case was overexpression of the HER2 protein or amplification of the *HER2* gene. In these cases, there was a close linkage between the target of the test drug and the diagnostic test measuring a genomic alteration known to constitutively activate an oncogene target of the test drug. Kinase inhibitors generally have multiple targets; therefore, such drugs may be active for some patients who are test-negative. The proportion of patients who are test-negative who benefit from such a drug and the degree of benefit are generally much less than the treatment effect of the drug for test-positive patients. Hence, use of the enrichment design is appropriate. Test-negative patients can later be the focus of a separate clinical trial of the same drug after the drug is demonstrated to benefit those for whom it is designed to benefit. The test-negative patients can be spared the toxicity of a drug from whom few are expected to benefit.

One of the main benefits of the enrichment design is efficiency; that is, reduced sample size requirements.[7] The sample size of a clinical trial can generally be expressed in terms of the significance level, the statistical power, and the treatment effect to be detected with that power. For example, in comparing two treatments with regard to survival, the number of endpoint events, D, that must be observed can be written as:

$$D = 4\frac{(k_\alpha + k_\beta)^2}{(\log HR)^2}$$

where, for a two-tailed 5% significance level, $k_\alpha = 1.96$ and for power 90%, $k_\beta = 1.28$. The hazard ratio (HR) is a measure of the expected difference in the survival curve for the test treatment group and the control group. Broad eligibility clinical trials are frequently sized to detect 25% to 33% reductions in the hazard of death. Those reductions in hazard correspond to hazard ratios of 0.75 or 0.67, respectively. Using the natural logarithm in the above equation, the D value of 508 total events for HR equals 0.75. That is, 508 events must be observed in order to have 90% power for detecting a 25% reduction in hazard using a two-sided significance level of 5%. If, by the time of the final analysis only 25% of the patients are expected to fail, then to observe 508 events, one needs to accrue 2,032 patients. In contrast, we only need to have 90% power for detecting a 33% reduction in hazard, that is, a hazard ratio of 0.67, then expression[1] indicates that we only need

to observe 262 events instead of 508. Therefore, a slight change in the size of the treatment effect to be detected can lead to a large reduction in the sample size requirement.

If we preselect patients as in an enrichment design so that we expect an even larger reduction in hazard, such as 50%, then expression[1] indicates that we only need to observe 88 events. Targeting a larger treatment effect by enriching the population of the clinical trial to exclude patients unlikely to benefit from the test treatment can thus dramatically reduce the number of randomized patients required. However, the number of patients screened with the diagnostic test to obtain the required number of randomized patients may still be substantial.

To use the enrichment design, one should have strong biologic rationale or phase II data that test-negative patients are very unlikely to benefit from the treatment compared with the test-positive patients. One should also have an analytically validated test for use for selecting patients in the phase III clinical trial. Overexpression of the EGFR protein was thought to be a predictive biomarker for identifying patients who could benefit from erlotinib, but it was not used as an eligibility factor. It later turned out that mutation in the kinase domain of EGFR was the appropriate biomarker for erlotinib in NSCLC, not overexpression of the protein. Hence, it was useful that the initial phase III studies did not employ an enrichment design with EGFR overexpression as a selection factor. Another case in which the enrichment design was not used came in the development of the monoclonal antibodies panitumumab and cetuximab against EGFR in the treatment of advanced colorectal cancer.[8] Overexpression of EGFR was not used to restrict eligibility and it later turned out that the appropriate biomarker was KRAS mutation. Patients with mutated KRAS did not benefit from the antibodies because their tumors were not driven by EGFR activation, but patients with wild-type KRAS did benefit from the antibodies. Therefore, the enrichment design should be used primarily when the mechanism of the biomarker in the disease is well understood. It is also useful to have phase II data confirming that the understanding is correct.

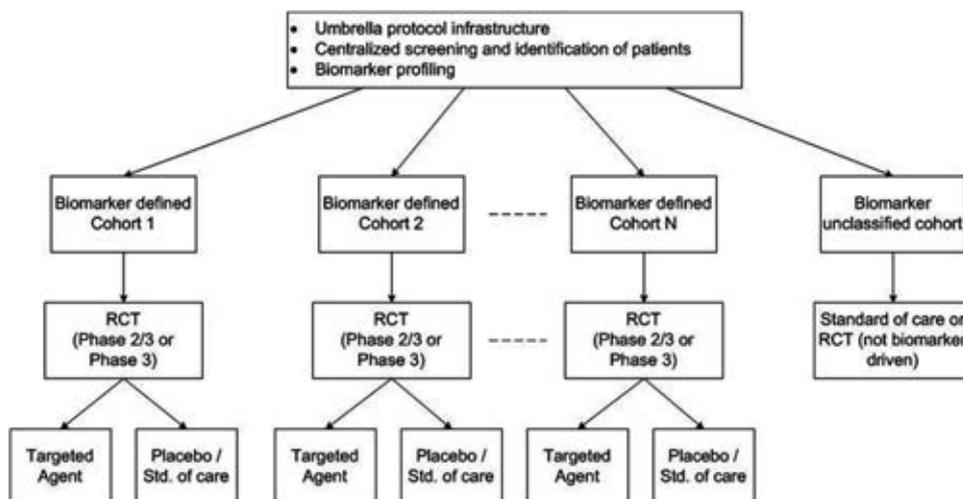
EXTENSIONS OF ENRICHMENT DESIGNS
Run-in Designs
The enrichment design has been most effectively used with genomic alterations of the drug target as detected by the diagnostic test. Gene expression profiles have rarely been useful as predictive biomarkers for identifying which patients benefit from a specific drug therapy, although they sometimes have been useful prognostic indicators. For some drugs, such as antiangiogenic agents and immunologic agents, it has been difficult to identify pretreatment predictive biomarkers. Hong and Simon[9] showed how the enrichment design can sometimes be used after a short run-in phase on the test drug. During the run-in phase, a pharmacodynamic response, immunologic response, or early tumor response is measured. The patients are randomized after the run-in phase to either continuing the test drug or to switch-

ing to a control regimen. The biomarker measured during the run-in can be used to restrict eligibility to the randomization. A variation of this approach is to use the control regimen during the run-in phase and to only randomize patients who do not have a strong initial response to the control. This was used successfully in a clinical trial of dose-dense intensification of chemotherapy for patients with poor-prognosis germ cell tumors.[10]

Adaptive Enrichment Designs
A second extension of the enrichment design is the adaptive enrichment approach described by Simon and Simon.[11] For example, one may have a companion diagnostic test to use with the drug, but a cut-point for test positivity may not have been adequately determined based on phase II trials. With the adaptive enrichment design, one initiates the trial without using the test result to limit eligibility. Interim analyses adaptively restrict eligibility to increase the cut point of the test and exclude from eligibility the patients who do not appear to benefit from the test drug based on interim data for a short-term endpoint. The adaptive enrichment approach can also be used when there are multiple candidate biomarkers.

UMBRELLA TRIAL DESIGNS
Having a national network of clinical sites doing molecularly targeted clinical trials using a common genomic screening platform is an important defining characteristic of the umbrella design and is essential for effectively conducting targeted clinical trials in an increasingly stratified set of tumors. The umbrella infrastructure usually has the flexibility to add (or drop/modify) subtrials of molecularly targeted drugs and companion diagnostics based on accumulating evidence from the ongoing trial (and newly emerging data). The umbrella design is essentially two or more enrichment designs linked through a common patient screening infrastructure. Patients are screened for a specific set of biomarkers and assigned to a biomarker-driven substudy (targeted design) if it is determined that they have one of the target biomarkers. See Fig. 2 for a schematic representation of this design.

The Lung MAP (Master Protocol- phase II/III Biomarker-Driven Master Protocol for Second Line Therapy of Squamous Cell Lung Cancer; NCT02154490) study in squamous cell lung cancer is an example of an umbrella protocol that is currently open at hundreds of sites in the United States. The tumors of patients with advanced squamous cell lung cancer with one previous treatment are screened for genetic alterations in over 200 genes using a standardized sequencing platform. As a result of this tumor characterization, patients are recommended to one of five subtrials within the umbrella framework. Four of the five clinical trials are enrichment trials with eligibility limited to those patients whose tumor harbors a specified genomic alteration in a gene, which is a target of the test drug for that clinical trial. The fifth clinical trial is for patients whose tumor characterizations do not qualify them for one of the other four clinical trials. Each of the com-

FIGURE 2. Schematic Representation of the Umbrella Trial Design


ponent clinical trials is a pivotal phase II/III clinical trial that can lead to the approval of a targeted drug with the genomic screening platform as companion diagnostic. Of note, a substantial amount of work is needed to analytically validate an assay to qualify it as a companion diagnostic. With the umbrella framework, this work qualifies the same platform for a large number of potential drugs.

The phase II/III design allows for early termination if the test treatment is not promising relative to the internal control based on progression-free survival (PFS) or may proceed to a phase III trial with PFS and overall survival (OS) as coprimary endpoints. The design within each substudy is standardized such that the phase II interim analysis is to occur on the observation of 55 progression events and the final phase III analysis is to occur on the observation of 256 deaths (provided the study proceeds to phase III). These are based on a phase II design with 90% power and 10% one-sided type I error to detect a two-fold increase in median PFS and a phase III design with 90% power and 1-sided 2.5% type I error to detect a 50% increase in median OS.

The ALCHEMIST (Adjuvant Lung Cancer Enrichment Marker Identification and Sequencing Trial) clinical trial uses the umbrella design to identify and screen patients with the EGFR (approximately 15% prevalence) and ALK (approximately 5% prevalence) mutations in early-stage resected nonsquamous NSCLC. The surgical specimen will be tested centrally through a clinical laboratory improvement amendments (CLIA)–certified laboratory for specific genomic alterations in the *ALK* or *EGFR* genes. If an ALK-EML4 rearrangement is found, the patient will be referred to a double-blind, RCT comparing crizotinib with placebo adjuvant therapy. Patients with an activating mutation in EGFR will be referred to a double-blind RCT comparing erlotinib with placebo as adjuvant therapy. In the setting of these two parallel clinical trials studying resected NSCLC in a rare, molecularly-defined subsets of patients, a central protocol infrastructure for the identification of potentially eligible patients, and for central screening for appropriate geno-

types is valuable. Furthermore, ALCHEMIST includes a collection of tumor and blood specimens at baseline for genomic discovery efforts, and at the time of disease recurrence (optional tumor collection) to understand mechanisms of drug resistance and genomic evolution. Such advanced genomic analysis, performed on a clinically uniform and well-characterized NSCLC population, will allow for new insights into the relationship between tumor biology and clinical outcome. Thus, the ALCHEMIST screening platform consists of three integrated protocols: ALCHEMIST-Screening (A151216; NCT02194738), ALCHEMIST-EGFR (A081105; NCT02193282), and ALCHEMIST-ALK (E4512; NCT02201992).

An estimated 8,000 patients will be screened through A151216 to facilitate accrual to the two substudies: ALCHEMIST-EGFR and ALCHEMIST-ALK. Both subtrials are harmonized in terms of primary endpoint (OS), as well as with regard to many of the trial logistics (eligibility criteria, follow-up schedule during treatment, and long-term follow-up, etc.). The ALCHEMIST-EGFR trial has a target accrual of 410 patients, with centrally-confirmed EGFR mutation status, to have at least 85% power to detect an HR of 0.67 in favor of the erlotinib arm, using a one-sided type I error rate of 5%. The ALCHEMIST-ALK trial has a target accrual of 378 patients, with centrally-confirmed ALK status, to have at least 80% power to detect a 33% reduction in the OS HR of 0.0105 to 0.0070 in favor of the crizotinib arm, using a one-sided type I error rate of 5%. As with the Lung MAP protocol, ALCHEMIST is set up to accommodate the addition of subtrials of targeted therapeutics in this setting if and when they are ready to be tested in a phase III setting.

Another example of the umbrella trial design is the FOCUS4 Master Protocol (molecular selection of therapy in colorectal cancer: a molecularly stratified RCT program).[12] It is an integrated protocol with parallel, molecularly stratified, randomized comparisons of maintenance therapies for patients with advanced or metastatic colorectal cancer after receiving first-line chemotherapy. It includes randomized phase II/III trials following the principles of the multi-arm

multi-stage[13,14] (MAMS) design for predefined molecular cohorts. Similar to Lung MAP, for patients whose biomarker panel results are unclassifiable or for those whose molecular cohort is temporarily not open for recruitment, and for any patients unable or unwilling to travel, a concurrent nonbiomarker-driven trial comparing capecitabine against no treatment is available. Four prespecified interim analyses are planned for each trial: stage I (assess safety), stage II (assess lack of benefit), stage III (assess efficacy for PFS), and stage IV (assess efficacy for OS). Stages I and II mirror a conventional phase II trial design, and stages III and IV are similar to a phase III trial design paradigm.

BASKET TRIAL DESIGNS

The discovery of driver oncogenes and the corresponding successful development of therapies targeting those genetic abnormalities have dramatically impacted clinical research, placing great focus on the biologic causes of dramatic responses to therapy among populations that do not derive treatment benefit overall. The first observation of this phenomenon was the discovery that imatinib effectively targets the BCR-ABL tyrosine kinase in chronic myeloid leukemia; this was subsequently followed by the discovery that EGFR mutations in NSCLC confer dramatic responses to treatment with gefitinib.[15-18] When an exceptional responder is observed, often referred to as the n-of-one phenomenon, further investigation of the tumor biology and the therapeutic mechanism of action may lead to formally testing a predefined hypothesis, which is that patients whose tumor harbor a particular genetic aberration respond to a specified targeted agent in the context of a prospective clinical study. Basket trials have come to be known as an efficient way of screening experimental therapeutics across multiple patient populations in early-phase drug development. Basket trials generally assign treatments to patients based on the molecular alterations that their tumors contain, regardless of the histologic type of the tumor. Like umbrella trials, there may be a common genetic screening platform, especially if the cohorts defined by the study are histology-independent and defined

only by the presence of a single molecular aberration; however the term basket trial has also been used to describe studies in which patients are assigned to cohorts by their cancer type. Whether cohort eligibility criteria are histology- or mutation-specific, these trials are generally conducted within the context of a single protocol. Figure 3 provides a generic representation of a basket trial design schema. There is perceived efficiency in running multiple cohorts in this way, since conducting a stand-alone study within each cohort separately would be exponentially more resource-intensive.

However, basket trials are not without their limitations. Paramount to their conduct is a strong scientific rationale for the molecular marker-drug pairing, as well as reliable assay development for the marker of interest. Genomic variants have unknown or differential variability across tumor types,[19] and there is often uncertainty about whether a particular mutation in a tumor of a particular histologic type should be considered actionable for treatment with a given drug. Resolving these uncertainties, however, is the reason for doing the study. These trials often study cancers so rare that it may be impossible to study them in a randomized setting, and usually require coordination and participation from multiple institutions to meet accrual objectives.[20] They can depend heavily on tumor availability for genetic screening, which can be difficult to obtain or to ethically justify in certain types of cancer. This design also depends on the availability of a sufficient number of drugs targeting diverse deregulated pathways.

Basket trials are discovery trials and there has been uncertainty about how to design such trials statistically. Consequently, in some basket trials, justification of sample sizes has been absent despite increased interest in efficacy endpoints, such as response, and the amendment process is frequently used to expand cohorts to sample sizes that would otherwise be sufficient for the proper conduct of a randomized phase II or III study.[21,22] The practice of not justifying sample size is particularly worrisome since it counters the intent of minimizing the number of patients exposed to toxic or ineffective drugs, and in light of this, investigators should consider early stopping rules and provide clearly defined criteria for study completion.[21] Additional steps should also be taken to ac-

knowledge the effect of patient and tumor heterogeneity on the numerical variability of results and the multiple comparisons issues that arise as a result of excessive testing of subgroups during the conduct of these trials.

The Molecular Analysis for Therapy Choice (MATCH) study is an example of a basket trial being led by the ECOG-ACRIN Cancer Research Group, along with the National Cancer Institute, and is slated to activate within the National Clinical Trials Network this year.[23] As many as 3,000 patients with refractory solid tumors or lymphoma and for whom no standard treatment prolonging survival exists will be screened with the goal of accruing approximately 35 patients (31 eligible) in as many as 20 to 25 biomarker-defined subgroups. Targeted agents for this trial were selected if: (1) a drug is U.S. Food and Drug Administration (FDA)–approved for a malignant indication and there is a molecular abnormality that can serve as a valid predictive marker, (2) the drug is investigational, but met a clinical endpoint (such as PFS or tumor response) in any malignancy, has evidence of target inhibition, and has evidence of a predictive molecular marker, and (3) the drug is investigational, but has demonstrated clinical activity in any malignancy and evidence of target inhibition, and has evidence of a predictive molecular marker.

Patients who are enrolled into the MATCH trial are assigned to histology-independent subgroups and treated with the agents matched to their tumor's identified molecular abnormality. If a patient's tumor harbors more than one molecular abnormality identified as actionable for treatment in MATCH, then treatment will be assigned based on the mutation detected in a higher percent of tumor cells; if this percentage is within 15% for two or more aberrations in more than one pathway, then the patient will be assigned to the treatment with fewer patients enrolled, or if equally enrolled, the patient will be randomized between the treatments under consideration.

The primary endpoint of each cohort is objective response (OR) rate and 6-month PFS. OR will be compared to a historic control of 5%, whereas 6-month PFS will be compared to a historic control of 15%. This design provides 92% power to test the alternative hypothesis that a drug confers an OR rate of 25% and 89% power that a drug provides a 6-month PFS rate of 38% while controlling the type I error rate at the one-sided 0.05 level. If the OR rate is greater than or equal to five out of 31 patients (16%) or PFS at 6 months is greater than or equal to nine out of 31 patients (29%), then an agent will be considered promising and worthy of further testing. For each arm, there is a futility rule provided as a guideline; an interim analysis will be performed after 15 eligible patients have been enrolled. If no response is observed among these patients and the 6-month PFS is two out of 15 patients or less (13%), the analysis result will be presented to the steering committee for further guidance on whether the arm should be stopped early.

CONCLUSION

The fundamental assumption of precision medicine is that using the genetic makeup of the tumor and the genotype of the patient will enable targeted therapeutics to improve clinical outcomes.[3] Although there have been notable successes with this approach, the methods for matching drugs to tumors is still rudimentary and numerous challenges remain to be addressed adequately. These include an understanding of the interaction of signaling pathways, the clonal evolution and heterogeneity of tumors, ability to obtain tumor biopsies (often multiple and over time), technical limitations with assays, centralized molecular testing, adequate resources and infrastructure for a quick turnaround of biomarker results to make these designs feasible, and effective multidisciplinary collaborations. Nevertheless, genomic technology has already become a part of routine clinical practice. Enrichment, umbrella, and basket trial designs are gaining popularity as they present novel strategies to accelerate the drug development process so that the right therapies can be delivered to the right patients quickly.

Overcoming Resistance to Anti-EGFR Therapy in Colorectal Cancer

Rodrigo Dienstmann, MD, Ramon Salazar, MD, MSc, and Josep Tabernero, MD, PhD

OVERVIEW

Our understanding of the genetic and nongenetic molecular alterations associated with anti–epidermal growth factor receptor (EGFR) therapy resistance in colorectal cancer (CRC) has markedly expanded in recent years. Mutations in *RAS* genes (*KRAS/NRAS* exons 2, 3, or 4) predict a lack of clinical benefit when anti-EGFR monoclonal antibodies (mAbs) are added to chemotherapy. Genetic events in additional nodes of the mitogen-activated protein kinase (MAPK)–phosphoinositide 3-kinase (PI3K) pathways that bypass EGFR signaling, such as *BRAF* or *PIK3CA* mutations or *KRAS*, *ERBB2*, or *MET* amplifications, also may confer resistance to cetuximab or panitumumab. Polymorphisms that block antibody binding as a result of EGFR extracellular domain mutations have been reported. Nongenetic mechanisms, including compensatory activation of receptor tyrosine kinases HER3 and MET, together with high expression of the ligands amphiregulin, transforming growth factor alpha heregulin, and hepatocyte growth factor in the tumor microenvironment also are thought to be involved in resistance. In one-third of the samples, more than one genetic event can be found, and nongenetic events most likely coexist with gene alterations. Furthermore, activation of a gene expression signature of epithelial-mesenchymal transition has been associated with reduced cellular dependence on EGFR signaling. Collectively, this body of work provides convincing evidence that the molecular heterogeneity of CRC plays an important role in the context of resistance to anti-EGFR therapy. Herein, we discuss how this knowledge has been translated into drug development strategies to overcome primary and acquired anti-EGFR resistance, with rational combinations of targeted agents in genomically selected populations, second-generation EGFR inhibitors, and other agents expected to boost the immune response at the tumor site.

Colorectal cancer is the third most common cancer type in Western countries, and mortality as a result of CRC has declined progressively in recent decades.[1] This can be attributed not only to cancer screening programs but also to the availability of more effective therapies, both for early-stage and advanced disease. Extensive investigations have uncovered several critical genes and pathways relevant to CRC initiation and progression. The knowledge about these driver molecular alterations has already translated into drug development and biomarker discovery, with EGFR being the most noticeable example. The specific genetic background of the tumor largely influences the efficacy of anti-EGFR therapies. Nearly 70% of CRC samples have heterogeneous genetic alterations in genes involved in EGFR signaling, which negatively affect response to the mAbs cetuximab and panitumumab. Furthermore, molecular heterogeneity of CRC has been recognized as pivotal in the evolution of clonal populations during anti-EGFR therapies.[2] In this manuscript, we summarize the current understanding about primary (de novo) and secondary (acquired) resistance to anti-EGFR thera-

pies in metastatic CRC (mCRC) and about emerging predictive biomarkers that could ultimately help define the optimal combination therapy for patients in routine clinical practice.

PRIMARY RESISTANCE TO ANTI-EGFR THERAPY IN ADVANCED CRC

Only 10% of patients with chemotherapy-refractory mCRC achieve objective responses to cetuximab or panitumumab as single agents.[3,4] In this setting, *KRAS* mutations in codons 12 and 13 (exon 2) were the first to be causally implicated in primary resistance to anti-EGFR mAbs.[5,6] Cetuximab and panitumumab provide similar overall survival benefit in *KRAS* exon 2 wild-type, chemotherapy-refractory mCRC.[7] Furthermore, in the first- or second-line settings, patients whose tumors harbor *KRAS* exon 2 mutations do not benefit from the addition of anti-EGFR mAbs to chemotherapy, providing compelling evidence of primary resistance.[8-11]

Because not all patients with *KRAS* wild-type disease benefit from targeted agents, many groups investigated addi-

tional biomarkers of resistance that could explain the heterogeneity in clinical response. The next step was to evaluate additional oncogenic events in the MAPK pathway. Approximately 20% of CRC samples harbor activating mutations in *BRAF* (V600E), *NRAS* (codons 12, 13, 59, 61, 117, and 146 in exons 2, 3, and 4), or rare variants in *KRAS* (codons 59, 61, 117, and 146 in exons 3 and 4). Retrospective studies indicate that these events could also underlie resistance to single-agent cetuximab or panitumumab in patients with chemotherapy-refractory mCRC.[12,13] More recently, randomized studies have shown that mutations in *KRAS* exons 3 and 4 or *NRAS* exons 2, 3, and 4 can also predict a lack of clinical benefit of anti-EGFR mAbs when given in combination with chemotherapy in the first-line setting.[14-16] Patients with CRC that is wild type for all *RAS* mutations (*KRAS* and *NRAS* exons 2, 3, and 4) showed higher response rates and overall survival when cetuximab or panitumumab, versus bevacizumab, was combined with standard chemotherapy. The *BRAF* V600E mutation, conversely, did not predict resistance to first-line anti-EGFR mAbs plus chemotherapy.[8,14] However, *BRAF* mutation is a strong marker of poor prognosis in mCRC. Interestingly, in the second-line setting, the addition of panitumumab to irinotecan had a detrimental effect on survival of a *BRAF* mutant population.[17] It is expected that combinations of anti-EGFR mAbs and selective *BRAF* inhibitors, which have had unprecedented response rates in early clinical trials,[18,19] may overcome this negative effect.

KEY POINTS

- EGFR is a validated target for cancer therapeutics, with cetuximab and panitumumab leading to significant overall survival benefits when added to first-line chemotherapy in patients with genomically selected (all *RAS* wild type) metastatic colorectal cancer.
- Multiple genetic alterations driving resistance to anti-EGFR monoclonal antibodies have been described, with significant overlap in primary and secondary resistance mechanisms, supporting clonal selection as a major determinant of the final outcome.
- Resistance to anti-EGFR therapy in colorectal cancer is also related to nongenetic mechanisms, such as compensatory activation of parallel receptor tyrosine kinases and overexpression of ligands involved in paracrine signaling networks in the tumor microenvironment.
- Increased knowledge of anti-EGFR resistance mechanisms has guided the development of effective therapies, with promising second-generation antibodies and combinations with pan-ERBB, the MET signaling pathway, or MEK inhibitors.
- The immune system has a crucial role in modulating response to monoclonal antibody therapy in cancer, with novel agents inducing potent cytotoxicity and combinations with immune checkpoint inhibitors worth exploring in the anti-EGFR resistance setting.

Molecular alterations in additional nodes of the EGFR pathway also seem to confer primary resistance to targeted therapies. Among them, *PIK3CA* exon 20 mutations and *PTEN* alterations, which frequently coexist with *RAS* mutations, have been associated with unresponsiveness to anti-EGFR mAbs.[12,20,21] Gene expression signatures that correspond to *KRAS*-, *BRAF*-, and *PIK3CA*-activating mutations predict efficacy of anti-EGFR therapy, suggesting that a shared downstream component of these pathways mediates resistance.[22] Moreover, *KRAS, ERBB2*, and *MET* amplifications have been shown to bypass EGFR signaling and activate the pathway.[23-26] The rarity of these gene amplifications and the relatively small sample size of each study preclude assessment of their clinical value as negative predictive biomarkers of response to anti-EGFR mAbs.

Additionally, the extensive crosstalk among the ERBB family of receptors leads to upregulation of parallel pathways after blockade of a particular receptor as a compensatory adaptive mechanism. One potential mechanism of resistance to anti-EGFR therapy in mCRC is related to the ability of EGFR to form heterodimers with HER3, which results in downstream PI3K and MAPK activation.[27-29] MET signaling also appears to cooperate with the EGFR pathway to promote the growth of CRC cells.[30,31] Signals produced by either the cancer cells themselves or by stromal fibroblasts, such as hepatocyte growth factor (HGF), activate parallel receptor tyrosine kinase (RTK) pathways that render CRC cells insensitive to anti-EGFR therapy.[31] These pathways may offer primary escape mechanisms, allowing tumors to circumvent one pathway that has been pharmacologically blocked.

Temporal heterogeneity has also been assessed as a potential mechanism of primary resistance to anti-EGFR therapy. However, when considering matched primary and metastatic samples not previously exposed to targeted agents, the mutational statuses of *KRAS, NRAS, BRAF*, and *PIK3CA* are highly concordant, exceeding 90%.[32] In fact, the effectiveness of the anti-EGFR mAbs in *RAS* wild-type CRC has largely been documented in trials that identified genetic mutations in archived diagnostic samples rather than in new biopsies from metastatic lesions. Importantly, mutations in *KRAS, NRAS*, and *BRAF* tend to be mutually exclusive at baseline samples.

Drug Development to Overcome Primary Resistance to Anti-EGFR Therapy

The first approach to increase the efficacy of anti-EGFR mAbs tested in the clinic was the combination with vascular endothelial growth factor receptor (VEGFR) pathway inhibitors. Despite positive effects on progression-free survival and objective response, cetuximab plus brivanib (a VEGFR multikinase inhibitor) increased toxicity and did not improve overall survival in patients with chemotherapy-refractory, *KRAS* wild-type mCRC.[33] Similarly, the addition of panitumumab or cetuximab to bevacizumab and oxaliplatin-based chemotherapy in the first-line setting did not improve outcomes in patients with *KRAS* wild-type disease.[34,35] These results raise the possibility of a negative interaction (pharma-

cokinetic and/or pharmacodynamic) between the targeted agents as well as an increased risk of toxicity, leading to frequent treatment delays and reduced dose intensity.

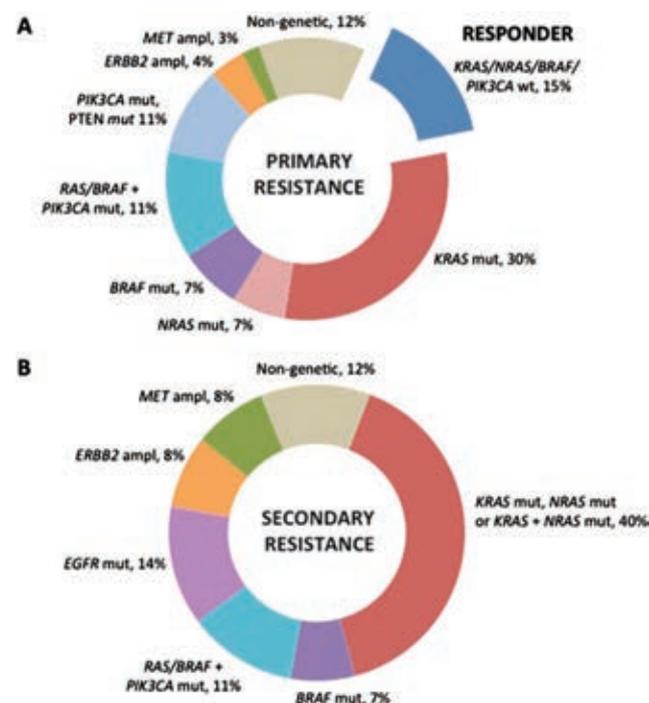
Our current knowledge about primary resistance to cetuximab and panitumumab in mCRC, summarized in Fig. 1A, has led to more promising drug development strategies. Quadruple-negative (*KRAS/NRAS/BRAF/PIK3CA* wild-type) tumors, which represent up to 30% of cases, are more likely to respond.[12] On the basis of preclinical data and early clinical trials, this type of tumor is particularly sensitive to dual-EGFR targeting (ERBB tyrosine kinase inhibitors [TKIs] added to anti-EGFR mAbs),[36] and this strategy is undergoing clinical validation, as shown in Table 1. The important role of compensatory HER3 signaling and PI3K pathway activation in the development of resistance to anti-EGFR mAbs also has been translated into clinical trials. Results of a randomized, phase II trial in chemotherapy-refractory, *KRAS* wild-type, anti-EGFR–naive mCRC also suggest a role for MET pathway targeting; the combination of an anti-HGF mAb and panitumumab led to higher response rates and a trend for a better outcome in the population with MET-overexpressing tumors.[37] Another strategy to overcome resistance in this setting is to boost the immune response by increasing the numbers of immune cells engaging in antitumor activity.[38] A growing body of preclinical and clinical evidence shows that the immune system contributes substantially to the thera-

peutic effects of mAbs in vivo.[39] The combination of immune modulators or checkpoint inhibitors with cetuximab is under evaluation as a first-line therapy of *KRAS* wild-type mCRC.

SECONDARY RESISTANCE TO ANTI-EGFR THERAPY IN ADVANCED CRC

The most common molecular mechanisms that drive secondary resistance to anti-EGFR mAbs in mCRC comprise genetic alterations known to confer primary resistance to cetuximab or panitumumab, as illustrated in Fig. 1B. *KRAS* and *NRAS* mutations, mostly affecting exons 3 and 4, were found to emerge in a significant proportion of tumor biopsies and circulating tumor DNA (ctDNA) from patients who had acquired resistance to anti-EGFR mAbs.[40-43] In one-third of patients, multiple genetic events coexisted in the same sample.[41,42] *BRAF* and *PIK3CA* mutations also were found in biopsies of patients who experienced relapse, although all of these mutations were absent in samples from the same patients at the beginning of the treatment.[42] Multiple repeated biopsies revealed that the percentage of mutant alleles increased under drug exposure and became undetectable after drug withdrawal.[44] These findings suggest that a clonal selection process achieved under treatment pressure plays a major role in determining the final clinical outcome. In addition to acquired PI3K and MAPK downstream mutations, *ERBB2* or *MET* gene amplifications also were described as drivers of acquired resistance to anti-EGFR therapy in cell models and patient samples.[24-26,45] Likewise, these events in RTKs leading to parallel signaling activation are enriched in post-treatment biopsies compared with primary tissues. Moreover, acquired *EGFR* extracellular domain mutations (exon 12) that disrupt cetuximab binding but may be permissive for interaction with panitumumab have been identified recurrently in cetuximab-treated mCRC samples with secondary resistance.[44,46,47] Of note, by using a highly sensitive sequencing technology, *EGFR* S492R was found in 16% of patients after cetuximab exposure and in only 1% after treatment with panitumumab.[47] This mechanism is analogous to other secondary genetic alterations in the target oncoprotein that perturb the conformational state of the kinase drug-binding sites and render the receptor insensitive to the drug (e.g., erlotinib/gefitinib and *EGFR* T790M).

Nongenetic mechanisms also have been linked to anti-EGFR resistance in mCRC. In biopsies from patients who experience disease progression while receiving cetuximab or panitumumab therapy, only a fraction of cells carry activating MAPK mutations, which suggests that wild-type cells also can survive the treatment. Preclinical findings point to the conservation of EGFR dependency in tumors that progressed during anti-EGFR therapy, most likely related to adaptive ligand overexpression.[48] Increased secretion of EGFR ligands amphiregulin and transforming growth factor alpha (TGF alpha) by limited *KRAS* mutant clones has been proposed as a paracrine resistance mechanism to anti-EGFR mAbs in CRC models.[49] In addition, ectopic production of HGF by stromal cells renders CRC cell lines insensitive to

FIGURE 1. Resistance to Anti-EGFR Therapies in Advanced CRC


(A) Genomic alterations linked to primary (de novo) resistance. Separated from the chart are quadruple-negative tumors, which have higher chances of response. (B) Secondary (acquired) resistance mechanisms, suggesting clonal selection as the major determinant of the final outcome.

Abbreviations: EGFR, epidermal growth factor receptor; CRC, colorectal cancer; ampl, amplified; mut, mutated; wt, wild type.

TABLE 1. Resistance Mechanisms to Anti-EGFR Therapies and Drug Development Strategies in Advanced CRC

Setting	Mechanism of Resistance	Strategy	Example	Trial
First-Line Anti-EGFR Therapy	**Nongenetic**			
	KRAS/NRAS/BRAF/PIK3CA wt	Anti-EGFR mAb + chemotherapy	Panitumumab + FOLFIRI	NCT01704703 (phase II)
	Immune evasion	Anti-EGFR mAb + immune checkpoint inhibitor	Cetuximab + pembrolizumab	NCT02318901 (phase I/II)
		Anti-EGFR mAb + immune modulator	Cetuximab ± complement receptor 3 modulator	NCT01309126 (phase III)
	Compensatory pathway activation			
	ERBB family receptors	Anti-EGFR/HER3 mAbs	MEHD7945A + FOLFIRI versus cetuximab + FOLFIRI	NCT01652482 (phase II)
		Anti-EGFR mAbs + irreversible ERBB TKIs	Cetuximab ± afatinib	NCT01919879 (phase II)
	PI3K-mTOR	Anti-EGFR mAbs + mTOR inhibitors	Panitumumab + everolimus + irinotecan	NCT01139138 (phase I/II)
Progressing in Third-Line Setting After Response to Anti-EGFR Therapy in First-Line Setting	**Nongenetic**			
	KRAS/NRAS/BRAF wt	Anti-EGFR mAb + chemotherapy (rechallenge)	Cetuximab + irinotecan-based therapy	NCT02296203 and NCT02316496 (phase II)
Acquired Resistance to Anti-EGFR Therapy	**Nongenetic**			
	KRAS/NRAS/BRAF/PIK3CA wt	Anti-EGFR mAbs + irreversible ERBB TKIs	Cetuximab + neratinib	NCT01960023 (phase II)
	Sustained EGFR addiction			
		Novel anti-EGFR mAbs	Sym004 versus investigator's choice	NCT02083653 (phase II)
	Genetic			
	ERBB2 amplification	Dual anti-EGFR/HER2 therapy	Trastuzumab + pertuzumab or lapatinib	Heracles trial (phase II)
	MET amplification	Anti-EGFR mAbs + MET inhibitors	Cetuximab + INC280	NCT02205398 (phase II)
	RAS mutations	Anti-EGFR mAbs + MEK inhibitors	Panitumumab + MEK162	NCT01927341 (phase II)
	EGFR mutations (S492R, K467T)	Panitumumab (if resistance to cetuximab), Sym004	Not available	Not available

Abbreviations: EGFR, epidermal growth factor receptor; CRC, colorectal cancer; wt, wild type; mAb, monoclonal antibody; FOLFIRI, fluorouracil, leucovorin, and irinotecan; TKIs, tyrosine kinase inhibitors; PI3K, phosphoinositide kinase-3; mTOR, mammalian target of rapamycin.

EGFR blockade.[31] An autocrine loop with the HER3 ligand hereglulin also has been associated with acquired resistance to cetuximab.[28] These experiments suggest that the relative expression of growth factor ligands in the tumor microenvironment and that a cross-talk driven by resistant subpopulations can relay redundant survival pathways and impair responsiveness to kinase inhibitors.

Drug Development to Overcome Secondary Resistance to Anti-EGFR Therapy

The first strategy to overcome acquired resistance to anti-EGFR mAbs in mCRC tested in the clinic was treatment with an alternative antibody. Panitumumab has minimal benefit in patients with KRAS wild-type mCRC who have experienced progression while receiving cetuximab as prior therapy.[50,51] Differences in response rates reported in small cohorts may be related to the inclusion of patients without objective disease progression while receiving cetuximab or for whom cetuximab-containing regimens may have been ceased as a result of toxicity in the absence of disease progression. In both circumstances, re-treatment with panitumumab is expected to demonstrate some degree of clinical

activity. Recently, with the hypotheses that the effect of pharmacologic treatment represents a selective pressure and that (preexisting) sensitive subclones may emerge after treatment breaks, the idea of re-exposure to anti-EGFR therapies has been revisited. As shown in Table 1, clinical trials are prospectively evaluating rechallenge with anti-EGFR mAbs in the third-line setting after a response to targeted therapies in the first-line setting. To increase the chances of treatment benefit, only patients with KRAS/NRAS/BRAF wild-type disease are being enrolled.

Second-generation anti-EGFR mAbs engineered to induce enhanced antibody dependent cell-mediated cytotoxicity (ADCC) or increased receptor internalization/downregulation also have been tested in the context of acquired resistance to cetuximab or panitumumab.[48,52-54] Imgatuzumab (GA201) is a dual-acting mAb glycoengineered for enhanced ADCC in addition to EGFR signaling inhibition, which has demonstrated superior preclinical in vivo efficacy to cetuximab in both KRAS wild-type and KRAS mutant xenograft models.[52] Although promising clinical efficacy was seen in a phase I trial of patients with mCRC,[52] a recently presented, randomized, phase II study comparing imgatuzumab with

cetuximab in *KRAS* exon 2 wild-type or with irinotecan-based chemotherapy alone in patients with *KRAS* exon 2 mutant disease has not shown any improvement in survival outcomes.[53] Another example is Sym004, a combination of two chimeric mAbs targeting nonoverlapping epitopes of the EGFR extracellular domain III designed to induce a much higher degree of receptor degradation. Encouraging results have been observed in the expansion of the phase I trial, with one-third of patients with anti-EGFR–refractory mCRC experiencing significant tumor shrinkage and prolonged disease stabilization.[54] This suggests that the dependency on EGFR ligands remains an oncogenic driver in this setting. Sym004 is under clinical evaluation in a randomized, proof-of-concept, phase II study in patients with *RAS* wild-type mCRC that is refractory to anti-EGFR mAbs.

Because acquired anti-EGFR resistance may result from compensatory signaling through ERBB receptors, cetuximab was investigated in combination with pertuzumab (an HER2 heterodimerization inhibitor) in patients with cetuximab-resistant *KRAS* wild-type mCRC (irrespective of *ERBB2* amplification). In a phase I trial, this regimen was not tolerated because of overlapping toxicities, but partial responses and disease stabilization were reported in some patients.[55] The results of clinical trials evaluating alternative combinations in genomically selected populations are highly anticipated.

When a genetic mechanism for secondary resistance is identified, promising strategies under investigation include the combination of anti-EGFR mAbs with MEK inhibitors (when *RAS* mutant clones emerge) or with HER2- or MET-targeted therapy (in the context of acquired receptor amplification). In principle, a parallel RTK pathway may be activated by compensatory ligand overexpression (nongenetic mechanisms), and the efficacy of these combinations may not be restricted to tumors with gene amplifications. Patients who have tumors that show the *EGFR* S492R mutation at relapse could be offered panitumumab-based therapy (in the setting of resistance to cetuximab), because panitumumab binds to a distinct epitope of the molecule. Indeed, investigators published a case report of a 5-month clinically beneficial response.[46] The novel anti-EGFR mAb Sym004 is active in preclinical models of acquired *EGFR* extracellular domain mutations.[44]

RESISTANCE TO ANTI-EGFR THERAPY IN EARLY-STAGE CRC

The improved survival with anti-EGFR mAbs added to chemotherapy in patients with *RAS* wild-type mCRC was the basis for exploring the role of targeted therapies in the adjuvant setting. However, two studies with cetuximab added to standard chemotherapy in stage III colon cancer did not show improved survival outcomes.[56,57] Although the reasons for these negative findings are not known, divergent effects of anti-EGFR therapy in early-stage versus advanced-stage CRC reinforce the theory that micrometastases behave differently than clinically apparent foci of metastatic disease. In one trial

(PETACC-8), a subgroup analysis showed that chemotherapy plus cetuximab was only advantageous for high-risk patients who had pT4pN2, which suggests that they resembled patients who have advanced disease.[56] Investigators also have raised the possibility of a negative interaction between the antibody and oxaliplatin. There is limited clinical evidence from a subgroup analysis (study N0147) suggesting that irinotecan could have been a better choice for combination with cetuximab.[58] Another interesting explanation comes from preclinical experiments that show reduced cellular dependence on EGFR signaling when a tumor cell has transitioned to a mesenchymal phenotype, which is known to support invasion and metastatic seeding of carcinomas.[59] In line with this hypothesis is the finding that early-stage CRC tumors with intrinsic mesenchymal signatures have reduced benefits from treatment with anti-EGFR mAbs given at the time of relapse.[60,61] In preclinical models, mesenchymal CRC cell lines were particularly sensitive to MET inhibitors.[60]

CONCLUSION

The elucidation of de novo and acquired resistance mechanisms arising in the setting of targetable tumor dependencies is guiding the development of rational therapeutic strategies. It is likely that a combination of targeted therapies will be necessary to effectively prevent and/or treat drug-resistant cancers. Colorectal tumors that initially respond to and then relapse after anti-EGFR targeted therapy eventually become highly molecularly heterogeneous. The significant overlap of genetic events associated with primary and secondary resistance supports clonal selection linked to tumor heterogeneity as a major determinant of treatment outcome. It also indicates that the same therapies used for acquired resistance— that is, salvage regimens— could be potentially useful in upfront therapy. The ultimate goals are to increase the magnitude and/or duration of clinical response and to delay the emergence of resistance when such combinations are administered as initial therapy. As recently highlighted by Misale et al,[2] the plethora of alterations that emerge at relapse biochemically converge to activate the EGFR/*RAS*/MAPK pathway (i.e., convergent evolution), which may facilitate drug development strategies in this setting.

Knowledge of the specific genetic mechanisms of drug resistance and the compensatory parallel signaling activation that occurs during anti-EGFR exposure have been fundamental for the study of alternative kinase inhibitors. Examples include combinations of pan-ERBB, MET, or MEK inhibitors with anti-EGFR mAbs, both in first-line and refractory settings, with promising results in early clinical trials. An alternative approach is to develop second-generation inhibitors of the oncoprotein. For a subset of mCRC tumors, this strategy also has been proven efficacious clinically, but the mechanisms underlying the sensitivity, such as sustained EGFR addiction as a result of ligand overexpression or increased ADCC at the tumor site, are still unknown.

Furthermore, because targeted gene analysis does not always explain the mechanism by which CRC becomes resis-

tant to anti-EGFR therapy, we believe that additional research should be directed toward understanding and controlling the evolutionary process in tumors, paying particular attention to gene expression profiling and interactions with the immune system and microenvironment. Incredible technological developments (e.g., ctDNA targeted sequencing) and advances in drug design will enable treatments that are precisely targeted to the unique molecular characteristics of an individual's cancer. However, until comprehensive mo-lecular profiles of individual tumors becomes feasible, it will be challenging to determine the presence of all of these modifiers of therapy efficacy in clinical practice. Finally, for successful drug translation to the adjuvant setting and increase curability of early-stage CRC, it is imperative to understand the micro- and macroenvironments in which targeted agents exert their effects and also to assess the activities of targeted agents with different chemotherapy backbones in preclinical models of early versus late-stage disease.

Resistance to Anti-HER2 Therapies in Breast Cancer

Mothaffar F. Rimawi, MD, Carmine De Angelis, MD, and Rachel Schiff, PhD

OVERVIEW

HER2 is amplified or overexpressed in 20% to 25% of breast cancers. HER2 is a redundant, robust, and powerful signaling pathway that represents an attractive therapeutic target. Anti-HER2 therapy in the clinic has resulted in significant improvements in patient outcomes and, in recent years, combinations of anti-HER2 therapies have been explored and carry great promise. However, treatment resistance remains a problem. Resistance can be mediated, among others, by pathway redundancy, reactivation, or the utilization of escape pathways. Understanding mechanisms of resistance can lead to better therapeutic strategies to overcome resistance and optimize outcomes.

HER2 is a member of a membrane tyrosine kinase receptor family (HER1–4). Although HER2 does not have any known ligands, there are more than 10 different ligands that activate other family receptors (Fig. 1).[1-7] On binding, ligands induce receptor homo- and heterodimerization activating a phosphorylation-signaling cascade. HER2 in cancer cells can be activated by either heterodimerization with other ligand-bound HER family members or, when overexpressed, by homodimerization.[8] The resulting downstream signaling regulates transcription of genes responsible for cell proliferation, survival, angiogenesis, invasion, and metastasis.[1-4,6,9,10]

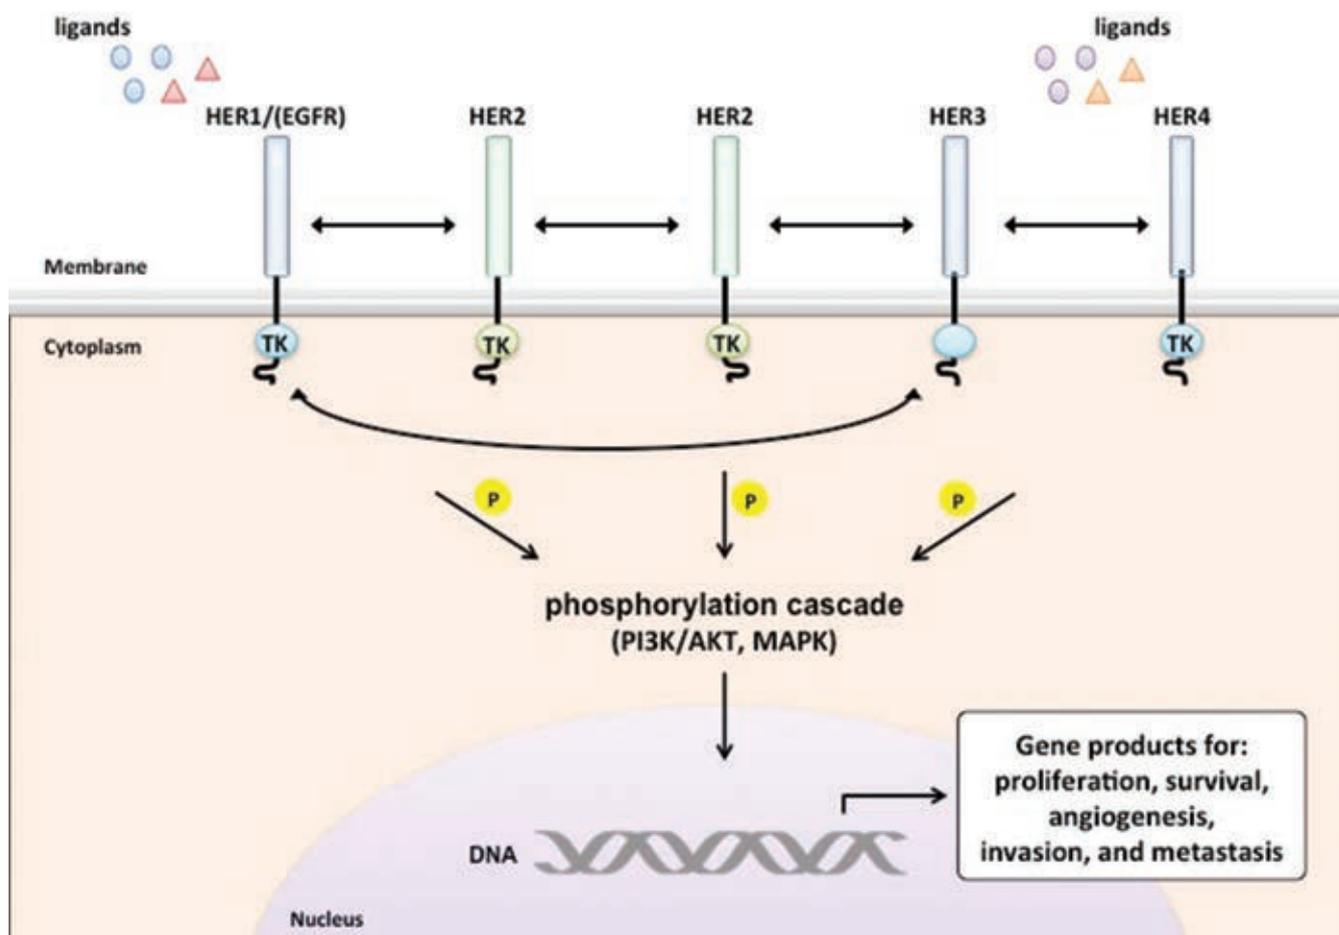
HER2 is amplified or overexpressed in 20% to 25% of breast cancers and results in aggressive behavior with rapid growth and frequent metastasis. Therefore, targeting HER2 represents an attractive treatment option, and that approach has been successful in the clinic.

The first targeted therapy against HER2 was the humanized monoclonal antibody trastuzumab. The mechanism of action of trastuzumab is not completely understood but it interacts with the extracellular domain of HER2 to inhibit its function. Trastuzumab has been suggested to inhibit signaling from HER2 homodimers better than heterodimers with HER1 (epidermal growth factor receptor [EGFR]) or HER3.[11-13] The resulting downregulation of the PI3K/AKT pathway signaling leads to induction of apoptosis in human tumors.[6,9,14] Trastuzumab has also been shown to work in part by inducing antibody-dependent cellular cytotoxicity. Although trastuzumab combined with chemotherapy reduces the risk for recurrence of HER2-positive tumors, many patients have tumors that exhibit de novo or acquired resistance.[15-18]

Many mechanisms for resistance to anti-HER2 therapy with trastuzumab have been suggested.[18,19] Those broadly fall under three major categories. The first category is redundancy within the HER receptor layer: the ability of the pathway to continue to signal despite being partially inhibited because of redundant ligands and receptors that enable alternative dimerization patterns. The second category is reactivation: the ability to reactivate pathway signaling at or downstream of the receptor layer such as with activating HER or downstream mutations, or loss of downstream pathway negative-regulating mechanisms. The third category is escape: the use of other pathways, which may pre-exist or be acquired at the time of resistance, but are not usually driving the cancer cell when HER2 is uninhibited. For purposes of this review, we will give an example from each of those resistance categories, focusing on mechanisms of resistance that have been best explored preclinically and in clinical trials: incomplete receptor family inhibition as an example of redundancy, deregulation of the PI3K pathway as an example of reactivation, and the role of the estrogen receptor (ER) in resistance as an example of escape. Additional roles for multiple other pathways and mechanisms involved in intrinsic and acquired resistance to HER-targeted therapy, including various receptor and cellular tyrosine kinases (e.g., MET, IGFR-1, c-SRC, and EphA2),[19-23] mucins,[24] regulators of cell cycle and apoptosis[19,25-27] and various elements of the tumor microenvironment and the host immune system,[28-31] have been recently thoroughly reviewed,[18] and are beyond the focus of the current paper.

INCOMPLETE RECEPTOR FAMILY INHIBITION

One mechanism for resistance to anti-HER2 therapy is incomplete blockade of the HER receptors. This occurs when the drug or drugs used do not effectively block signaling from

FIGURE 1. HER Pathway Signaling Network


HER2 is a member of the HER network consisting of three additional transmembrane receptor tyrosine kinases, HER1 (epidermal growth factor receptor [EGFR]), HER3, and HER4 plus more than 10 ligands. HER2 is the only receptor member for which a specific ligand has not been identified; whereas, HER3 lacks intrinsic kinase activity. On ligand binding, HER receptors form homodimers or heterodimers that, after transphosphorylation of their kinase domains, trigger downstream signaling cascades via key intermediates such as the phosphatidylinositol-3 kinase (PI3K)/AKT and the RAS/mitogen-activated protein kinase (MAPK) pathways. Activation of these downstream signaling intermediates promotes the expression of genes involved in tumor cell proliferation, survival, angiogenesis, invasion, and metastasis. HER2 is the preferred heterodimerization partner for other HER proteins and HER2/HER3 is considered the most oncogenic heterodimer. When HER2 is gene-amplified and/or overexpressed (20% of breast cancers), it can also be activated by homodimerization.

all HER family dimer pairs and, thus, do not fully inhibit downstream signaling. Several preclinical studies have explored regimens that more completely block HER2 as the major driver pathway and increase efficacy of anti-HER2 therapy by using combinations of targeted agents.

In addition to trastuzumab, several other drugs are available to inhibit the HER receptor layer more completely. Table 1 lists these inhibitors, with a focus on key agents that are already in clinical use or that have been rigorously investigated alone or in combination in preclinical and clinical studies of HER2-positive breast cancer. Pertuzumab binds to the heterodimerization domain of HER2 and blocks its interaction with HER1 and HER3.[32] Lapatinib, afatinib, and neratinib are dual kinase inhibitors (HER1, HER2).[33] T-DM1 (ado-trastuzumab emtansine) is an antibody-drug conjugate.[34] Gefitinib and erlotinib are potent kinase inhibitors of HER1.[35]

In animal models, various doublet and triplet combinations for HER2-positive tumor xenografts were studied. One

KEY POINTS

- Successful targeting of HER2 has improved outcomes in HER2-positive breast cancer, but treatment resistance remains a problem.
- Treatment resistance can be caused by pathway redundancy, pathway reactivation, or escape pathways.
- Use of combination anti-HER2 treatments for potent inhibition of the HER family signaling is biologically sound and offers great clinical promise.
- Estrogen receptor (ER) is a potential resistance pathway to anti-HER2 treatments. Concomitant inhibition of ER with potent HER2 inhibition is being investigated in clinical trials.
- PI3K pathway activation is also a potential mechanism of resistance and represents another attractive therapeutic target to overcome or prevent anti-HER2 treatment resistance.

TABLE 1. Key Monoclonal Antibodies and Small Molecules Targeting HER Family Receptors

Drug	Category	Mechanism	Phase of Development
Pertuzumab	Monoclonal antibody	HER2 dimerization inhibitor	Clinically available
T-DM1	Antibody-drug conjugate	Microtubule polymerization inhibitor; ADCC	Clinically available
MM-121	Monoclonal antibody	HER3-targeted antibody	II
MM-111	Monoclonal antibody	Bispecific antibody targeting HER2/HER3	I
Afatinib	Small molecule	Irreversible pan-HER tyrosine kinase inhibitor	III, available for lung cancer
Neratinib	Small molecule	Irreversible pan-HER tyrosine kinase inhibitor	III
Gefitinib	Small molecule	EGFR tyrosine kinase inhibitor	Development stopped
Erlotinib	Small molecule	EGFR tyrosine kinase inhibitor	Available for lung cancer

Abbreviations: ADCC, antibody-dependent cell-mediated cytotoxicity; EGFR, epidermal growth factor receptor; T-DM1, trastuzumab-derivative of maytansine.

study showed that the three-drug combination of gefitinib, pertuzumab, and trastuzumab, which blocks signaling from all HER1, HER2, and HER3 receptor homo- and heterodimer pairs, is much more effective than any of the single agents or two-drug combinations like trastuzumab and pertuzumab. The combination was capable of eradicating HER2 overexpressing xenografts in mice.[36] Two other studies showed that the two-drug combination of lapatinib and trastuzumab was also effective in eradicating HER2 over-expressing xenografts.[37,38] Interestingly, inhibition of HER1 (EGFR) activity increased efficacy even though this receptor is expressed at very low levels in some of these models. In ER-positive tu-

mors, endocrine therapy was also required for optimal antitumor effects.[36,37] Moreover, these studies showed that even lower drug doses and intermittent therapy with this lapatinib/trastuzumab regimen was effective in eradicating most tumors.[37]

These and other studies provided a strong biologic rationale for clinical trials that combined two anti-HER2 agents (dual inhibition). These trials showed increased efficacy when combined with chemotherapy in the metastatic setting,[39,40] and improved outcomes for patients. This approach was also extensively studied in the neoadjuvant and adjuvant setting, with some trials still ongoing.

TABLE 2. Randomized Neoadjuvant Trials Testing Dual HER2-Targeted Therapy in Combination with Chemotherapy[42-47]

Study	Phase	Patient Population	No. of Patients	Regimen Chemotherapy	Anti-HER2 Therapy	Duration (Weeks)	pCR (%)
NeoALTTO	III	Operable BC, T2-4*	455	Paclitaxel	Trastuzumab	18	29.5
					Lapatinib		24.7
					Trastuzumab + lapatinib		51.3
NSABP B-41	III	Operable BC	519	AC → paclitaxel	Trastuzumab	28	53.5
					Lapatinib		52.5
					Trastuzumab + lapatinib		62.0
CALGB 40,601	III	Operable BC, stage II-III	305	Paclitaxel	Trastuzumab	16	46
					Lapatinib		-
					Trastuzumab + lapatinib		56
TRYPHAENA	II	Operable BC, stage II-III**	225	FEC → docetaxel	Trastuzumab + pertuzumab	18	61.6
					Trastuzumab + pertuzumab		57.3
				Carboplatin + docetaxel	Trastuzumab + pertuzumab		66.2
CHER-LOB	II	Operable BC, stage II-IIIA	121	Paclitaxel → FEC	Trastuzumab	26	25.0
					Lapatinib		26.3
					Trastuzumab + lapatinib		46.7
NeoSphere	II	Operable BC, T2-4	417	Docetaxel	Trastuzumab	12	29.0
					Pertuzumab		24.0
					Trastuzumab + pertuzumab		45.8

Abbreviations: BC, breast cancer; AC, doxorubicin and cyclophosphamide; CALGB, Cancer and Leukemia Group B; CHER-LOB, Chemotherapy Herceptin and Lapatinib in Operable Breast Cancer; FEC, 5-fluorouracil, epirubicin, and cyclophosphamide; NeoALTTO, Neoadjuvant Lapatinib and/or Trastuzumab Treatment Optimization; NeoSphere, Neoadjuvant Study of Pertuzumab and Herceptin in Early Regimen Evaluation; NSABP, National Surgical Adjuvant Breast and Bowel Project; pCR, pathologic complete response; Pts, Patients.
*Excluding inflammatory breast cancer.
**Including inflammatory and locally advanced (no prior chemotherapy).

TABLE 3. Completed and Ongoing Neoadjuvant Trials Testing Dual HER2-Targeted Therapy without Chemotherapy[43,49,66]

Study	Phase	No. of Patients	Regimen		pCR
			Hormonal Therapy	HER2-Targeted Therapy	
NeoSphere	II	107	None	Trastuzumab + pertuzumab	17%
TBCRC 006	II	64	Estrogen deprivation for ER-positive tumors*	Trastuzumab + lapatinib	27%
TBCRC 023	II	33	Estrogen deprivation for ER-positive tumors*	Trastuzumab + lapatinib 12 weeks	12%
		61		Trastuzumab + lapatinib 24 weeks	28%
PAMELA	II	150	Estrogen deprivation for ER-positive tumors**	Trastuzumab + lapatinib 18 weeks†	Not available

Abbreviations: ER, estrogen receptor; NeoSphere, Neoadjuvant Study of Pertuzumab and Herceptin in Early Regimen Evaluation; TBCRC, Translational Breast Cancer Research Consortium; pCR, pathologic complete response; Pts, patients.
*In combination with ovarian suppression in premenopausal women.
**Letrozole or tamoxifen according to patient's menopausal status.
†Paclitaxel will be added to dual HER2 blockade if tumor progression is observed by ultrasound at week 6.

In the neoadjuvant (or preoperative) setting, combination anti-HER2 therapies have been investigated to directly test the hypothesis that more potent inhibition of the HER2 pathway would increase treatment efficacy, as suggested by the preclinical evidence discussed above.[36,37,41] Serial tumor biopsies obtained from patients on these trials also provide an invaluable resource to explore mechanisms of resistance and biomarkers of response. Some of the important clinical trials that tested this concept are summarized in Table 2.[42-47] These trials investigated the addition of a second anti-HER2 agent, namely lapatinib or pertuzumab, to trastuzumab plus chemotherapy. All of these trials used pathologic complete response (pCR), an endpoint that has variable definition and some limitations in correlation to outcomes. However, it is an endpoint that the U.S. Food and Drug Administration (FDA) has sanctioned as grounds for drug approval.

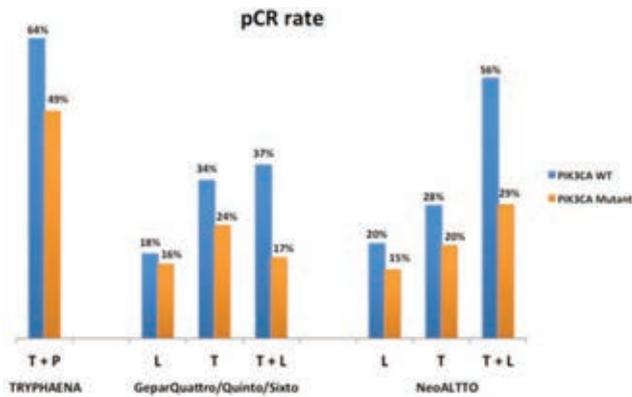
These neoadjuvant dual inhibition trials generally showed similar results: that combining dual inhibitors of HER2 with chemotherapy is a more effective strategy than trastuzumab plus chemotherapy as measured by pathologic complete response. The trials that utilized pertuzumab plus trastuzumab as their anti-HER2 therapy led to FDA approval of pertuzumab in the neoadjuvant setting in combination with trastuzumab and chemotherapy.

However, first results from the ALTTO trial[48] did not confirm results reported in the neoadjuvant trials (Neo-ALTTO and NSABP B-41).[42,44] The ALTTO trial is a study of more than 8,000 women randomly assigned to receive adjuvant trastuzumab, lapatinib, their sequence, or their combination. The study showed no significant difference in disease-free survival between patients who received trastuzumab only or those who received trastuzumab plus lapatinib at median follow-up of 4.5 years.[48] There are many possible factors that may have contributed to these results, including the high percentage of patients with small and node-negative tumors (40% each), and the use of aggressive chemotherapy (anthracyclines and taxanes), which might abrogate or mask benefit from dual inhibition. The results of the APHINITY trial, a randomized trial of adjuvant trastuzumab compared with trastuzumab plus pertuzumab plus chemotherapy, are eagerly awaited. So far, results from ALTTO[48] argue that dual

inhibition combined with chemotherapy is not for everyone and proper patient selection based on clinical and biologic characteristics is important. It also argues for a de-escalation strategy that carefully selects appropriate therapy for patients, and for switching more toxic treatment like chemotherapy (at least in part, and in some patients) with less toxic treatment, like targeted therapy.

As part of that de-escalation strategy, another approach that is biologically sound and clinically less toxic is to target HER2-positive tumors with potent anti-HER2 targeted agents without chemotherapy. Table 3 summarizes results from the trials that explored this concept, most notably, NeoSphere (targeted therapy alone arm: pertuzumab plus trastuzumab) and TBCRC 006 (lapatinib plus trastuzumab, with endocrine therapy if ER-positive).[43,49] Both of these trials showed that, in a subgroup of patients, pCR can be achieved in a proportion of patients without chemotherapy. It is important to use tissue acquired through serial tumor biopsies in these trials to identify molecular markers that can help determine which patients may benefit from a targeted therapy alone approach. It is clear that chemotherapy plays an important role in improving outcomes for many patients. The challenge remains to identify which group is which.

The drug trastuzumab emtansine (T-DM1), an antibody-drug conjugate is a first-in-class agent where molecules are attached to the antibody trastuzumab by a linker. On binding, the compound is internalized. This way, the drug would achieve the goal of inhibiting HER2, while delivering a cytotoxic agent to the cancer cell, theoretically enhancing efficacy and decreasing toxicity.[34] T-DM1 performed well in clinical trials in the second-and third-line treatment of HER2-positive metastatic breast cancer,[50,51] and as a result was approved for that indication by the FDA. This drug is currently being studied in the first-line setting in metastatic disease and in early-stage curable HER2-positive breast cancer. The MARIANNE trial randomized 1,095 patients to one of three arms: a taxane plus trastuzumab (the standard of care at the time the study was designed), T-DM1, and T-DM1 plus pertuzumab. A recent press release from the manufacturer stated that neither of the T-DM1-containing arms achieved

FIGURE 2. Reported *PIK3CA* Mutation Analyses in Neoadjuvant Trials of HER2-Targeted Therapy[56-58]


The percentage of patients who obtained a pathologic complete response (pCR) are reported for each treatment arm (L, lapatinib; P, pertuzumab; T, trastuzumab). Orange bars represent patients harboring *phosphatidylinositol-3 kinase* (*PIK3CA*) mutations; blue bars represent patients with *PIK3CA* wild type (WT).

superiority compared with trastuzumab plus a taxane. Results are expected to be presented at the 2015 ASCO Annual Meeting. Close examination of these results is important but, so far, it appears that T-DM1 will remain as a therapeutic option for HER2-positive metastatic breast cancer that is resistant to first-line chemotherapy plus trastuzumab and pertuzumab. Further investigation into the mechanism of action of T-DM1 and how best to combine it with other agents is warranted.

ACTIVATION OF THE PI3K PATHWAY

The phosphoinositide 3-kinase (PI3K)/AKT pathway is a powerful downstream signaling pathway activated by HER2

signaling. Constitutive activation of the PI3K/AKT pathway by reduced levels of its tumor suppressor PTEN or by activating mutations in PIK3CA results in resistance to trastuzumab and other anti-HER2, according compelling preclinical evidence.[52,53] Activation of PI3K signaling by enrichment or emergence of *PIK3CA* mutations may also contribute to acquired resistance to lapatinib in experimental models.[54] Other studies, however, suggest that PTEN status may not affect sensitivity of HER2-positive breast cancer cells to lapatinib.[55]

This mechanism of resistance has been explored in clinical samples. Tumor tissue samples acquired at baseline from patients who participated in neoadjuvant clinical trials with anti-HER2 agents were studied for *PIK3CA* mutations, and some trials also examined expression of PTEN.[56-58] As shown in Fig. 2, these trials consistently showed that patients with tumors that harbor an activating *PIK3CA* mutation have a lower chance of achieving pCR after neoadjuvant therapy with anti-HER2 agents. This difference seems to be more notable in the group of patients who received dual anti-HER2 inhibitors compared with those who received a single anti-HER2 agent. Although the majority of these studies co-administered chemotherapy, which may confound their results, there are concordant results from TBCRC006,[58] a neoadjuvant clinical trial in which patients with HER2-positive breast cancer received dual anti-HER2 therapy alone, allowing for a purer biologic signal. This trial also demonstrated that *PIK3CA* mutations or low PTEN levels are associated with treatment resistance.

Conflicting results were reported, however, about the role of PTEN in resistance to HER2-targeted therapies in other clinical trials. Reasons for these conflicting results may po-

TABLE 4. Impact of Hormone Receptor Status on Pathological Complete Response Rate in Neoadjuvant Studies with HER2-Targeted Therapies[42,43,45,49,67]

Study	No. of Patients	Regimen		Overall pCR Rate (%)	pCR rate According to HR (%)	
		Concurrent Therapy	Anti-HER2 Therapy		HR+	HR−
NeoALTTO	455	Paclitaxel	Trastuzumab	29.5	22.7	37.5
			Lapatinib	24.7	16.1	33.7
			Trastuzumab + lapatinib	51.3	41.6	61.3
GEPARQUINTO	620	EC → docetaxel	Trastuzumab	30.3	25.8	38.7

			Pertuzumab	24	17.4	30
			Trastuzumab + pertuzumab	45.8	26	63.2
		None	Trastuzumab + pertuzumab	16.8	5.9	29.1
TRYPHAENA	225	FEC → docetaxel	Trastuzumab + pertuzumab	61.6	49	65
			Trastuzumab + pertuzumab	57.3	46	79
		Carboplatin + docetaxel	Trastuzumab + pertuzumab	66.2	50	84
TBCRC 006	64	Letrozole* for ER-positive pts	Trastuzumab + lapatinib	27	21	36

Abbreviations: ER, estrogen receptor; HR, hormone receptor; NeoALTTO, Neoadjuvant Lapatinib and/or Trastuzumab Treatment Optimization; EC, epirubicin/cyclophosphamide; NeoSphere, Neoadjuvant Study of Pertuzumab and Herceptin in Early Regimen Evaluation; pCR, pathological complete response; TBCRC, Translational Breast Cancer Research Consortium; FEC; 5FU/epirubicin/cyclophosphamide; Pts, patients.
*In combination with ovarian suppression in premenopausal patients.

tentially be related to different PTEN assays and cutoff values.[59] Low levels of PTEN, but not necessarily complete loss, can activate the PI3K pathway and reduce treatment efficacy.[58] Preclinical studies suggest that the addition of PI3K/mTOR/AKT inhibitors to anti-HER2 treatment can overcome resistance in tumors with *PIK3CA* mutations,[53,54] a strategy currently being investigated in the clinic.

ESTROGEN RECEPTOR

About half of HER2-positive breast cancer tumors also express ER. The ER and the HER pathways, via a complex bidirectional cross talk, positively and negatively regulate each other,[18,60] so that one pathway can become the escape route to therapy targeted against the other pathway. Indeed, multiple preclinical studies using various HER2-positive breast cancer models have demonstrated the role of ER and its signaling in evading HER2 inhibition and promoting resistance. In ER-positive/HER2-positive breast cancer cells, it has been shown that pre-existing or restored ER levels and/or activity can mediate de novo or acquired resistance to potent anti-HER2 therapy.[27,61] In these resistant cells with sustained HER2 inhibition, ER and its downstream antiapoptotic protein Bcl2 provide key alternative survival stimuli, which in turn sensitize the cells to anti-ER therapies.[61] A study using specimens from a neoadjuvant trial with lapatinib[62] demonstrated a parallel increase in ER and Bcl2 levels after lapatinib treatment.[26] Finally, several studies using ER-positive/HER2-positive xenograft models further showed that a concomitant blockade of ER was crucial to eradicate these aggressive tumors with potent anti-HER2 drug combinations.[37,36,61]

Substantial clinical evidence also supports ER pathway as a mechanism to escape HER2 inhibition.[63-65] Table 4 further shows this important and intriguing finding that was seen consistently across all neoadjuvant trials with dual inhibitors. ER-positive tumors achieved a lower pCR rate than ER-negative tumors. Importantly, among those trials, only the TBCRC 006 trial (trastuzumab plus lapatinib with no chemotherapy) added concurrent endocrine therapy if tumors were ER-positive.[49]

Collectively, the experimental and clinical findings suggest that ER may act as an escape pathway for these tumors, and that concomitant inhibition of ER along with potent anti-HER2 therapy and chemotherapy may abrogate that difference. This concept is currently being tested in the NSABP-B52 trial.

In conclusion, the HER2 pathway represents an attractive therapeutic target that has been successfully attacked in clinic and has resulted in large and meaningful improvements in patient outcomes. However, treatment resistance remains a problem, and can be mediated by several mechanisms. Deciphering these resistance mechanisms is necessary to better tailor therapy to individual patient tumors, optimize patient outcomes, and avoid unnecessary toxicity and cost.

Combating Acquired Resistance to Tyrosine Kinase Inhibitors in Lung Cancer

Christine M. Lovly, MD, PhD

OVERVIEW

The prospective identification and therapeutic targeting of oncogenic tyrosine kinases with tyrosine kinase inhibitors (TKIs) has revolutionized the treatment for patients with non–small cell lung cancer (NSCLC). TKI therapy frequently induces dramatic clinical responses in molecularly defined cohorts of patients with lung cancer, paving the way for the implementation of precision medicine. Unfortunately, acquired resistance, defined as tumor progression after initial response, seems to be an inevitable consequence of this treatment approach. This brief review will provide an overview of the complex and heterogeneous problem of acquired resistance to TKI therapy in NSCLC, with a focus on *EGFR*-mutant and *ALK*-rearranged NSCLC. In vitro models of TKI resistance and analysis of tumor biopsy samples at the time of disease progression have generated breakthroughs in our understanding of the spectrum of mechanisms by which a tumor can thwart TKI therapy and have provided an important rationale for the development of novel approaches to delay or overcome resistance. Numerous ongoing clinical trials implement strategies, including novel, more potent TKIs and rational combinations of targeted therapies, some of which have already proven effective in surmounting therapeutic resistance.

Therapeutic targeting of oncogenes has emerged as a preeminent treatment paradigm for patients with non–small cell lung cancer (NSCLC). Beginning in 2004 with the initial identification of epidermal growth factor receptor (*EGFR*) mutations in a subset of lung adenocarcinomas,[1-3] molecular profiling of lung cancer, particularly lung adenocarcinoma, has evolved into a complex spectrum of clinically relevant and therapeutically actionable genomic alterations. These alterations occur at varying frequencies and, at present, have varying levels of clinical evidence to support the use of targeted inhibitors in each setting. To date, the most well-described molecular cohorts of NSCLC are those defined by the presence of *EGFR* mutations and *ALK* rearrangements. Treatment for patients with *EGFR*-mutant and *ALK*-rearranged NSCLC with specific tyrosine kinase inhibitors (TKIs) that target the EGFR and ALK tyrosine kinases, respectively, has led to remarkable clinical responses, including often-dramatic tumor shrinkage and increased progression-free survival (PFS) compared with standard cytotoxic chemotherapy.[4-10]

Unfortunately, despite the exciting results, virtually every patient who receives TKI therapy and has an antitumor response will eventually experience disease progression. This tumor relapse while the patient is still receiving drug therapy is called acquired resistance and typically occurs within 1 to 2 years after the initiation of the TKI.[4-8,11,12] The development of drug resistance remains a major limitation to the successful treatment for patients with advanced NSCLC. Therefore, numerous preclinical and clinical studies have been directed at identifying and understanding on a mechanistic level the tumor-specific factors that lead to acquired resistance in NSCLC. Given the complexity of the topic, we will specifically focus in this review on *EGFR*-mutant and *ALK*-rearranged NSCLC as paradigms for the use of targeted therapies and the battle to overcome acquired TKI resistance in this disease.

EGFR-MUTANT NSCLC

EGFR is the gene that encodes for the EGFR tyrosine kinase. EGFR propagates growth and survival signals through several downstream pathways within the cell, including the RAS-RAF-MEK-ERK (mitogen-activated protein [MAP] kinase) and the phosphoinositide 3-kinase (PI3K)–AKT–mammalian target of rapamycin (mTOR) pathways. In NSCLC, *EGFR* mutations are typically detected in exons 18 to 21, which encode part of the *EGFR* tyrosine kinase domain. Approximately 90% of these mutations are small in-frame deletions in exon 19 or point mutations in exon 21 (L858R).[13] These mutations activate EGFR kinase activity and are typically detected in lung adenocarcinomas with a frequency of approximately 10% of patients with NSCLC in the United States and of approximately 35% in Asia.[1-3]

EGFR mutations confer sensitivity to and are strong predictors of efficacy for the EGFR TKIs. Several classes of EGFR

TKIs have been tested in tumors that harbor activating *EGFR* mutations, including the first-generation drugs erlotinib and gefitinib and the second-generation drugs, afatinib, dacomitinib, and neratinib. Several randomized, phase III studies have now demonstrated that patients with *EGFR*-mutant tumors (particularly those with the exon 19 deletion and L858R mutations) display an approximately 60% to 70% radiographic response rate (RR) and a PFS of approximately 10 to 13 months with erlotinib, gefitinib, or afatinib therapy.[4-8,14,15] These treatment outcomes are superior to those obtained with standard platinum-based chemotherapy in the same patient population. Therefore, EGFR TKIs are now recommended as first-line therapy for patients with *EGFR*-mutant lung cancer. In the United States, erlotinib and afatinib are both approved by the U.S. Food and Drug Administration (FDA) as first-line therapies for patients with *EGFR*-mutant lung cancer.

ACQUIRED RESISTANCE TO EGFR TKI THERAPY

Acquired resistance to EGFR TKIs is a complex and heterogeneous phenomenon, with multiple potential mechanisms whereby the tumor evades the anti-EGFR– directed therapy. However, the end result for each potential mechanism is sustained signaling through downstream pathways, such as the MAP kinase and PI3K-AKT-mTOR pathways, which prop-

---

KEY POINTS

- The identification of clinically relevant molecular cohorts of patients with non−small cell lung cancer (NSCLC), defined by the presence of actionable genomic alterations, has revolutionized the care of patients with this disease.
- Treatment for patients whose lung tumors harbor specific oncogenic mutations often results in dramatic response to targeted therapies, such as tyrosine kinase inhibitors (TKIs). This is best exemplified by *EGFR*-mutant and *ALK*-rearranged NSCLCs treated with *EGFR* TKIs and *ALK* TKIs, respectively.
- Resistance to TKI therapy appears to be an inevitable consequence of this treatment approach. Resistance can be either primary (de novo) or acquired. Specifically, acquired resistance is defined by tumor growth after initial tumor regression while the patient is still receiving the TKI therapy.
- Mechanisms of acquired resistance include drug target gene modification (amplification, second-site mutations), activation of bypass tracks, which serve as compensatory signaling loops, and/or histologic transformation.
- Rebiopsy at the time of acquired resistance is essential for understanding the specific mechanism(s) of resistance at play in the tumor and for directing the patient to the most appropriate line of therapy. Several strategies to overcome acquired resistance, including novel, more potent inhibitors and rational combinations of targeted inhibitors, have already proven successful in clinical trials.

---

agate progrowth and prosurvival signals within the tumor. Numerous in vitro studies modeling EGFR TKI resistance in *EGFR*-mutant lung cancer cell lines as well as studies of actual patient tumor samples at the time of disease progression during EGFR TKI therapy[16,17] have yielded important insights into the underlying molecular pathogenesis of acquired resistance (Fig. 1). These mechanisms include (1) modification of the target oncogene, particularly the T790M second-site mutation, (2) upregulation of parallel signaling pathways, such as MET or HER2, to circumvent the inhibited EGFR, and (3) histologic transformation, such as epithelial to mesenchymal transition (EMT) or small cell transformation. Overall, a thorough understanding of the mechanistic basis for acquired resistance is paramount for developing strategies to delay or overcome resistance. Here, we will focus on clinically relevant mechanisms of acquired resistance and proposed strategies to treat progressive disease.

Strategies to Overcome Resistance Mediated by *EGFR* Target Modification

Genomic alterations in the drug target, such as amplification and/or second-site mutations, have been shown to occur as a common mechanism of resistance in many oncogene-driven cancers treated with kinase inhibitor therapy. For example, second-site mutations within the target oncogene have been described for *BCR-ABL* in chronic myeloid leukemia,[18] *EGFR* in NSCLC,[19,20] *ALK* in NSCLC,[21,22] and *ROS1* in NSCLC.[23] In the case of *EGFR*-mutant NSCLC, the most common second-site mutation involves substitution of a methionine in place of a threonine at position 790 (T790M) in the EGFR kinase domain. This T790M gatekeeper mutation is the most common target-specific alteration; it is identified in approximately 50% of patients with acquired resistance to the EGFR TKIs erlotinib and gefitinib.[19,20] The T790M mutation is thought to confer TKI resistance through steric hindrance that interferes with drug binding and/or through alterations in the ATP affinity of the EGFR kinase.[24] Several other second-site mutations within the EGFR kinase domain also have conferred resistance to EGFR TKI therapy, though these mutations appear to occur at a much lower frequency.[25]

In the case of T790M-mediated resistance, one potential strategy to overcome resistance is through the development of novel EGFR inhibitors with increased potency. Erlotinib and gefitinib are first-generation EGFR TKIs that were designed against wild-type EGFR and that reversibly bind to the EGFR kinase domain. Second-generation inhibitors, such as afatinib, neratinib, and dacomitinib, irreversibly bind to the EGFR kinase domain and have activity against other EGFR (ErbB1) family members, including HER2 (ErbB2), HER2 (ErbB3), and/or HER4 (ErbB4). The initial hypothesis was that these second-generation inhibitors would be able to overcome the T790M mutation. Indeed, preclinical data in cell line models did show that the irreversible inhibitors can overcome T790M in vitro.[26-28]

Although the second-generation EGFR/HER2 TKI afatinib is FDA approved for first-line therapy in *EGFR*-mutant NSCLC,[8] this agent has not yet proven to be a promising ther-

FIGURE 1. Mechanisms of Acquired Resistance to First- and Second-Generation EGFR TKIs in EGFR-Mutant NSCLC

Resistance can be mediated by *EGFR* target modifications, most commonly the *EGFR* T790M second-site mutation, through bypass signaling pathways that circumvent the inhibited driver oncogene (*EGFR*) and through histologic transformation (in this case, change in histology from NSCLC to SCLC). Potential strategies to overcome resistance are noted in the white boxes.
Abbreviations: EGFR, epidermal growth factor receptor; TKIs, tyrosine kinase inhibitors; NSCLC, non-small cell lung cancer; SCLC, small cell lung cancer.

apy in the setting of acquired resistance to first-generation EGFR TKIs, such as erlotinib and afatinib, despite the in vitro studies that suggest that afatinib can overcome T790M. In the phase III LUX-lung 1 study, patients with advanced NSCLC who had previously been treated with erlotinib or gefitinib for at least 12 weeks were randomly assigned to receive afatinib or placebo. Molecular selection for *EGFR* mutation was not required for entrance into the study, and the molecular mechanism(s) underlying the patient's progressive disease during treatment with erlotinib or gefitinib were unknown. The RR and PFS were superior with afatinib, but the study did not meet its primary endpoint of improved overall survival in all study participants or in the subset of patients with known *EGFR*-mutant lung cancer.[29] Likewise, there were no responses in patients with known T790M in clinical trials of other second-generation EGFR TKIs, including neratinib[30] and dacomitinib.[31]

More recently, there has been tremendous excitement surrounding the clinical development of third-generation, mutant-specific EGFR inhibitors. These third-generation EGFR TKIs are irreversible inhibitors, analogous to the second-generation EGFR TKIs; however, they have higher specificity for mutant EGFR (including T790M) than wild-type EGFR. Several agents, including AZD9291, rociletinib (CO-1686), HM61713, ASP8273, and EGF816, are in this class. Of these agents, the mutant-specific EGFR TKIs with the most clinical data reported to date are AZD9291 and rociletinib (CO-1686). Both AZD9291 and rociletinib have activity against EGFR activating mutations (e.g., L858R, exon 19

deletion) and EGFR resistance mutations (e.g., T790M), with little inhibition of wild-type EGFR.[32,33]

Results of a phase I study of AZD9291, which included both the dose-escalation and dose-expansion cohorts, were presented at the 2014 Congress of the European Society for Medical Oncology.[34] Among all evaluable patients, the overall RR in the T790M-positive cohort was 61% (78/127 patients) and the PFS was 9.6 months. In the T790M-negative cohort, the overall RR was 21% (13/61 patients) and the PFS was 2.8 months. The most common adverse events were diarrhea (39%), rash (36%), and nausea (18%), most of which were mild. Overall, AZD9291 appears to be well tolerated, and dose reductions were infrequently needed in the study population.

Analogously, promising results were reported for the phase I/II trial of rociletinib (CO-1686). In the TIGER-X study, two formulations and multiple doses/schedules of rociletinib were evaluated.[35] Data from 56 T790M-positive patients who were treated with rociletinib at the recommended phase II dose of 625 mg twice a day (30 patients) and the step-down dose of 500 mg twice a day (26 patients) indicated an overall RR of 67% in the 27 patients who had evaluable disease. The median PFS was 10.4 months. CO-1686 is well tolerated; hyperglycemia was a frequent adverse event (32%, all grades; 14%, grades 3 to 4).

Numerous other mutant-specific EGFR inhibitors, including HM61713 (NCT01588145), ASP8273 (NCT02192697, NCT02113813), and EGF816 (NCT02108964), are being evaluated in clinical trials. Overall, these mutant-specific

EGFR TKIs appear to be the most effective therapeutic strategy tested to date to overcome T790M-mediated acquired resistance to erlotinib, gefitinib, and afatinib. In fact, both AZD9291 and rociletinib received FDA breakthrough status in 2014.

Despite the excitement surrounding the shown efficacy of mutant-specific EGFR TKIs in T790M-positive tumors, there still remains a large cohort (40% to 50%) of patients with T790M-negative tumors who have developed acquired resistance to erlotinib, gefitinib, or afatinib. One potential strategy that has been postulated for this cohort includes a combination of the EGFR monoclonal antibody cetuximab with afatinib in patients with acquired resistance. This combination, which dually targets *EGFR*, has been studied preclinically[36] and in phase I clinical trials.[37] Among the 126 patients treated with this combination, the objective RR was 29% and was comparable in patients with T790M-positive and T790M-negative tumors (32% vs. 25%; p = 0.341). The median PFS was 4.7 months. Adverse events included expected toxicities of *EGFR* inhibitors, such as rash, diarrhea, and fatigue. Therapy-related grades 3 and 4 adverse events occurred in 44% and 2% of patients, respectively. Studies of afatinib and cetuximab in the first-line setting and at the time of acquired resistance are being planned.

Strategies to Overcome Resistance Mediated by Bypass Signaling Pathways

The majority of focus and attention with respect to acquired resistance to EGFR TKIs has centered on overcoming resistance mediated by the T790M mutation. However, several recent reports have described alternative ways in which a tumor may circumvent inhibited *EGFR*, specifically through activation of collateral signaling networks that can transmit the same downstream progrowth and prosurvival effects within the tumor. Therapeutic strategies aimed at overcoming resistance mediated by this bypass signaling are typically devised to provide continuous inhibition of the driver oncogene (e.g., *EGFR*) while also coinhibiting the compensatory signaling loops that circumvent the inhibited driver. Activation of several different receptor tyrosine kinases, including MET,[16,17] HER2,[38] HER3,[39] insulin-like growth factor 1 receptor (IGF-1R),[40] fibroblast growth factor receptor 1 (FGFR1),[41] and AXL.[42] In addition, activation of the MAP kinase pathway can drive EGFR TKI resistance in vitro and in vivo.[43] The MAP kinase pathway may be activated in this context by virtue of mutations in *BRAF*, a component of the MAP kinase signaling cascade, as well as through reduced expression of neurofibromin, a RAS GTPase-activating protein encoded by the *NF1* gene, which functions as a negative regulator of RAS.[44] Finally, activation of the PI3K-AKT-mTOR pathway, by virtue of *PIK3ca* mutations, can drive resistance to erlotinib and gefitinib.[17]

Numerous clinical trials have been designed to test rational drug combinations that may overcome therapeutic resistance by targeting bypass signaling pathways. Unfortunately, results to date have been somewhat disappointing. (For a review, see Yu et al.[45])

Strategies to Overcome Resistance Mediated by Histologic Transformation

Changes in tumor histology, including EMT and transformation to small cell lung cancer (SCLC), have been documented at the time of acquired resistance to EGFR TKIs.[16,17] The molecular mechanisms initiating these phenotypic changes have not been clearly elucidated to date. In the fraction of patients with EGFR TKI resistance driven by SCLC transformation (3% to 14%), the original *EGFR* mutation is retained. These patients may benefit from treatment with standard platinum-based chemotherapy regimens used in the standard management for SCLC.[46,47]

ALK-REARRANGED NSCLC

ALK is the gene that encodes for the anaplastic lymphoma kinase (ALK). ALK is a receptor tyrosine kinase that is normally expressed in the developing nervous system[48]; however, genomic alterations in *ALK*—including *ALK* amplification, activating point mutations in the *ALK* kinase domain, and *ALK* chromosomal rearrangements—are found in a wide variety of malignancies.[49] In NSCLC, *ALK* is activated through chromosomal rearrangements, most commonly *EML4-ALK*, which is a fusion between the echinoderm microtubule-associated protein-like 4 gene *EML4* and *ALK*, both on chromosome 2. Analogous to EGFR, ALK fusion proteins signal downstream through the MAP kinase and the PI3K-AKT-mTOR pathways. *ALK* rearrangements are typically detected in lung adenocarcinoma and occur at a frequency of approximately 3% to 7%.[11,50]

Several large clinical trials have shown now that patients who have advanced NSCLC and harbor *ALK* rearrangements derive clinical benefits from treatment with ALK TKI therapy. Crizotinib is the first-in-class ALK TKI to be tested in this patient population. Of note, in addition to ALK, crizotinib also targets MET and ROS1. In the phase I, first-in-man study (PROFILE 1005) of crizotinib in patients who have advanced NSCLC and harbor an *ALK* rearrangement, the objective RR was 60.8% (87/143 patients), and the median PFS was 9.7 months.[11,12] On the basis of the high RRs documented in this study, crizotinib was granted FDA approval in 2011 for the treatment of advanced, *ALK*-rearranged NSCLC. Crizotinib also has been studied in randomized, phase III trials. In PROFILE 1007, crizotinib was compared with single-agent chemotherapy (pemetrexed or docetaxel) in patients with *ALK*-rearranged NSCLC who had experienced disease progression after first-line platinum-based chemotherapy. Crizotinib therapy resulted in higher RRs (65% with crizotinib vs. 20% with chemotherapy) and a significantly longer PFS (7.7 months with crizotinib vs. 3.0 months with chemotherapy).[9] There was no difference in overall survival between the groups (20.3 months with crizotinib vs. 22.8 months with chemotherapy), likely because of significant crossover of patients from the chemotherapy arm at the time of disease progression. In the PROFILE 1014 study, crizotinib was evaluated in the first-line setting versus chemotherapy (cisplatin or carboplatin plus pemetrexed) in

343 patients who had advanced *ALK*-rearranged NSCLC.[10] The objective RR was 74% with crizotinib versus 45% with chemotherapy, and the PFS was significantly longer (10.9 months with crizotinib vs. 7.0 months with chemotherapy). The median overall survival was not reached in either group. Therefore, crizotinib is now recommended as first-line therapy for patients who have *ALK*-rearranged lung cancer.

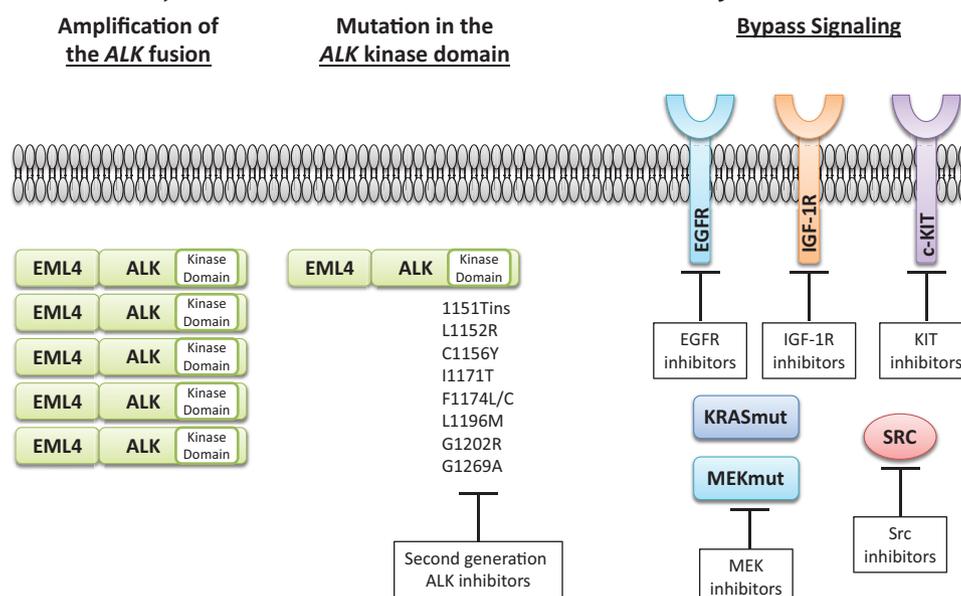
ACQUIRED RESISTANCE TO ALK TKI THERAPY

Analogous to *EGFR*-mutant lung cancer treated with EGFR TKI therapy, acquired resistance to the ALK TKI therapy remains a barrier to the most effective management of this disease. Also analogous to EGFR, acquired resistance to ALK inhibition appears to be a complex and heterogeneous phenomenon that can be mediated through modification of the target oncogene and upregulation of parallel signaling pathways to circumvent the inhibited ALK fusion protein. Acquired resistance to ALK TKI therapy, particularly crizotinib, has been the focus of intense basic science and clinical research (Fig. 2). Target gene modification, including *ALK* amplification and mutation within the *ALK* kinase domain, have been described in both preclinical models and patient tumor samples at the time of disease progression during crizotinib therapy.[21,22,51] Unlike *EGFR*, for which T790M is the predominant mutation found in 50% to 60% of patients with EGFR TKI resistance, only approximately one-third or fewer of patients with crizotinib-resistant tumors harbor an *ALK* kinase domain mutation, and there are numerous mutations that can drive resistance. The two most common mutations described to date are L1196M, which is at the gatekeeper position and is analogous to *EGFR* T790M, and G1269A—

G1269 is the residue immediately before the conserved *DFG* activation motif in the kinase domain.[21,22] Other *ALK* kinase domain mutations that can drive resistance include T1151ins, L1152R, C1156Y, I1171T, F1174L, G1202R, and S1206Y.[21,22,52-54] Interestingly, these different mutations can confer a variable degree of crizotinib resistance in vitro.[21] In addition, to underscore the heterogeneity of crizotinib resistance, the C1156Y and L1196M *ALK* mutations were both found at different tumor sites within the same patient at the time of crizotinib resistance.[52]

Activation of alternative signaling pathways that can bypass the drug-inhibited ALK fusion protein also has been described as a mechanism of crizotinib resistance. This bypass pathway activation can be driven by both genomic and nongenomic changes. For example, increased EGFR phosphorylation (without *EGFR* mutation or amplification) was observed in four of nine tumor biopsy samples at the time of crizotinib resistance compared with the precrizotinib tumor samples.[21] These clinical data are in accord with what has been described for cell line models of ALK inhibitor resistance.[53,55] In addition, increased IGF-1R phosphorylation was observed in cell culture models of ALK TKI resistance, and this result was mirrored in patient tumor biopsy samples taken at the time of progressive disease.[56] Most recently, Src activation also was found to be a driver of crizotinib resistance.[57] The end result of activation of each of these proteins is continued signaling through redundant downstream pathways, despite the presence of the *ALK* inhibitor.

Genomic mechanisms that can drive ALK TKI resistance include mutations in *KRAS* and *MAP2K1*. A *KRAS* point mutation were found in two of 12 patients who had ALK-positive, crizotinib-resistant tumors.[22] Mutations in

FIGURE 2. Mechanisms of Acquired Resistance to Crizotinib in *ALK*-Rearranged NSCLC


Resistance can be mediated by *ALK* target modifications, including *ALK* amplification and *ALK* kinase domain mutations, and through bypass signaling pathways that circumvent the inhibited driver oncogene (the *ALK* fusion). Potential strategies to overcome resistance are noted in the white boxes.
Abbreviation: NSCLC, non-small cell lung cancer.

MAP2K1, which encodes the protein MEK, were found in one of nine patients who had ALK-positive, crizotinib-resistant tumors.[57] Of note, both of these alterations activate the MAP kinase pathway. Furthermore, amplification of the *cKIT* receptor tyrosine kinase was detected in two of six patient samples with matched pre- and post-crizotinib tumor biopsies.[21]

Strategies to Overcome Resistance Mediated by *ALK* Target Modification

Several second-generation ALK inhibitors are currently being developed clinically. In general, these ALK inhibitors have more on-target efficacy against ALK in vitro than crizotinib and can overcome some of the ALK kinase domain mutations associated with crizotinib resistance.

The most well-studied second-generation ALK inhibitor to date is ceritinib (LDK-378). This agent potently inhibits ALK in vitro in addition to the IGF-1R and insulin receptor. Preclinical studies have shown that ceritinib can overcome the L1196M and G1269A mutations, which appear to be the most common mutations associated with crizotinib resistance.[58] In a phase I study of ceritinib, which included an expansion cohort at the maximum-tolerated dose (750 mg daily), the overall RR was 58%, and the median PFS was 7.0 months among the 114 patients who received at least 400 mg daily.[59] Among the 80 patients who had previously been treated with crizotinib, the RR was 56%, and responses were observed in tumors both with and without detected crizotinib resistance mutations. The most common adverse events reported were elevated liver enzymes and gastrointestinal toxicity (nausea, diarrhea). On the basis of this study, ceritinib was granted accelerated approval by the FDA in April 2014. Finally, ceritinib has documented efficacy against central nervous system (CNS) disease.

Alectinib (CH5424802) is also a second-generation ALK TKI with a distinct chemical structure that can overcome some of the crizotinib resistance mutations, such as the L1196M gatekeeper.[60] In a phase I/II study of this agent in Japan, 43 of 46 patients with ALK inhibitor–naive disease who were treated with the recommended phase II dose achieved an objective response.[61] Alectinib also has been tested in a cohort of patients who experienced progression during treatment with crizotinib or who were intolerant of crizotinib.[62] Of 44 evaluable patients, the objective RR was 55% (24/44 patients). Crizotinib resistance mechanisms were not reported. The CNS RR in patients with CNS metastases at baseline was 52% (11/21 patients). The most common adverse events reported were fatigue, myalgia, and peripheral edema. Alectinib received a breakthrough therapy designation from the FDA in 2013. A randomized, phase III study (ALEX) comparing alectinib to crizotinib in treatment-naive patients with *ALK*-positive lung cancer is ongoing (NCT02075840).

Several other next-generation ALK inhibitors are being studied. Like ceritinib and alectinib, X-396 is more potent against *ALK* in vitro and can overcome crizotinib resistance mutations.[63] A phase I/II trial of this agent is ongoing (NCT01625234); preliminary results indicate that 59% of patients (10/17 patients) achieved a partial response, including patients who had received prior crizotinib.[64] Adverse events were mild and included rash, nausea, vomiting, fatigue, and edema. AP26113, which targets ALK and has activity against the EGFR T790M mutation in vitro, has been tested in a phase I/II study (NCT01449461). The objective RR was 72% and the median PFS was 56 weeks in the 72 patients who had *ALK*-positive NSCLC at the time of data cutoff.[65] In the 65 patients who had received prior crizotinib, the RR was 69%, and the median PFS was 47.3 weeks. CNS responses were documented. Finally, PF-06463922 is a derivative of crizotinib designed to be a more potent ALK/ROS1 inhibitor. This agent also was optimized to overcome some of the pharmacokinetic limitations of crizotinib.[66] A phase I/II trial is ongoing (NCT01970865).

Strategies to Overcome Resistance Mediated by Bypass Signaling Pathways

Such strategies to combat ALK TKI resistance mediated by bypass signaling are only beginning to emerge. Possible rational-combination therapies that have been postulated include an ALK inhibitor plus either an EGFR inhibitor, IGF-1R inhibitor, Src inhibitor, or MEK inhibitor, based on the studies described above. It is also worth noting that ALK inhibitors have been tested in combination with heat shock 90 (HSP90) inhibitors. ALK fusions are known HSP90 client proteins, and in vitro studies demonstrate the efficacy of HSP90 inhibitors in both ALK TKI–sensitive and ALK TKI–resistant models.[67] Furthermore, clinical responses have been documented in patients with *ALK*-positive lung cancer, both in the crizotinib-naive and -resistant states.[67,68] The combination inhibition of ALK plus HSP90 is being evaluated in clinical trials (NCT01579994, NCT01712217, NCT01772797).

CONCLUSIONS

The identification and prospective targeting of oncogenic driver mutations have revolutionized the care of patients who have NSCLC. However, therapeutic resistance remains a significant barrier to the successful management of this disease. Using the two most well-established molecular cohorts of NSCLC, those defined by *EGFR* mutations and *ALK* rearrangements, we have reviewed the molecular mechanisms of acquired resistance and the strategies to overcome resistance. The development of more potent and more selective second- and third-generation oncogenic kinase inhibitors appears to be the strategy with the most momentum and the most documented clinical success to date in both of these cohorts of patients with lung cancer.

However, there are several challenges to address and opportunities to explore moving forward, including:

- How do we effectively address the heterogeneity of resistance mechanisms between different individuals and even in one individual patient? Will multiple biopsies at different sites of disease be necessary, or fea-

sible? Will blood-based markers, such as circulating free DNA, become a way for clinicians to adequately assess resistance mechanisms?

- How do we design and implement novel clinical trials that take into consideration the rapid pace of scientific discovery and the demand to bring more effective therapies into the forefront of care? Furthermore, how do we design these trials to encompass systematic analysis of biomarkers that are found in increasingly smaller percentages of patients? Cooperative group trials, such as the NCI ALK Master Protocol, which is currently being developed, will certainly assist in achieving this design goal.

- What other effective combination therapies can be devised to tackle the problem of TKI resistance? Will cotreatment with different classes of drugs, such as TKIs and immune checkpoint inhibitors, be effective in overcoming resistance? How should these agents be dosed: simultaneously or sequentially?

- Finally, how can cutting-edge studies of TKI resistance in NSCLC be translated to other malignancies? Many of the current and emerging therapeutic targets in NSCLC, such as *ALK, ROS1,* and *RET,* also are found in other malignancies. To more broadly tackle and surmount the problem of acquired resistance, studies in NSCLC, we hope, can be used to inform management in distinct tumor types that harbor these same targets.

Overall, a thorough understanding of the mechanistic basis for acquired resistance and the development of innovative therapeutic strategies to overcome resistance are paramount to most effectively combat resistance and, therefore, to improve the care of patients who have lung cancer.

OVERVIEW

Advances in tumor genome sequencing have enabled discovery of actionable alterations leading to novel therapies. Currently, there are approved targeted therapies across various tumors that can be matched to genomic alterations, such as point mutations, gene amplification, and translocations. Tools to detect these genomic alterations have emerged as a result of decreasing costs and improved throughput enabled by next-generation sequencing (NGS) technologies. NGS has been successfully utilized for developing biomarkers to assess susceptibility, diagnosis, prognosis, and treatment of cancers. However, clinical application presents some potential challenges in terms of tumor specimen acquisition, analysis, privacy, interpretation, and drug development in rare cancer subsets. Although whole-genome sequencing offers the most complete strategy for tumor analysis, its present utility in clinical care is limited. Consequently, targeted gene capture panels are more commonly employed by academic institutions and commercial vendors for clinical grade cancer genomic testing to assess molecular eligibility for matching therapies, whereas whole-exome and transcriptome (RNASeq) sequencing are being utilized for discovery research. This review discusses the strategies, clinical challenges, and opportunities associated with the application of cancer genomic testing for precision cancer medicine.

Genomic sequencing technologies have enabled identification of actionable targets (e.g., *BRAF* in melanoma, *EGFR* in lung cancer) thus facilitating treatment selection beyond what is offered by conventional histopathologic methods (Fig. 1). Although NGS has helped identify genomic alterations and uncover novel targets for therapies, there are several barriers for translating this into clinical practice, such as informed consent, choosing a scalable cost-effective testing strategy, turnaround time, and clinical interpretation of results. Several pilot studies have addressed some of these hurdles and demonstrated the feasibility of offering genomic testing for patients with advanced cancer within a clinically relevant time frame and interpreting the results to facilitate new treatment options for patients.[1-6] Today, cancer genomic testing has become more widely available in academic cancer centers and commercial testing labs.

Although whole-genome, whole-exome, and whole-transcriptome sequencing offer an unbiased approach and opportunities for discovery, their immediate effect on clinical decision making is limited, as only a fraction of cancer genes are well characterized in terms of biology and therapeutic relevance. Further, these unbiased sequencing approaches remain expensive and time consuming and are burdensome for computational analysis. All of these limitations make these approaches less amenable to meet standards required for clinical testing, such as Clinical Laboratory Improvement Amendments (CLIA) and College of American Pathology certification. Instead, many academic cancer centers and commercial testing labs have developed focused cancer gene panels ranging from 25 to 400 genes. These cancer gene panels are more cost-effective, have faster turnaround times, and are more scalable for clinical grade testing (Sidebar 1). As an example, Foundation Medicine offers a targeted approach for the entire coding sequence of 315 cancer-related genes plus selected introns from 28 genes often rearranged in solid tumors.[7] Caris provides an assay that combines immunohistochemistry, fluorescence in situ hybridization (FISH), and NGS for selected hotspot mutations involving select exons. However, ARUP Labs offers a targeted DNA sequencing assay for solid tumors for hotspot mutations in 48 genes.

Although genomic tumor testing has become available for patients and oncologists, there are several limitations to consider in practice including specimen quality, distinguishing driver and passenger mutations, tumor heterogeneity, and incidental germ-line mutations. Genomic testing and interpretation can be limited by tumor content and the quality of small, formalin-fixed tumor samples. Although formalin-fixed paraffin embedded (FFPE) samples may be subject to degradation complicating sequencing, strategies that accommodate FFPE samples have been successfully developed.[8,9] At times, there may be a need for repeat or fresh frozen tumor

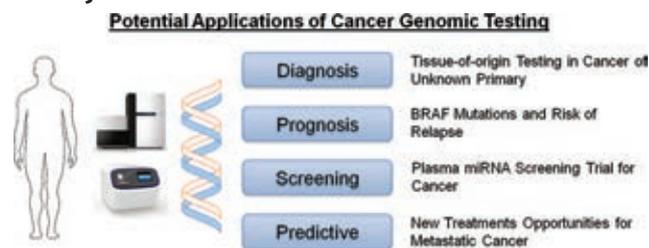
FIGURE 1. Potential Applications of Cancer Genomic Testing

Potential Applications of Cancer Genomic Testing

Diagnosis	Tissue-of-origin Testing in Cancer of Unknown Primary
Prognosis	BRAF Mutations and Risk of Relapse
Screening	Plasma miRNA Screening Trial for Cancer
Predictive	New Treatments Opportunities for Metastatic Cancer


Cancer genomic sequencing assays can aid clinical decision making with potential implications for diagnosis, prognosis, and treatment. Several assays are available to aid in identifying tissue-of-origin in cancer of unknown primary, which may lead to identification of potential favorable subsets and their appropriate treatment options. For patients with metastatic or refractory cancer, multiple testing strategies are available to identify genomic alterations that may provide molecular eligibility for novel targeted therapies in clinical trials.

biopsies as these may provide better quality for sequencing and can support specialized research assays. Although cancer gene panels focus on identification of potentially targetable driver mutations that provide a selective growth advantage for tumors, it is often hard to discern the role of passenger or bystander mutations. Also, pretreatment of tumors with cytotoxic therapies can often lead to increased genomic instability and alterations, making interpretation of tumor evolution and heterogeneity an arduous task.[10] Gerlinger et al highlighted the challenges associated with tumor heterogeneity and the potential limitations of a single biopsy, as different sites of metastases may have different tumor subclones and mutations.[11] However, it is expected that the dominant mutations exist as "trunk" mutations and would be the priority target for therapy. Finally, to aid in distinguishing driver and passenger mutations, it may also be helpful to have tumor and normal genomic testing by assessing germ-line DNA obtained from blood or buccal smears to allow distinction of somatic variants from germ line. However, germ-line sequencing also presents issues including the need for informed consent, counseling, expertise to interpret germ-line

KEY POINTS

- Targeted gene capture panels are more commonly employed in clinical practice because of reduced costs and faster turnaround time.
- In addition to gene expression and fusions, RNA sequencing also facilitates the profiling of noncoding RNAs.
- Germ-line DNA testing can help distinguish somatic mutations from inherited variants but has logistic challenges.
- Tumor heterogeneity, discerning drivers from passenger mutations, and acquired resistance are potential challenges with developing genomics-driven targeted therapies.
- Genomic tumor sequencing can explain how some patients develop exceptional response to therapies and help further development of a therapy.

SIDEBAR 1. Pros and Cons for In-House versus Outsourced Cancer Genomic Testing

- Customizable gene panel content
- Access to quality metrics and variant frequencies
- Cost-effective in the long run
- Integration of reports into electronic health records
- Unified platform for clinical use and discovery

findings, and disclosure.[12] This requires substantial resources and time and limits the broader use of germ-line tissue in oncology practices. Consequently, most commercial vendors offer tumor only testing.

STRATEGIES FOR MOLECULAR PROFILING

Whole-genome sequencing offers the most comprehensive strategy for tumor genomic analysis; however, it is currently limited in its clinical applicability because of cost and turnaround time for sequencing and analysis. Therefore, strategies that incorporate targeted gene sequencing are preferred for clinical applications, reducing cost, and offering a faster turnaround time. Nonetheless, since these panels test for select genes, they may miss opportunities for discovery that are afforded by other intermediate approaches, such as whole exome and transcriptome sequencing, which focuses on the expressed components of the genome.

Targeted DNA Sequencing

Although comprehensive approaches are necessary to achieve a complete genomic characterization of a patient's tumor, many clinical laboratories have employed targeted DNA sequencing approaches as a practical alternative.[7,13-15] Targeted sequencing of hundreds of genes selected according to their relevance to cancer enables cheaper and higher-throughput molecular profiling of patients' tumors and incurs more manageable computational requirements with regard to data storage and analysis. Further, the deeper sequence coverage afforded by targeted sequencing can result in increased detection sensitivity for mutations in heterogeneous or low purity tumors. Consequently, large numbers of patients can be screened for genomic alterations, predicting response to approved and investigational targeted therapies, with high confidence that all clinically significant mutations will be detected.

Several products are available for capturing and sequencing genomic regions of interest—all compatible with FFPE tumor tissue. Target capture methods fall into two main classes: enrichment by amplification and enrichment by hybridization. Enrichment by amplification, or amplicon capture, relies on a highly multiplexed polymerase chain reaction involving locus-specific primer pairs simultaneously amplifying target regions in the genome. Amplicon capture can produce deep sequence coverage with very little DNA, but it is typically suitable only for a limited number of genes.

Further, amplicon capture methods may not be reliable for the detection of structural alterations such as copy number gains or losses and translocations. Panels based on amplicon capture often target hotspots of recurrent somatic mutations rather than the entire coding sequence of the genes and are typically coupled with benchtop DNA sequencers, such as the Illumina MiSeq and the Ion Torrent Personal Genome Machine. Enrichment by hybridization, or hybridization capture, utilizes synthetic DNA or RNA probes that bind to and enrich for complementary genomic DNA. Hybridization capture usually requires more input DNA than amplicon capture, but it can scale to a larger number of genes (up to the whole exome). Panels based on hybridization capture typically target all coding sequences of all genes and can be coupled with either benchtop or production sequencers, such as the Illumina HiSeq and the Ion Torrent Proton. Importantly, hybridization capture methods enable the accurate detection of copy number alterations and selected structural rearrangements.[16] Both amplicon and hybridization capture methods benefit greatly from the use of sample barcodes, which permit many tumors to be profiled in a single NGS run.

One of the most important decisions in the development of any cancer gene panel is what the content should be. Ideally the test will encompass all genes with "actionable" mutations that may affect a patient's treatment course. Additional genes may be considered if they have demonstrated biologic importance based on preclinical evidence. Custom panels afford the flexibility to target noncoding sequence, such as promoters and regulatory regions in the assay. By capturing introns of recurrently rearranged genes, it is possible to detect genomic breakpoints that produce gene fusions—many of which may be targeted by approved or experimental therapies. Ultimately, decisions about which and how many genes to sequence are best made by individual clinical laboratories according to their anticipated volume of cases, desired turnaround time and cost, and whether matched normal tissue is available for companion analysis.

RNA Sequencing in the Clinic

In addition to targeted DNA sequencing, RNA sequencing (RNAseq) can be supplemented by profiling the cancer transcriptome. RNAseq can provide data on gene expression, mutations, and gene fusions in cancer. Gene fusions have long been recognized as important in the oncogenesis of hematologic malignancies (e.g., *BCR-ABL1* fusion in chronic myeloid leukemia); however, these were not well studied in solid tumors until the advent of NGS. RNASeq can be utilized for detection of novel fusions at a fraction of the cost of whole-genome sequencing. This has resulted in the characterization of novel oncogenic fusions with matching targeted therapies across various tumors (e.g., *ALK, ROS1, RET* fusions in lung cancers).[17,18] Also, RNASeq can detect cryptic or novel translocations or gene fusions in leukemia that are not detectable by standard karyotyping or FISH.[19] Nevertheless, RNAseq sequencing remains expensive and not easily implemented in clinical labs. Therefore, strategies that utilize targeted RNASeq may be preferable for rapid turnaround

and reduced cost.[20] For example, Zheng et al implemented an anchored multiplex RNAseq strategy to detect selected gene fusions in cancer. For sarcomas, Qadir et al demonstrated the feasibility of targeted RNAseq to detect prototypic fusions, which could replace costly FISH assays and facilitate detection of novel fusions.[21] Several commercial and academic entities are developing additional clinical grade RNAseq strategies. Consequently, we anticipate a combination of DNA and RNA sequencing may have synergy as a clinical tumor sequencing strategy, incorporating data on DNA mutations and gene expression.

In addition to gene expression and fusions, RNASeq permits broader profiling of the cancer transcriptome, including detection of noncoding RNAs (ncRNA) such as microRNAs (miRNAs), small interfering RNAs, ribosomal RNAs, small nucleolar RNAs, and long noncoding RNAs. In fact, more than half of the cancer transcriptome consists of ncRNAs.[22] These ncRNAs have been shown to be important in multiple cellular processes, such as gene silencing, DNA replication, and regulation of transcription and translation.[23] Although the majority of these RNAs may not be applicable for clinical use, there is abundant potential for biomarker discovery and development. For example, miRNA profiling has been utilized to develop cancer-specific signatures that could be developed as diagnostic, early screening, prognostic, and treatment predictive biomarkers.[24] A commercially available test has been developed to help classify tissue of origin in patients with cancer of unknown primary. These tissue-of-origin tests assess miRNA signatures that were derived from miRNA profiling 20 to 40 cancer subtypes and can help clinicians identify favorable subsets for cancer of unknown primary that may lead to treatment decisions.[25,26] In another example, Sozzi et al developed a signature of miRNA from plasma of patients with lung cancer, and they are studying whether this test can improve accuracy of screening in combination with CT scans in a prospective screening study for lung cancer.[27] Thus, there is great potential for ncRNA-specific signatures to aid diagnostic dilemmas and potentially identify new treatment options as we learn more about ncRNA biology.

IMPLEMENTATION OF A CLINICAL SEQUENCING WORKFLOW
Challenges and Considerations

When developing clinical sequencing workflows, academic and commercial laboratories must confront many challenges. In contrast to the research setting, where large, high-purity, fresh-frozen tumors can be prioritized for analysis, clinical laboratories must be equipped to analyze specimens of all sizes and qualities. These may include small biopsies, fine-needle aspirates, or FFPE samples that are heterogeneous or admixed with normal tissue. Sequencing protocols must be optimized for low-quality specimens and low-input quantities and still deliver deep coverage sequence data for the reliable detection of mutations with low allele frequency. Further, laboratories must be able to deliver results with a

rapid turnaround time at a reasonable cost. The use of germ-line DNA from blood or healthy tissue as a normal control has major benefits for the analysis and interpretation of somatic mutations, but it creates logistic challenges involving tracking and transporting separate samples from the same patient. As multiple tumor samples from a given patient may occasionally be sequenced to monitor tumor progression and acquired resistance to therapy, flexible workflows are necessary to accommodate longitudinal analysis. Though the nature of these issues may vary for different laboratories depending on their throughput and sequencing platforms, they represent technical challenges common to all clinical laboratories.

Bioinformatics and analysis requirements collectively represent another important challenge in establishing a clinical sequencing workflow. The bioinformatics algorithms and software required to call different classes of genomic alterations (sequence mutations, insertions, deletions, copy number gains and losses, and structural rearrangements) are constantly evolving, and there remains no consensus on the best approach or standardized pipeline. Laboratories performing NGS have the choice of utilizing third-party software for data analysis, which can be costly and limits flexibility, or developing custom pipelines in-house, which requires considerable time and expertise to build and maintain. Either way, a significant informatics infrastructure is needed to manage, store, and archive the data generated by the sequencing instruments and the results produced by bioinformatics pipelines. Access to high-performance computing resources for processing and analyzing sequence data is required. Laboratory information management systems and associated databases are typically also needed to track samples, experiments, and results. For hospitals and clinical laboratories that have not traditionally employed many computational biologists and software engineers, the recruitment and training of bioinformatics staff is challenging yet essential.

Regulatory requirements, including the up-front analytic and clinical validation of assays, must also be met in any clinical sequencing workflow. Clinical laboratories producing results that are returned to patients and used in treatment decisions are subject to legal obligations designed to ensure that tests are reproducible and adhere to high standards of sensitivity and specificity. Such labs, whether commercial or academic, must be compliant with the CLIA, under the oversight of the Centers for Medicare & Medicaid Services. Accordingly, extensive documentation and technical validation of diagnostic assays are a requirement for patient testing and subsequent billing to insurance companies and Medicare. The model that some institutions have adopted wherein large-scale sequencing is performed in research labs, followed by confirmation in CLIA-compliant labs, is unsustainable over the long-term if the costs of NGS cannot be recovered through reimbursement.

To achieve maximum clinical benefit from a diagnostic sequencing assay, results must be reported to clinicians in a clear and easily digestible way, yet with all supporting information necessary to interpret the significance of the collection of genomic alterations that were detected.[28] The interpretation of results is frequently dependent on tumor type and other clinical factors and must be considered in that context. Also, although the goal is to identify actionable driver mutations, clinical sequencing assays typically turn up far more passenger mutations with unclear biologic and clinical significance. This is especially true in tumors with a high background mutation rate because of environmental exposures or abnormalities in DNA mismatch repair. It can be very difficult for a clinician to distinguish between key driver alterations that should affect treatment and passenger mutations with no apparent significance. Many academic cancer centers have created genomic or molecular "tumor boards" to collectively discuss and interpret challenging cases and recommend a course of action that the treating physician can take.[4,29] As this process does not easily scale to accommodate the large number of tumors being sequenced today, groups have attempted to curate and codify biologic and clinical information about mutations into databases that can be queried or utilized to annotate molecular diagnostic reports.[9,30] These "knowledge bases" must be granular enough to account for the fact that different sequence variants in the same gene may have opposite effects, and the same variant in different tumor types may have different clinical consequences. They should also enable the enumeration of clinical trials that might be beneficial to the patient, given their molecular profile. Nevertheless, no knowledge base is comprehensive or will ever include information on all possible alterations that a sequencing assay may reveal. Further, the co-occurrence of multiple driver mutations may have implications that cannot be inferred from the functions or clinical consequences of each individual mutation alone.

With the exception of targeted panels focused on mutational hotspots, germ-line DNA is typically used as a normal control to distinguish somatic mutations from inherited variants. In the absence of germ-line DNA, variants identified from tumor sequencing must be filtered according to databases of common single nucleotide polymorphisms. This can lead to false-positive mutation calls at sites of rare inherited single nucleotide polymorphisms, including cancer susceptibility alleles. The inclusion of germ-line DNA enables somatic mutations to be unambiguously called; yet it also enables the detection of pathogenic variants in the genes that are sequenced. This has considerable ethical and logistic implications. Incidental findings may emerge as a result of tumor sequencing that relate to a patient's inherited susceptibility to cancer or other diseases, with unanticipated yet significant consequences for family members who share these variants.[31,32] At present, tests specifically designed to search for inherited genetic variants typically require that patients sign informed consent and are properly educated of the benefits and risks of the test by a genetic counselor. For laboratories setting up large-volume tumor sequencing initiatives, individual pretest genetic counseling of all patients may be untenable. Computational subtraction of germ-line variants during mutation calling may circumvent the requirement for

TABLE 1. Commercial Targeted DNA Tumor Sequencing

Vendor	Name	No. of Genes	Results	Time
Foundation Medicine	Foundation One	315 (plus introns from 28 genes)	SNVs, CNVs, fusions	12-14 days
Caris Life Sciences	MI Profile	46	Hotspot mutations	14 days
ParadigmDx	PCDx	114	SNVs, CNVs, fusions	4-5 days
ARUP Labs	Solid Tumor Mutation Panel	48	Hotspot mutations	14 days
PathGroup	SmartGenomics	35	Hotspot mutations	7-10 days
Knight Diagnostic Labs	GeneTrails Cancer Gene Panel	38	Hotspot mutations	10-14 days
Life Technologies	Pervenio Lung NGS Assay	25	SNVs, fusions	7 days

Abbreviations: SNV, single nucleotide variation or point mutation; CNV, copy number variation; NGS, next-generation sequencing.

pretest counseling, but it also has the consequence that inherited variants with potential clinical significance are willfully disregarded.[33] Regardless of the circumstances, when an inherited predisposition to cancer (or another disease) is discovered, care must be taken to ensure the privacy and autonomy of patients and their families and to help manage the emotional and psychologic consequence of such a diagnosis.

As discussed above, the sustainability of clinical NGS initiatives depends on reimbursement from insurance companies and Medicare. However, at present, molecular diagnostic testing is only reimbursed in a small number of tumor types where there are approved drugs whose administration depends on a positive or negative test result and where there are clear clinical guidelines mandating the use of molecular testing. Examples include lung adenocarcinoma, colorectal cancer, and melanoma. In other tumor types where comparable guidelines do not exist, more data are needed to determine the clinical utility of NGS-based molecular profiling. As a result, large academic cancer centers are investing considerable philanthropic and other institutional funds into clinical sequencing of nonbillable tumor types. Demonstrating the clinical utility of tumor sequencing across additional cancer types is essential to ensure greater reimbursement and promote broader access to testing outside of the largest centers. A related issue emerges when actionable mutations are detected in unexpected tumor types, and insurance companies are not always willing to reimburse the cost of the drug for an off-label indication. The emergence of molecularly guided clinical trials encompassing multiple tumor types, or "basket" clinical trials, may help some patients in this situation.

In-house versus Outsourcing

With all of these challenges inherent to the establishment of clinical sequencing infrastructure, it is tempting for academic cancer centers and community oncology practices to outsource the entire process to a commercial reference laboratory. For many centers, this may be the best decision given financial, volume, and staffing considerations. However, there are many advantages to setting up these processes in-house that can justify the effort and expense from an institutional perspective (Table 1).

First, developing and validating a tumor sequencing test in-house gives the laboratory ultimate control over the content of the assay. Panels can be designed to include targets of all clinical trials open within the institution as well as genes and noncoding regions suggested by preclinical research studies. Further, as new clinical knowledge emerges and new clinical trials are developed, additional genes and biomarkers can rapidly added. Second, the laboratory and collaborating investigators will have access to all raw data, including sequence quality metrics and mutation allele frequencies, which one would not expect to receive from an outside provider. This can enable the development of custom bioinformatics pipelines to explore additional features of the data such as tumor heterogeneity and clonal evolution, and the reanalysis of data as new tools and algorithms are created. Importantly, data access will also facilitate data mining initiatives through integration of clinical and phenotypic data for the patients whose tumors were sequenced. Third, though the establishment of clinical NGS tests requires a large upfront investment, it may ultimately lead to lower costs than commercial providers will offer, especially for large-volume laboratories. Additionally, as discussed above, institutions can use philanthropic and institutional funds to pay for nonbillable tests that will produce data to possibly justify reimbursement in the future. Fourth, analysis results and molecular reports can be integrated directly with the hospital information systems. This can facilitate rapid reporting, deposition into institutional databases, and the screening and selection of patients for clinical trials. As clinical trials in oncology increasingly require the presence of particular (often rare) genomic alterations, an institutional molecular database can help identify the patients that meet all eligibility criteria and are most likely to benefit from a new drug. Fifth, the same test that is validated and approved for clinical use can also be used to retrospectively analyze archived tumors, such as those obtained from "exceptional responders," for research purposes.[34,35] This allows data from a single platform to be merged and mined with greater power to discover biomarkers that correlate with clinical outcomes and/or response or resistance to therapy. It also provides additional flexibility to further develop and optimize the assay for other types of specimens, such as cell-free DNA from plasma or cerebrospinal fluid.

IMPACT OF CANCER GENOMIC TESTING IN THE CLINIC

Although the availability of cancer genomic testing in the clinic has led to opportunities in oncology such as drug target discovery, it has also led to challenges including how to develop targeted therapies for small populations of patients with rare mutations. For example, in contrast to the frequency of *ERBB2* amplification in breast cancer and *BRAF* mutations in melanoma (20% and 45%, respectively), the majority of actionable genomic alterations revealed by clinical tumor sequencing typically occur at frequencies of 2% to 5%. This has raised several challenges for delivering treatment to patients and developing novel therapies in clinical trials.

For example, cancer genomic sequencing enabled discovery of novel activating somatic point mutations the *ERBB2* gene in patients with breast cancer who were negative for *ERBB2* gene (HER2) amplification, but these mutations are only found in 1% to 2% of patients with breast cancer.[36] In vitro studies demonstrated that these activating mutations conferred resistance to reversible inhibitor lapatinib but were sensitive to neratinib, an irreversible *ERBB2* inhibitor.[36] This has led to a phase II study of neratinib for patients with metastatic *ERBB2*-mutant breast cancer.[2] Although this strategy appears rational for a disease- and mutation-specific trial, moving forward for other uncommon genomic alterations within a single tumor type, typical large randomized phase III trials will not be pragmatic for each disease and each mutation subset. Meanwhile predictive biomarker selection has led to exceptional tumor responses to matching therapies, and phase II trials may provide convincing evidence of clinical activity and benefit.[37-39] The low prevalence of actionable oncogenic mutations has led to the evolution of "basket trials." Unlike a conventional tumor histology–based clinical trial, patient selection is based on a specific genomic alteration and not on tumor type.[40] This is different from BATTLE or I-SPY trials in which adaptive design is utilized to enrich patients into specific molecular cohorts based on initial efficacy results, while restricted to a single tumor type. Presently, basket trial approaches will unlikely lead to regulatory drug approval in a specific tumor type, but they help assess whether all or selected cancer types with specific genomic alterations (e.g., *FGFR, BRAF*) would indeed respond to a matching targeted therapy, and they help consider other endpoints, such as magnitude of response, duration of responses, and the study of novel predictive biomarkers for sensitivity and resistance.[41] Finally, basket trials enable enrollment of multiple tumor types and facilitate patient accrual for both rare cancers and genomic alterations.

In addition to prospective trials, cancer genomic testing may help us understand clinical responses retrospectively based on patients who have exceptional responses to therapy. Iyer et al observed a complete, durable response of more than 2 years in a single patient with metastatic bladder cancer with everolimus treatment on a clinical trial that did not meet its primary endpoint. They performed whole-genome sequencing of the tumor, which revealed a mutation in *TSC1*, a gene involved in the mTOR pathway. They subsequently demonstrated a basis for clinical response to everolimus, an mTOR inhibitor.[34] Similarly, whole-exome sequencing on a patient with metastatic anaplastic thyroid cancer, who had an exceptional response to everolimus, identified a mutation in *TSC2*, a negative regulator of the mTOR pathway.[42] These individual patients highlight an application of genomic sequencing to understand how we can learn from exceptional responders to guide further development of targeted therapies. The National Cancer Institute and academic cancer centers are actively seeking to apply this approach in ongoing clinical trials across the country to guide drug development based on novel predictive biomarkers.

Finally, as we learn to identify the correct genomic alteration that can predict response to a therapy, we must also prospectively consider how cancers become resistant to therapy. Although targeted therapies may lead to remarkable initial responses for patients with selected biomarkers, metastatic cancers inevitably acquire resistance. NGS has been utilized to characterize mechanisms of secondary resistance to identify potential combinatorial therapies that can prevent or delay emergence of resistance. Wagle et al performed NGS in a patient with metastatic melanoma who developed resistance to vemurafenib after showing initial response. They identified an acquired mutation in *MEK1,* conferring resistance to RAF or MEK inhibition.[43] Tumor sequencing has also helped identify resistance mechanisms in long-established therapies, such as estrogen blockade in breast cancer, where ligand-binding domain mutations in *ESR1* (the estrogen receptor) mediate acquired resistance to antihormonal therapy.[44,45] Similarly, whole-exome sequencing has been utilized to study acquired resistance to the recently approved BTK inhibitor ibrutinib in relapsed chronic lymphocytic leukemia and has identified a mutation in *BTK* that limits drug binding.[46]

CONCLUSION

Although the application of clinical tumor sequencing has enabled identification of actionable genomic alterations that could provide molecular eligibility to matching targeted therapies, clinical application and interpretation does have some challenges. Intratumor heterogeneity, discerning drivers from passenger mutations, lack of sustained response, and acquired resistance to targeted therapies are some of the issues that limit the potential of genomics-driven targeted therapies. Further, responses to targeting tend to vary across tumors and within a tumor depending on the treatment context. Biopsies at multiple time points, rational combination therapies, and basket trial designs can help address some of these issues. As oncology is migrating to a more molecularly matched therapy paradigm, a strong collaboration between basic scientists, molecular pathologists, bioinformaticians, and oncologists is paramount in an effort to identify novel cancer therapies that lead to improvement in patient survival.

Clinical Trials of Precision Medicine through Molecular Profiling: Focus on Breast Cancer

Dimitrios Zardavas, MD, and Martine Piccart-Gebhart, MD, PhD

OVERVIEW

High-throughput technologies of molecular profiling in cancer, such as gene-expression profiling and next-generation sequencing, are expanding our knowledge of the molecular landscapes of several cancer types. This increasing knowledge coupled with the development of several molecularly targeted agents hold the promise for personalized cancer medicine to be fully realized. Moreover, an expanding armamentarium of targeted agents has been approved for the treatment of specific molecular cancer subgroups in different diagnoses. According to this paradigm, treatment selection should be dictated by the specific molecular aberrations found in each patient's tumor. The classical clinical trials paradigm of patients' eligibility being based on clinicopathologic parameters is being abandoned, with current clinical trials enrolling patients on the basis of specific molecular aberrations. New, innovative trial designs have been generated to better tackle the multiple challenges induced by the increasing molecular fragmentation of cancer, namely: (1) longitudinal cohort studies with or without downstream trials, (2) studies assessing the clinical utility of molecular profiling, (3) master or umbrella trials, (4) basket trials, (5) N-of-1 trials, and (6) adaptive design trials. This article provides an overview of the challenges for clinical trials in the era of molecular profiling of cancer. Subsequently, innovative trial designs with respective examples and their potential to expedite efficient clinical development of targeted anticancer agents is discussed.

Personalized medicine is defined by the National Cancer Institute (NCI) as "a form of medicine that uses information about a person's genes, proteins and environment to prevent, diagnose and treat disease."[1] In oncology, this is a dynamically evolving field, with an increasing list of molecular markers from tumor tissue dictating the treatment selection of patients with several cancer diagnoses (Table 1). In the setting of breast cancer, personalized medicine was first exemplified with the introduction of hormone receptor (HR) assessment and the subsequent use of endocrine treatment changing the natural history of HR-positive breast cancer.[2] Interestingly, the first clinical trials demonstrating clinical benefit deriving from the use of tamoxifen in the setting of breast cancer were performed for all cancers, irrespective of HR positivity.[3,4] As a result of the high frequency of this overexpression in breast cancer, efficacy signals were captured even within this unselected patient population.

On the contrary, the success story of trastuzumab for patients with HER2 positivity, defined as protein overexpression and/or gene amplification, used a different route: the respective clinical trials in both metastatic and early-stage disease recruited exclusively patients with HER2-positive breast cancer.[5,6] Subsequent studies assessing other HER2 blocking agents have been conducted within this particular molecular niche of breast cancer, for which four different tar-

geted agents have been approved at present.[7] Other tumor entities provide similar examples of how molecular preselection of patients for study enrolment can accelerate efficient clinical development of molecularly targeted agents. In the case of non–small cell lung cancer (NSCLC), the IPASS (Iressa Pan-Asia Study) study randomly assigned 1,217 unselected patients with previously untreated advanced disease to receive gefitinib or carboplatin/paclitaxel. In the final analysis performed according to epidermal growth factor receptor (EGFR) biomarker status, it was reported that progression-free survival (PFS) was significantly longer with gefitinib for patients whose tumors had both high *EGFR* gene copy number and EGFR mutation (hazard ratio [HR], 0.48; 95% CI, 0.34 to 0.67, p < 0.001) but significantly shorter when high *EGFR* gene copy number was not accompanied by *EGFR* mutation (HR, 3.85; 95% CI, 2.09 to 7.09, p < 0.001).[8] This finding confirmed the previously established knowledge that administration of EGFR-blocking agents should be dictated by the presence of *EGFR* mutations in NSCLC.

In the setting of breast cancer, multiple oncogenic signaling pathways have been identified as promoters of the malignant progression with numerous aberrations, such as mutations and/or copy number variations affecting their molecular components. Such pathways operate in (1) bulk tumor cells, (2) a subset of tumor initiating cells, and/or (3)

TABLE 1. Molecular Aberrations Defining Administration of Approved Targeted Agents in Different Solid Tumor Diagnoses

Cancer Type	Molecular Target	Aberration	Method of Assessment	Approved Targeted Agent
Breast Cancer	ER	Overexpression	IHC	Tamoxifen
				AIs
				Fulvestrant
	PgR	Overexpression	IHC	Tamoxifen
				AIs
				Fulvestrant
	HER2	Overexpression and/or amplification	IHC	Trastuzumab
				Pertuzumab
			FISH	Lapatinib
				T-DM1
Colorectal Cancer	KRAS*	Mutation	DNA	Cetuximab
				Panitumumab
Gastric Cancer	HER2	Overexpression and/or amplification	IHC	Trastuzumab
			FISH	
GIST	KIT	Mutation	IHC	Imatinib
Melanoma	BRAF	Mutation	DNA	Vemurafenib
				Dabrafenib
Non-Small Cell Lung Cancer	EGFR	Mutation	DNA	Gefitinib
				Erlotinib
	ALK	Rearrangement	FISH	Crizotinib
	RET	Rearrangement	FISH	Vandetanib
	ROS	Rearrangement	FISH	Crizotinib

Abbreviations: AI, aromatase inhibitor; ALK, anaplastic lymphoma kinase; EGFR, epidermal growth factor receptor; ER, estrogen receptor; FISH, fluorescent in situ hybridization; GIST, gastrointestinal stromal tumor; HER2, human epidermal growth factor receptor 2; IHC, immunohistochemistry; PgR, progesterone receptor; T-DM1, trastuzumab DM1.
*KRAS mutations predict lack of benefit derived from EGFR-blocking agents.

the tumor microenvironment. An expanding arsenal of targeted agents is currently under clinical development, aiming to block specific molecular aberrations[9] ; however, the extended tumor heterogeneity seen poses impediments to their success.[10] The increasing number of targeted agents warranting clinical assessment, coupled with the increasing molecular fragmentation of breast cancer and thus the respective decrease in prevalence of putative predictive biomarkers, render the current clinical trial paradigm inefficient. New study designs are needed to facilitate the successful clinical development of targeted agents within specific molecular niches of breast cancer.[11]

KEY POINTS

- The success stories of trastuzumab and endocrine treatment for patients with HER2-positive and hormone receptor-positive breast cancer exemplify the potential of personalized cancer medicine.
- High-throughput molecular profiling techniques reveal the extensive molecular diversity of breast cancer, leading to an increased molecular fragmentation.
- There is an increasing number of targeted agents that need to be assessed in the setting of breast cancer.
- Clinical assessment of targeted agents within small molecularly defined breast cancer segments poses challenges to the design and conduct of clinical trials.
- New, innovative study designs are being introduced to overcome these challenges.

MOLECULAR PROFILING IN BREAST CANCER

The advent of gene-expression profiling analysis led to the identification of four intrinsic subtypes of breast cancer, associated with different prognostication and sensitivity profiles to treatment,[12] namely: (1) luminal A, being HR-positive with low proliferation rates, (2) luminal B, HR-positive with higher proliferation rates, (3) HER2-like, characterized by amplification of the *ERBB2* gene as well as other genes in the same amplicon, and (4) basal-like, largely showing a triple phenotype with lack of expression of estrogen receptor, progesterone receptor, and HER2. Of note, these subtypes show distinct molecular profiles, as indicated by studies that coupled gene expression profiling with genome copy number analysis.[13,14] Subsequent studies, implementing this powerful technique to larger collections of primary breast tumors, have led to further molecular fragmentation of this common

TABLE 2. Approaches of Next-Generation Sequencing

Approach	Advantages	Disadvantages
Whole-Genome Sequencing	· Potential for identification of previously unrecognized cancer related genes and aberrations · More efficient interrogation of structural variations	· Higher costs · Longer turnaround time · Laborious bioinformatics work · High storage capacity needed · Challenging clinical interpretation/reporting · Low reproducibility of FFPE tumor material analysis
Targeted Sequencing	· Lower costs	· Limited potential for identification of previously unrecognized cancer-related genes
Whole-Exome Sequencing	· Shorter turnaround time	· Reduced capacity to interrogate of structural variations
Targeted Gene Sequencing	· Easier data interpretation · Lower data storage capacity needed · Easier clinical interpretation/reporting · Ready to be used for FFPE	

disease. An integrated analysis of almost 2,000 primary breast cancers combining copy number and gene expression data from the METABRIC (Molecular Taxonomy of Breast Cancer International Consortium) group revealed a total of 10 different subgroups with distinct prognoses.[15] Further molecular classes have been identified within basal-like breast cancerbreast cancer, such as: (1) the claudin-low tumors characterized by a gene expression profile similar to that of mammary stem cells and mesenchymal features,[16] and (2) molecular-apocrine tumors characterized by expression of androgen receptor and consecutive downstream signaling.[17]

More recently, there have been studies employing next-generation or massively parallel sequencing (NGS and MPS, respectively) in breast cancer, expanding further our understanding of the underlying molecular heterogeneity.[18-22] NGS is a powerful molecular profiling tool, deciphering DNA sequences and informing us about a variety of different molecular aberrations, namely nucleotide substitution mutations, insertions and deletions, copy number variations, and structural rearrangements.[23] Importantly, the ability of NGS to quantify the allelic frequency of any mutational event captured enables the reconstruction of the clonal architecture of any given tumor sequenced.[24,25] These studies document the extensive intertumor heterogeneity of breast cancer, as exemplified by the study of Stephens et al, in which among the 100 sequenced breast cancers there were 73 different combination of possibilities of mutated cancer genes.[22] Additionally, a repetitive finding from these studies is that unlike some few commonly mutated cancer genes such as *TP53* and *PIK3CA*, most of the gene mutations are seen in less than 10% of the cases that are sequenced.[26,27] Last, the determination of the allelic frequencies indicates than not all mutated genes reported are of clonal nature, since some of them are found in a subclonal population of cancer cells.

There has been an increasing availability of NGS techniques to many investigators thanks to a steep decrease in the financial costs involved that surpassed to what Moore's law foresaw.[28] Currently, different applications of NGS are under use that could be summarized as follows: (1) Whole-genome sequencing (WGS), with the first whole cancer genome to be sequenced being that of a cytogenetically normal myeloid leukemia.[29] Subsequently, several studies have employed this approach in the setting of breast cancer.[22,30,31] However, the implementation of WGS in clinical practice has been questioned, since the use of archived formalin-fixed paraffin-embedded tumor material is problematic. Additionally, high computational power and delicate bioinformatic tools are needed for data interpretation, posing further challenges in the clinical implementation of WGS.[32] (2) Targeted sequencing, referring to either whole-exome sequencing, or targeted-gene sequencing, is conducted using panels of selected cancer-related genes. Such approaches have certain advantages (Table 2), such as shorter turn-around times, lower costs, and less laborious data interpretation; presently, they are available in several Clinical Laboratory Improvement Amendments (CLIA)– certified laboratories; however, there is a compromise in the ability to detect translocations and other structural rearrangements.[33]

INNOVATIVE CLINICAL TRIAL DESIGNS

Currently, there is an increasing use of the afore-mentioned molecular profiling for patients with breast cancer, in particular in the setting of high-volume academic institutions, where extended profiling programs are being developed, sometimes in a CLIA environment.[34] Such initiatives can be used to guide patients in clinical trials assessing targeted agents.[35] However, several challenges can be identified, in regard to the success of trials assessing such experimental anticancer compounds (Table 3). To address these ever more frequently met challenges, new transformative clinical trial designs are needed. In such innovative trials, eligibility is based on the genotype of breast cancer, rather than the classic clinic-pathologic characteristic of the disease (Table 4). These study designs hold the promise to reduce the high attrition rates seen in oncology drug development, as well as to keep the number of patients recruited in the respective trials at reasonable levels. To this end, several innovative study designs are being developed.

TABLE 3. Challenges Encountered in Current Clinical Trials Assessing Targeted Anticancer Agents and Proposed Mechanisms to Circumvent Them

Phenomenon	Consequence	Potential Solution
Intertumor heterogeneity	Molecular fragmentation of the disease	· Innovative study designs such as master protocols to reduce screening failures · Statistical tools to reduce sample sizes needed (e.g., relaxing type I error) · Revisiting regulatory pathways for approval
	· Increased costs for molecular profiling	· Risk-sharing strategies · Greater pharmaceutical industry participation
	· Variable functional output of different aberrations	· Functional validation · Well-characterized xenograft tumor models
Intratumor heterogeneity	· Need to assess multiple molecular aberrations from one tumor sample	· Multiplexed molecular profiling to reduce tissue requirements · "Liquid" biopsies/plasma-based molecular profiling
	· Increased costs for molecular profiling	· Risk-sharing strategies · Greater pharmaceutical industry participation
Clonal evolution	· Emergence of treatment resistance	· "Liquid" biopsies/plasma-based molecular profiling
	· Discordances of aberrations between primary and metastatic disease	· Longitudinal cohorts of patients with profiling of both primary and metastatic tumor tissue · Biopsies/plasma-based molecular profiling

Longitudinal Cohort Studies with or without Downstream Clinical Trials

This study design can be exemplified by the AURORA (Aiming to Understand the Molecular Aberrations in Metastatic Breast Cancer) program initiated by the Breast International Group.[36] This represents a collaborative effort of European hospitals to conduct large-scale molecular profiling of patients with metastatic breast cancer who are prospectively followed (Fig. 1). This molecular profiling, of one metastatic lesion and of the primary tumor, can support the conduct of genotype-driven "nested" or "downstream" clinical trials,[37] offering a dual benefit: (1) facilitate the molecular preselection of patients eligible to be enrolled in genotype-driven clinical trials and (2) identify potential predictive biomarkers, through the coupling of the molecular and clinical outcome data captured for the patients enrolled in such a program. An important additional benefit that can be expected through this approach is the fact that clinicians become familiarized to the reporting of genomic data. Furthermore, such programs can improve our knowledge of prognosis for molecularly defined subsets of cancer, through the prospective follow-up of patients for clinical outcome. An already completed initiative from this category is the SAFIR01 program that recruited 423 patients with metastatic breast cancer.[38] Patients were subjected to biopsy of metastatic site, with the tissue analyzed by comparative genomic hybridization as well as Sanger sequencing of the *PIK3CA* and *AKT1* genes. This study, with a primary endpoint of the proportion of patients that could be entered into trials of targeted agents, demonstrated that personalization of treatment for patients with this disease is feasible in clinical practice. A subsequent effort, SAFIR02, is currently recruiting patients with HER2-negative metastatic breast cancer who have received no more than one line of chemotherapy. Metastatic tissue from these patients will be analyzed by NGS; after six to eight cycles of cytotoxic chemotherapy, patients with no progression of their disease will be randomly assigned to receive the standard of care or targeted therapy according to a list of 51 molecular alterations.

Studies Assessing the Clinical Utility of Molecular Profiling

The advent of molecular profiling in cancer has generated another study design, which assesses the clinical utility of

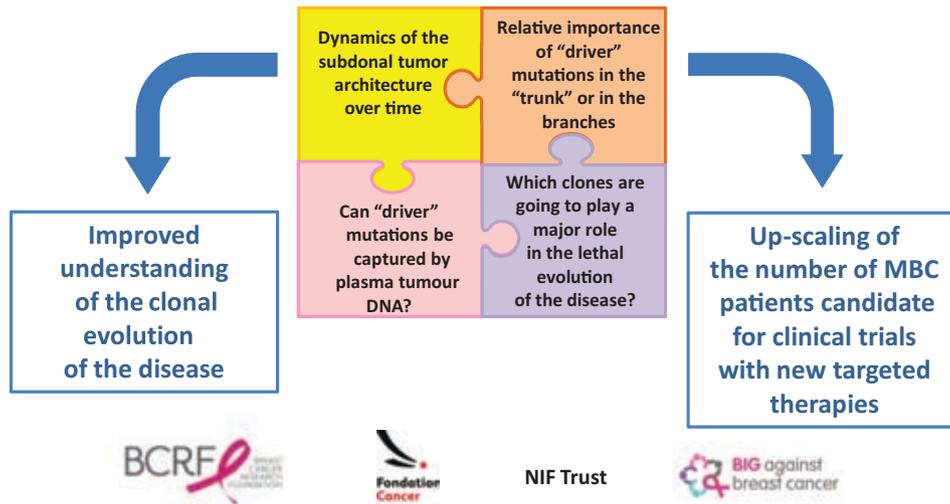
TABLE 4. Examples of Ongoing Genotype-Driven Clinical Trials in Breast Cancer

Clinicaltrials.gov Identifier	Phase (No. of Patients)	Genotype Targeted	Agent	Molecular Target	Design	Primary Endpoint
NCT01277757	II (40)	AKT mutations, PIK3CA mutations, PTEN loss	MK2206	AKT	Single-arm, monotherapy	ORR
NCT01219699	I (200)	PIK3CA mutations	BYL719	Alpha-isoform PI3K	Single-arm, BYL719 combined with fulvestrant	MTD
NCT01589861	I/II (106)	PIK3CA mutations, PTEN loss	BKM120	All isoforms PI3K	Single-arm, BKM120 combined with lapatinib	MTD, ORR
NCT01670877	II (29)	ERBB2 mutation	Neratinib	EGFR/HER2/HER4	Single-arm, monotherapy	CBR

Abbreviations: CBR, clinical benefit rate; EGFR, epidermal growth factor receptor; MTD, maximum tolerated dose; ORR, objective response rate; PI3K, phosphatidylinositol-4,5-bisphosphate 3-kinase; PTEN, phosphatidylinositol 3,4,5-trisphosphate 3-phosphatase.

FIGURE 1. The AURORA Initiative for Metastatic Breast Cancer

The AURORA Program

A prospective, longitudinal study of 1,300 women with Metastatic Breast Cancer recruited at 81 centers across 15 European countries


choosing targeted therapeutics based on the molecular profiling as compared with conventional treatment. This design does not assess individual targeted agents and should be therefore perceived as proof of concept. Tsimberidou et al reported promising results from a nonrandomized, phase I clinical trials program, according to which tumor tissue from patients with several advanced solid tumors diagnoses (1,144 tumors) were analyzed by molecular profiling: disease in patients having one molecular aberration who were treated based on the genotype of their disease (175 patients) demonstrated an increased overall response rate (27% vs. 5%; p < 0.0001), longer time-to-treatment failure (5.2 months vs. 2.2 months; p < 0.0001), and longer overall survival (13.4 vs. 9.0 months; p = 0.017) compared with patients who received conventional treatment (116 patients).[35] Currently, there is an ongoing randomized, proof-of-concept, phase II trial comparing targeted therapy based on tumor tissue molecular profiling compared with conventional treatment for patients with several advanced cancer types called SHIVA (NCT01771458).[39] This study incorporated a feasibility part, which demonstrated the feasibility and safety of incorporating biopsy of metastatic disease for the first 100 patients who enrolled.[40]

Master-Protocol Trials

This study design can assess different targeted agents in parallel within independent cohorts of patients defined by specific molecular aberrations that could predict sensitivity to the investigational agent under assessment. This approach reduces the percentage of screening failures, since patients with different aberrations can be enrolled in one of the different molecularly-defined cohorts. An important effort using this approach, recently initiated by the NCI, is the master protocol for second-line treatment of squamous NSCLC. An important effort using this approach recently initiated by the NCI is the master protocol for second-line treatment of squamous NSCLC. This trial will evaluate targeted agents matched to specific molecular segments of this type of cancer, with frequencies ranging between 9.3% and 20%. This is an initiative that aims to establish a novel approach to the clinical development of targeted agents and their subsequent regulatory approval, according to which treatment selection will be based on the results of NGS from a panel of approximately 250 cancer-related genes.[41] The study design that has been incorporated has five study strata with a total of 10 treatment arms; within each stratum a phase II/III study design has been adopted, with specific thresholds of efficacy that have to be met before moving to the phase III component. An important aspect of this trial that is currently recruiting patients is its collaborative nature, with multiple major partners working together, including the Southwestern Oncology Group, NCI, the Foundation for the National Institutes of Health, the Friends of Cancer Research, and the U.S. Food and Drug Administration. In the setting of breast cancer, the Breast International Group currently is designing such a study with input from the North American Breast Cancer Group, assessing targeted agents for patients with aggressive metastatic

triple-negative breast cancer. In particular, patients with this breast cancer phenotype whose disease develop early systematic relapse will be eligible. Once metastatic tumor tissue has been analyzed by NGS and upon availability of these results, the patients will be entered into one of multiple parallel, molecularly-driven arms, randomly assigned between the standard of care or the respective targeted agent(s), dictated by the genotype of their disease.

Basket Trials

This is an innovative, histology-independent trial design, in which patients with cancer diagnoses of different histologies can be enrolled in the study protocol based on the presence of a specific molecular aberration. There is an ongoing clinical trial that aims to develop a small molecule HER2 blocking agent for patients with *ERBB2*-mutated cancers that exemplifies this approach.[42] The main disadvantage in this innovative design is a biology-driven one; in particular this is the issue of the potentially different functional outputs that a specific molecular aberration could have among different types of cancer. This has been reported in studies documenting lack of antitumor efficacy of vemurafenib, a *BRAF* small molecule inhibitor, in the setting of *BRAF*-mutated metastatic colorectal cancer; these findings are in direct contradiction with the dramatic antitumor activity seen among patients with metastatic melanoma bearing the V600E *BRAF* mutation.[43] A major advantage of this study design is that it is very informative about which are the tumor types where single-agent therapy is worth pursuing in phase III trials versus other types where combination treatment strategies should be prioritized. Interestingly, there is an ongoing study by the NCI, called MATCH (Molecular Analysis for Therapy Choice) that combines elements from both master and basket trial design. In particular, this trial will assess molecularly targeted agents within specific molecular niches of cancer types such as erlotinib for EGFR-mutated NSCLC and crizotinib for cases with EML4-ALK translocations (master-trial component), as well as across different tumor types sharing a molecular aberration, e.g., vemurafenib in BRAF-mutated melanoma, thyroid cancer, and NSCLC (basket-trial component).

Adaptive Trials

Adaptive trials represent another transformative study design, recently exemplified by the BATTLE (Biomarker-Integrated Approaches of Targeted Therapy for Lung Cancer Elimination)-1 and -2 clinical trials, focusing on patients with metastatic NSCLC,[44] or the I-SPY (The Investigation of Serial Studies to Predict Your Therapeutic Response with Imaging and Biomarker Analysis) 1 and 2 trials conducted in the neoadjuvant setting of breast cancer.[45-47] These are dynamically evolving trials, with the particular aspect of during the initial phase of the adaptive study patients are recruited in the different arms at an equal ratio; however, as more patients are enrolled and efficacy data are being generated and pooled from the different treatment arms, the adaptive phase follows. During this second, adaptive phase, randomization ratios can be changed and treatment arms can be dropped

and/or added, in cases where either predefined thresholds of efficacy are not reached or new promising data for new compounds emerge, respectively.[48] Additionally, in trials having an adaptive design, the biomarker selection strategy can be changed, even when the treatment assignment remains the same, depending on emerging evidence associating new biomarkers not previously identified with (lack of) sensitivity to one or more of the treatments under assessment.

N-of-1 Trials

This is a study design that has been more frequently employed in fields of clinical research other than oncology, such as trials conducted for patients with musculoskeletal or pulmonary conditions.[49,50] The defining characteristic is the recruitment of patients exposed to different experimental agents or placebo in different sequencing, with washout periods in between.[51] This type of design practically renders each involved patient to serve as his or her own comparator, through the comparison of the efficacy seen for the different experimental agents that the patient receives. In oncology, a modified N-of-1 study design has been performed, which assessed the antitumor activity of different anticancer compounds matched to the genotype of the patients.[52] This trial recruited 86 patients with different types of advanced tumor who had been heavily pretreated, that had molecular profiling. Sixty-six of these patients were treated according to these results. Concerning the efficacy, 18 patients had a PFS ratio of 1.3 or higher (95% CI, 17% to 38%; one-sided, one-sample $p = 0.007$). The study met its primary endpoint, which was the comparison of PFS obtained by the targeted treatment with the PFS achieved by the previous systemic treatment within each individual patient. This is an approach that could be of help for molecular aberrations of really low prevalence, where randomized studies are extremely challenging.

Window-of-Opportunity Trials

Window-of-opportunity trials incorporate a design assessing the administration of an investigational agent over a short period of time, most often in the presurgical setting allowing serial tumor biopsies, though such studies can be conducted in the metastatic setting as well.[53,54] These trials do not have an efficacy endpoint, since it is the in vivo biologic effects of an experimental agent and not the antitumor activity with officially predefined measures of outcome that they aim to assess. An ongoing study utilizing this innovative design is the D-beyond trial, a preoperative window study evaluating denosumab, a RANK ligand inhibitor, and its biologic effects for premenopausal women with early breast cancer.[55] Patients entering this trial receive preoperatively two doses of 120 mg of denosumab subcutaneously 1 week apart that will be followed by surgery. Ten to 21 days after the first administration, surgical excision of the primary tumor will take place; the primary objective is the antiproliferative effect exerted by denosumab, as indicated by Ki67 immunohistochemistry-based assessment. Another example of a window-of-opportunity trial that will soon be initiated is the RHEA (Biomarker Research Study for PF-03084014 in

Chemoresistant Triple-Negative Breast Cancer) trial. This is a single-arm, phase II, open-label, preoperative study of a small-molecule NOTCH inhibitor that is administered for 9 days after completion of neoadjuvant chemotherapy in patients with triple-negative breast cancer that is chemotherapy-resistant.

CONCLUSION

To the present day, great progress has been made in the molecular profiling of breast cancer, with an expanding array of molecular aberrations being identified. The subsequent development of experimental targeted agents promises to improve cancer treatment for patients bearing specific molecular aberrations. A major challenge is the assessment of the functional significance of such aberrations and the verification of their relevance as predictors of sensitivity to their matched targeted agents under development. The latter can be achieved through well-conducted clinical trials that match several specific genotypes of the disease with a number of targeted agents. To this end, innovative study designs must be implemented to expedite anticancer drug development. Such studies need to be coupled with next-generation molecular profiling techniques that have been validated to secure findings' reproducibility. The one-size-fits-all paradigm of conventional study design must be abandoned, and the approval strategies revisited in some cases. More extensive collaboration between academia around the world, regulatory agencies, and pharmaceutical companies developing new anticancer compounds is becoming a necessity for these innovative study designs to be successfully implemented.

Managing Immune Checkpoint-Blocking Antibody Side Effects

Michael A. Postow, MD

OVERVIEW

Immune checkpoint-blocking antibodies that enhance the immune system's ability to fight cancer are becoming important components of treatment for patients with a variety of malignancies. Cytotoxic T-lymphocyte–associated antigen 4 (CTLA-4) was the first immune checkpoint to be clinically targeted, and ipilimumab, an inhibitor of CTLA-4, was approved by the U.S. Food and Drug Administration (FDA) for patients with advanced melanoma. The programmed cell death-1 (PD-1) receptor and one of its ligands, PD-L1, more recently have shown great promise as therapeutic targets in a variety of malignancies. Nivolumab and pembrolizumab recently have been FDA-approved for patients with melanoma and additional approvals within this therapeutic class are expected. The use of anti-CTLA-4 and anti-PD-1/PD-L1 antibodies is associated with side effects known as immune-related adverse events (irAEs). Immune-related adverse events affect the dermatologic, gastrointestinal, hepatic, endocrine, and other organ systems. Temporary immunosuppression with corticosteroids, tumor necrosis factor-alpha antagonists, mycophenolate mofetil, or other agents can be effective treatment. This article describes the side-effect profile of the checkpoint-blocking antibodies that target CTLA-4 and PD-1/PD-L1 and provides suggestions on how to manage specific irAEs.

The immune system plays an important role in controlling and eradicating cancer. Recently, strategies that enhance T-cell function by blocking negative regulatory components on T cells, which are called checkpoints, have led to remarkable success for patients with many different malignancies. CTLA-4 was the first T-cell checkpoint to be clinically targeted. Ipilimumab, an anti-CTLA-4 antibody, was approved by the FDA for patients with advanced melanoma based on an overall survival benefit.[1,2] A second immunologic checkpoint, known as PD-1, and its predominant ligand, PD-L1, also is demonstrating incredible promise as a therapeutic target. Nivolumab and pembrolizumab (anti-PD–1 blocking antibodies) have been FDA-approved for patients with advanced melanoma.[3,4] Nivolumab and pembrolizumab, and additional antibodies that target the PD-1 axis, are also effective in additional cancers such as non-small cell lung cancer, renal cell cancer, bladder cancer, and Hodgkin lymphoma.[5-9]

Although these antibodies can be associated with substantial benefits, by increasing immune system function, immune-checkpoint blockade can lead to inflammatory side effects called immune-related adverse events (irAEs). Immune-related adverse events can affect any organ system, but they typically involve the skin, gastrointestinal, hepatic, and endocrine systems. Temporary use of immunosuppressive medications can suppress these side effects without eliminating the possibility of a favorable antitumor response.

This review focuses on irAEs associated with antibodies that block the immunologic checkpoints, CTLA-4 and PD-1, including antibodies that block the ligand of PD-1/PD-L1. These agents have been studied most extensively in patients with melanoma, and experience and recommendations are based primarily on data obtained from studies involving patients with melanoma. Nevertheless, the principles of irAE recognition and management are relevant across the oncologic spectrum and will become increasingly important as the use of these antibodies expands.

SPECIFIC TYPES OF IMMUNE-RELATED ADVERSE EVENTS AND MANAGEMENT
Rash and Mucosal Irritation

The most common and typically earliest onset (Fig. 1) irAE associated with checkpoint inhibitors is dermatologic toxicity.[10] Nearly 50% of patients treated with ipilimumab will experience rash and/or pruritus. Rashes associated with checkpoint blockade often appear as faintly erythematous, reticular, and maculopapular. Typically, the trunk and extremities are involved.[11] In one case, neutrophilic infiltration, diagnostic of Sweet's Syndrome, was reported.[12] Vitiligo also can be seen, although it typically does not appear until months after the initiation of checkpoint blockade.

Topical corticosteroid creams can be used to treat rash induced by checkpoint blockade. Oral antipruritics (hy-

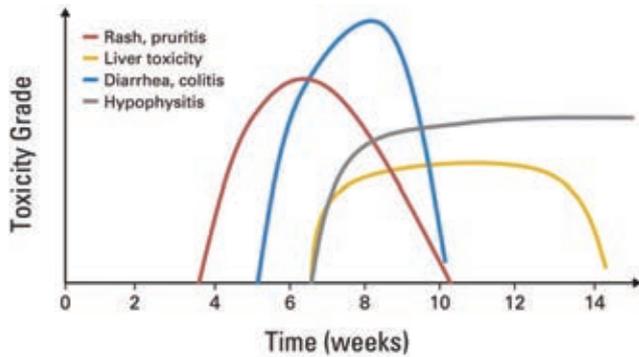
FIGURE 1. Kinetics of Appearance of Immune-Related Adverse Events


droxyzine HCl or diphenhydramine HCl) can help if pruritus is problematic. Severe rashes (grade 3 and above) should be managed with oral corticosteroids. Consideration of permanent discontinuation of checkpoint blockade because of reactions such as Stevens-Johnson syndrome/toxic epidermal necrolysis rarely have been reported. Such reactions require hospitalization for intravenous corticosteroids, dermatologic evaluation, and fluid/electrolyte management.

Antibodies that block PD-1/PD-L1 also can result in dermatologic/mucosal toxicity. Anecdotal cases of patients with oral mucositis and/or dry mouth symptoms have been described with PD-1/PD-L1 treatment. In a large phase I trial of nivolumab, 6.5% of patients had symptoms of dry mouth; one patient had symptoms of grade 3 dry mouth.[13] Oral corticosteroid rinses or lidocaine can treat this symptom effectively. Since many patients with this complaint may be receiving concomitant immunosuppression to treat another irAE, oral candidiasis remains in the differential diagnosis.

KEY POINTS

- Immune checkpoint-blocking antibodies can cause immune-mediated adverse events involving the skin, liver, gastrointestinal, endocrine, neurologic, and other organ systems.
- If appropriate immunosuppressive treatment is used, patients generally completely recover from immune-mediated adverse events.
- The use of immunosuppressive treatment to treat an immune-mediated adverse event does not impair the efficacy of immune-checkpoint blockade.
- There does not appear to be a strong correlation between the occurrence of an immune-mediated adverse event and long-term outcomes to immune checkpoint-blocking antibody therapy.
- Patients who stop immunotherapy because of side effects can still have excellent long-term outcomes.

DIARRHEA/COLITIS

Diarrhea is common in patients undergoing treatment with checkpoint-blocking antibodies. However, there is a much higher incidence of diarrhea in patients receiving CTLA-4 blocking antibodies compared to those targeting PD-1/PD-L1. When considering the occurrence of this irAE, distinguishing diarrhea (increase in frequency of stool) from colitis (abdominal pain, radiographic or endoscopic findings of colonic inflammation) is important. For patients with melanoma undergoing CTLA-4 blockade with ipilimumab, approximately 30% had diarrhea of any grade and less than 10% had severe (grade 3/4) diarrhea.[1] Rates of grade 3/4 colitis have been found to affect only approximately 5% of treated patients.[1,14] Patients should be informed that diarrhea/colitis does not typically begin with initiation of checkpoint blockade; instead, it usually begins approximately 6 weeks into treatment (Fig. 1).[15]

Diarrhea/colitis with CTLA-4 blockade is more common than with PD-1/PD-L1 blockade. The rate of grade 3/4 diarrhea in patients treated with PD-1/PD-L1 agents is very low (1% to 2%).[8,13,16] Although the precise safety profile is still under evaluation, patients who had significant diarrhea/colitis during CTLA-4 blockade have been treated with PD-1 therapy without diarrhea/colitis recurrence.[17] Nonetheless, ongoing trials and clinical experience are necessary to more fully understand the safety of PD-1/PD-L1 blockade in this setting.

When a patient presents with mild diarrhea, clinicians should consider other etiologies that may be responsible, such as *Clostridium difficile* infection or other bacterial/viral pathogens. Patients should be counseled on the importance of maintaining oral hydration. Some clinicians find that the American Dietary Association's colitis diet and antimotility agents (oral diphenoxylate HCl and atropine sulfate 4 times a day) can be helpful. If symptoms persist for more than 3 days, or increase, and/or no infectious causes are readily identified, the use of oral or intravenous corticosteroids are required.

In severe cases or situations in which symptoms do not improve with oral corticosteroids, hospitalization for intravenous corticosteroids, hydration, and electrolyte management is required. A colonoscopy is not necessarily indicated unless the diagnosis is unclear. If intravenous corticosteroids (up to 2 mg/kg methylprednisolone twice a day) do not lead to symptom resolution, infliximab (Remicade; Janssen Biotech, Horsham, PA) at a dose of 5 mg/kg, once every 2 weeks can be helpful.[18-20] The use of infliximab in this setting is based on its use in patients with inflammatory bowel diseases.[21] In very rare cases, colitis can result in bowel perforation that can potentially require colostomy.

Unfortunately, there are no proven treatments to prevent the occurrence of diarrhea. In one study, prophylactic use of the matrix-release corticosteroid budesonide was not found to be helpful.[22] Nevertheless, some clinicians find budesonide to be helpful in early treatment for mild noninfectious

diarrhea symptoms that persist but do not escalate after 2 to 3 days of dietary modification and antimotility agents.

HEPATOTOXICITY

Hepatitis, as determined by elevations in aspartate aminotransferase (AST), aminotransferase (ALT) and less commonly, total bilirubin, occasionally is seen in patients treated with checkpoint blockade. Although most episodes present only as asymptomatic laboratory abnormalities, some patients have an associated fever. Rates of AST and ALT elevations with CTLA-4 blockade vary among clinical trials, but they typically have been reported in less than 10% of patients.[14,23,24] In large trials of PD-1– blocking antibodies, the rates of hepatitis were similarly low (below 5%) and grade 3/4 toxicity was even rarer.[3,13,16]

Among patients who develop hepatitis, the most common onset is 8 to 12 weeks after initiation of treatment, although early or delayed events also may be seen (Fig. 1).[10] Radiographic findings are not typical. In severe cases, however, findings on CT scans may include mild hepatomegaly, periportal edema, or periportal lymphadenopathy.[25] Liver biopsies have described pathologic changes that include severe panlobular hepatitis with prominent perivenular infiltrate with endothelialitis or a primary biliary pattern with mild portal mononuclear infiltrate around bile ductules.[25,26]

Hepatic function (transaminases and bilirubin) should be monitored before each dose of ipilimumab. If AST and ALT increase, viral and other drug-induced causes of hepatitis should be excluded. As with treating other irAEs, if no other cause is obvious, prompt treatment with corticosteroids is necessary. In rare cases, elevations in AST and ALT are steroid-refractory and 500 mg every 12 hours of mycophenolate mofetil (CellCept; Genentech, South San Francisco, CA) may be helpful. The use of antithymocyte globulin therapy also was described in a case report.[27] Unlike for patients with diarrhea/colitis, infliximab should not be given to patients with hepatitis because infliximab carries a risk of hepatotoxicity. Hepatitis may persist for quite some time and require prolonged or repeated corticosteroid tapers (minimum of 3 weeks suggested) and/or additional immunosuppression.

ENDOCRINOPATHY

Immune-related adverse events that affect the pituitary, adrenal, and thyroid glands often present with nonspecific symptoms such as nausea, headache, and fatigue. The incidence of endocrinopathy has been difficult to precisely determine because of the variable methods of assessment, diagnosis, and monitoring in each clinical trial. Nonetheless, hypophysitis (pituitary inflammation) and hypothyroidism are the most common endocrinopathies and are typically believed to occur in up to 10% of patients treated with CTLA-4 blockade.[28,29]

When hypophysitis is suspected, all or some of the hormones released by the pituitary may be reduced (adrenocorticotropic hormone [ACTH], thyroid stimulating hormone [TSH], follicle stimulating hormone, luteinizing hormone, growth hormone, prolactin). Typically, hypophysitis is diagnosed by clinical symptoms of fatigue and headache, radiographic findings (enhancement and enlargement of the pituitary[30,31]), and biochemic evidence of pituitary dysfunction (low ACTH and TSH). Biochemical tests associated with hypophysitis are distinct from primary adrenal insufficiency (low cortisol or inappropriate cortisol stimulation test; high ACTH) and primary hypothyroidism (low free T4; high TSH).

When hypophysitis is suspected, some clinicians have anecdotally described that a course of high-dose corticosteroids (1 mg/kg of prednisone daily) given during the acute phase can reverse the inflammatory process and prevent the need for longer-term hormone replacement. In almost all patients, however, longer-term supplementation of affected hormones is necessary because of secondary hypothyroidism (treated with levothyroxine) or secondary hypoadrenalism (treated with replacement doses of hydrocortisone, typically 20 mg each morning and 10 mg each evening). Some authors have described that patients can be successfully weaned from replacement corticosteroids over time, but this is likely the exception.[32] The immunologic mechanisms of hypophysitis are unknown, but they may be related to the development of humoral (antibody) immunity against the pituitary gland and subsequent complement activation.[33]

Since routine monitoring of thyroid function tests (TSH) is required before each dose of ipilimumab, patients often are diagnosed with thyroid abnormalities (hyperthyroidism and hypothyroidism) as a result of checkpoint blockade. Hypothyroidism is believed to occur far more commonly than hyperthyroidism. When patients are evaluated for fatigue that is possibly a result of endocrinopathy, it is important to distinguish primary hypothyroidism (low free T4 and high TSH) from hypophysitis, which can result in secondary hypothyroidism (low free T4 and low TSH). Management of hypothyroidism involves replacement with thyroid hormone (levothyroxine).

The most emergent endocrinopathy is an adrenal crisis associated with dehydration, hypotension, and electrolyte imbalances such as hyperkalemia and hyponatremia. When this occurs, intravenous corticosteroids and immediate hospitalization is required. Consultation with an endocrinologist, aggressive hydration, and evaluation for sepsis is critical.

The frequency of endocrinopathy in patients treated with PD-1/PD-L1 agents is not known yet, but it may differ from those seen with CTLA-4 blockade. Hypophysitis rarely has been described in published trials of PD-1 blockade for patients with advanced melanoma.[3,13] Thyroid disorders have been described in less than10% of patients.[3,16] Some cases, however, can be severe.[34] Treatment of endocrinopathy with PD-1/PD-L1 agents is approached in a way similar to treating patients undergoing CTLA-4 blockade.

LESS FREQUENTLY INVOLVED ORGANS

Lung

Several pulmonary inflammatory conditions have been seen in patients treated with ipilimumab, including sarcoidosis[35,36] and organizing inflammatory pneumonia.[37] Pneumonitis also has been described in patients treated with PD-1 blocking agents (< 10%)[3,5,16,38] but with occasional fatal consequence in early trials.[5] In any patient presenting with pulmonary symptoms, such as an upper respiratory infection, new cough, or shortness of breath, pneumonitis should be considered and evaluated with imaging. In moderate to severe cases, a bronchoscopy should be performed to exclude infectious etiologies before starting immunosuppression. In severe cases, treatment should consist of high doses of corticosteroids such as 2 mg/kg of intravenous methylprednisone. Additional immunosuppression with infliximab, mycophenolate mofetil, or cyclophosphamide is reasonable.

Eye

Inflammation of components of the eye has been described with CTLA-4 blockade. These include episcleritis, conjunctivitis, and uveitis. Typically, the incidence is believed to be less than1%, and symptoms can include photophobia, pain, dryness of the eyes, and blurry vision.[39] Consultation with an ophthalmologist is recommended, and treatment with topical intraocular corticosteroids such as 1% prednisolone acetate suspension may be helpful. Oral corticosteroids can be used for more severe (grade 3/4 or refractory) cases. The incidence of ophthalmologic toxicity in patients treated with PD-1/PD-L1 blockade is less-well described, but it is likely an infrequent side effect.

Kidney

Several case reports have described patients treated with ipilimumab who have developed renal insufficiency believed to be related to treatment. Histopathologic analyses of kidney biopsies have described several different pathologic processes, including acute granulomatous interstitial nephritis[40] and lupus membranous nephropathy.[41] Treatment with oral or intravenous corticosteroids in these cases has been associated with improvement in renal function.[42,43] Renal insufficiency with PD-1 agents and the combination of CTLA-4 and PD-1 blockade similarly has been reported in several patients with anecdotal findings of interstitial nephritis and response to corticosteroids.[16,44]

Pancreas

The routine monitoring of amylase and lipase values in otherwise asymptomatic patients treated with checkpoint blockade is not recommended. Similarly, corticosteroids are not indicated in patients with asymptomatic elevations in amylase/lipase without other symptoms of pancreatitis. Nevertheless, when pancreatitis is suspected clinically, amylase and lipase should be checked since immune-related pancreatitis has been reported in patients treated with CTLA-4 and PD-1 blockade.[38,45] The high rate of asymptomatic elevations in amylase/lipase in clinical trials of patients receiving CTLA-4 and PD-1/PD-L1 blockade is of uncertain clinical significance since these patients did not meet the diagnostic criteria for pancreatitis.[46]

Neurologic Syndromes

Neurologic syndromes have been associated with checkpoint blockade with ipilimumab. These include posterior reversible encephalopathy syndrome,[47] aseptic meningitis,[48] enteric neuropathy,[49] and transverse myelitis.[50] Cases of Guillain-Barre syndrome are particularly notable[51] because one case resulted in a treatment-related death in a postsurgical adjuvant study of ipilimumab.[52] As with other irAEs, corticosteroids can be helpful. In consultation with a neurologist, plasmapheresis and intravenous immunoglobulin may be considered.

Hematologic Syndromes

Red cell aplasia,[53] neutropenia,[54] and acquired hemophilia A[55] also have been described in patients treated with ipilimumab, as has thrombocytopenia.[56] Similar to many of the irAEs described above, the standard approach remains initial immunosuppression with corticosteroids. A bone marrow biopsy may be necessary in some cases, particularly when the diagnosis remains unclear.

IMMUNE-RELATED ADVERSE EVENTS ASSOCIATED WITH COMBINATION OF CONCURRENT CTLA-4 AND PD-1 BLOCKADE

The distinct action mechanisms of CTLA-4 and PD-1 blockade have led to investigations treating patients with both CTLA-4 and PD-1/PD-L1 in those who develop a variety of malignancies. Published data on the combination of ipilimumab and nivolumab exist for patients with advanced melanoma.[44] The rate of published grade 3/4 treatment-related adverse events related to therapy in patients receiving this treatment is approximately 50%, which is numerically higher than rates described for patients receiving either CTLA-4 or PD-1/PD-L1 agents as single agents.[1,3,5,8,16] Many grade 3/4 irAEs in this trial, however, were asymptomatic, abnormal laboratory values. This included a high rate of patients with asymptomatic elevations in lipase (over 10%), none of whom developed pancreatitis. No new toxicities were attributed to the combination of ipilimumab and nivolumab that have not been seen with ipilimumab or nivolumab alone.

The combination of ipilimumab and nivolumab may have a different safety profile in patients with other advanced malignancies, and this combination remains under active investigation. Other studies seek to test similar combinations using different CTLA-4 and PD-1/PD-L1– blocking antibodies (NCT01975831, NCT02089685, NCT01928394).

COMBINATION OF IMMUNE CHECKPOINT-BLOCKING ANTIBODIES AND TARGETED THERAPY

The treatment of many malignancies has improved with the discovery of oncogenic proteins amenable to targeted inhibi-

tion. One of these momentous advances has been targeting mutant *BRAF* and the mitogen-activated protein (MAP) kinase pathway in patients with melanoma.[57-62] Based on preclinical evidence that suggests RAF inhibitors can have positive immunologic effects,[63-68] there has been great interest in exploring combinations of targeted agents that inhibit mutant *BRAF* with immune checkpoint- blocking antibodies.

The toxicity profile of combinations of targeted agents and immune-checkpoint blockade, however, is just beginning to be explored. In the only published prospective study, treatment with vemurafenib and ipilimumab was associated with a high rate of grade 3 transaminase elevations that required cessation of further exploration of this combination as concurrent therapy.[69] Rash was also an important problem with this combination, which is consistent with similar findings when vemurafenib was administered soon after completing ipilimumab.[70]

The irAE profile of ipilimumab in combination with RAF inhibitors may vary by specific RAF inhibitor. In a separate phase I study, dabrafenib was combined with ipilimumab and preliminarily, no major safety concerns with this doublet combination have been seen.[71] The safety of ipilimumab with dabrafenib and trametinib, however, may be more problematic because some patients treated with this triplet had severe colitis with perforation.

Future investigations of targeted agents and immune checkpoint-blocking antibodies should continue in patients who develop multiple diseases, and that dose and schedule will be critical to the safety and possibly efficacy of these combination approaches. It is expected that combinations of targeted agents with PD-1/PD-L1 antibodies may show a more favorable side-effect profile than combinations with ipilimumab; however, this is the subject of ongoing investigation.

COMBINATION OF IPILIMUMAB AND GRANULOCYTE-MACROPHAGE COLONY-STIMULATING FACTOR

Granuloycte-Macrophage Colony-Stimulating Factor (GM-CSF) (Leukine; Genzyme, Ridgefield, NJ) currently is not indicated to prevent or treat irAEs. Nonetheless, combining GM-CSF with immune-checkpoint blockade is of interest based on favorable preclinical data suggesting GM-CSF–secreting tumor vaccines enhanced the activity of CTLA-4 blockade.[72] The combination of GM-CSF and ipilimumab was tested in patients with advanced melanoma in a phase II randomized study (ipilimumab 10 mg/kg plus GM-CSF vs. ipilimumab 10 mg/kg alone). Interim results indicate that the combination prolonged survival and was associated with fewer irAEs than ipilimumab 10 mg/kg alone.[73]

Reasons for the decreased rate of side effects are unclear, but GM-CSF has been implicated in the pathogenesis of inflammatory bowel disease.[74] Whether GM-CSF would result in similar effects in patients treated with the commercially available dose of ipilimumab (3 mg/kg) is unknown. Additional studies are necessary before GM-CSF is routinely recommended for patients being treated with ipilimumab.

OPPORTUNISTIC INFECTIONS IN IMMUNOSUPPRESSED PATIENTS

Since prolonged immune suppression is occasionally used to treat irAEs, patients can be at risk for unusual or opportunistic infections. Though anecdotal cases of these infections, such as *Aspergillus* pneumonia, have been reported,[75] the true incidence of these opportunistic infections remains unknown. *Pneumocystis jiroveci* prophylaxis with cotrimoxazole, atovaquone, or pentamidine should be considered in patients treated with 20 mg of prednisone equivalent daily for at least 4 weeks, based on the National Comprehensive Cancer Network guidelines for the Prevention and Treatment of Cancer-Related Infections (Category 2B recommendation). The role of prophylactic antiviral or antifungal therapy in this setting is unclear.

INVESTIGATIONS CORRELATING IMMUNE-RELATED ADVERSE EVENTS WITH EFFICACY

The correlation between efficacy of checkpoint-blocking antibodies and the occurrence of irAEs is controversial.[76,77] Patients can benefit from checkpoint-blocking antibodies without developing irAEs. Any potential association between PD-1/PD-L1– blockade and irAEs will be hard to determine as the incidence of significant irAEs is low.

SAFETY OF IMMUNE-CHECKPOINT INHIBITION IN PATIENTS WITH UNDERLYING AUTOIMMUNE CONDITIONS

The safety of immune-checkpoint inhibitors in patients with an unrelated autoimmunity disorder (e.g., rheumatoid arthritis, systemic lupus erythematosus) is unknown. Both CTLA-4 and PD-1 have an important function in maintaining immunologic homeostasis, and there is theoretic concern that therapeutic blockade of these receptors could lead to exacerbations of underlying autoimmune conditions. Preclinical models suggest CTLA-4 blockade can exacerbate autoimmune diseases.[78,79] Since patients with underlying autoimmune conditions were not included in clinical trials of checkpoint-blocking antibodies, clinical evidence of the safety of this approach requires further study. Anecdotally, some patients with underlying autoimmune conditions have been treated safely with ipilimumab,[80,81] but one patient with multiple sclerosis reported worsening symptoms after ipilimumab.[82] Given the profound potential benefits of these checkpoint- blocking antibodies in patients with life-threatening malignancies, clinicians should engage patients with autoimmune diseases in thoughtful discussion about the possible benefits and risks of immunologic checkpoint blockade.

CONCLUSION

Immunologic-checkpoint inhibition targeting CTLA-4 and PD-1/PD-L1 has dramatically improved the care of patients

with many advanced malignancies. Treatment is associated with typically transient irAEs, but irAEs occasionally can be severe and fatal. Rapid identification of these side effects and initiation of systemic immunosuppression can improve outcomes without compromising the efficacy of immune-checkpoint inhibition. Although no prospective data exist to guide recommendations for the best specific immunosup-

pressive treatment, adherence to established guidelines based upon collective clinical experience is recommended. Clinical experience with immune-checkpoint inhibitors in a variety of disease settings and in novel combinations ultimately will refine knowledge and management of irAEs and provide the opportunity to obtain the full therapeutic potential of this promising treatment modality.

Locally Advanced Rectal Cancer: Time for Precision Therapeutics

Martin R. Weiser, MD, Zhen Zhang, MD, PhD, and Deborah Schrag, MD, MPH

OVERVIEW

The year 2015 marks the 30th anniversary of the publication of NSABP-R01, a landmark trial demonstrating the benefit of adding pelvic radiation to the treatment regimen for locally advanced rectal cancer with a resultant decrease in local recurrence from 25% to 16%. These results ushered in the era of multimodal therapy for rectal cancer, heralding modern treatment and changing the standard of care in the United States. We have seen many advances over the past 3 decades, including optimization of the administration and timing of radiation, widespread adoption of total mesorectal excision (TME), and the implementation of more effective systemic chemotherapy. The current standard is neoadjuvant chemoradiation with 5-fluorouracil (5-FU) and a radiosensitizer, TME, and adjuvant chemotherapy including 5-FU and oxaliplatin. The results of this regimen have been impressive, with a reported local recurrence rate of less than 10%. However, the rates of distant relapse remain 30% to 40%, indicating room for improvement. In addition, trimodality therapy is arduous and many patients are unable to complete the full course of treatment. In this article we discuss the current standard of care and alternative strategies that have evolved in an attempt to individualize therapy according to risk of recurrence.

The current standard of care for patients with stage II (T3/T4N0) and stage III rectal cancer (TanyN1/N2) is trimodality therapy including chemotherapy, radiation, and surgery with complete TME.[1] The primary rationale for systemic chemotherapy is to reduce the risk of distant recurrence, whereas the rationale for pelvic radiation is to prevent local recurrence and, in some cases, convert a patient from requiring abdominoperineal resection—which requires a permanent ostomy—to a sphincter-sparing low anterior resection. The trimodality approach has gained widespread acceptance, with numerous publications reporting a substantial reduction in local recurrence rates and prolongation of disease-free survival.[2-6] Since its inception, progress within each of the three therapeutic modalities has continued.

The decision to use short-course radiotherapy (25 Gy in 5 fractions) versus long-course therapy (50.4 Gy delivered in 28 fractions with concurrent fluoropyrimidine) has largely depended on geography. Short-course regimens are generally favored in Northern Europe and Scandinavia, whereas long-course chemoradiation is advocated in North America and Central Europe. A Polish randomized trial compared long-course and short-course radiochemotherapy in patients with T3/4 mid- to low-lying rectal tumors, investigating the efficacy of each regimen. Higher rates of complete pathologic response were observed in patients treated with long-course chemoradiotherapy (16% vs. 1%). Although the rate of positive circumferential resection margin (CRM) was signifi-

cantly higher in patients receiving short-course therapy (13% vs. 4%; p = 0.017), no differences in local recurrence, disease-free survival, or overall survival were observed.

The German CAO/ARO/AIO 94 trial, published 11 years ago, compared preoperative and postoperative long-course chemoradiotherapy for stage II and III rectal cancer.[7] The preoperative treatment group demonstrated a significant (p = 0.006) decrease in local recurrence rate after 5 years, without a difference in rates of distant metastasis or overall survival. Additional benefits of preoperative versus postoperative chemoradiation included a significant decrease in short-term and long-term toxicity; for example, the incidence of grade 3 or higher toxicity was reduced from 40% in the postoperative group to 27% in the preoperative group (p = 0.001). Over the past decade, preoperative chemoradiation has become the standard of care in the United States. Although this shift has certainly reduced treatment toxicity for many patients, many clinicians have questioned whether it has also resulted in excessive radiation exposure for individuals with easily resectable tumors (e.g., T3N0) who might not have required any pelvic radiation at all had they first undergone surgery.

TME involves removal of the rectum together with its cylindrical mesentery and associated nodal tissue. The development and dissemination of this technique represented an incremental advance in oncologic surgery. TME involves sharp dissection between the visceral and parietal layers of

the endopelvic fascia. Anatomic resection ensures complete removal of all locoregional lymph nodes, while maintaining negative CRMs, minimizing blood loss, and preserving the autonomic pelvic nerves. Although no prospective randomized trial has compared TME with conventional proctectomy, numerous retrospective and cohort studies demonstrate excellent local recurrence-free survival in patients undergoing TME.[8-10]

The Dutch trial, published in 2001, was the first study to integrate TME into a control arm and underscored the importance of quality surgical technique. This trial compared the combination of preoperative radiation therapy and TME to TME alone, demonstrating a significant (p < 0.001) decrease in local recurrence in patients receiving preoperative short-course radiation. Critics have argued that, although the quality of surgery was controlled, up to one-quarter of patients had inadequate mesorectal excision on pathologic analysis, which led to a significantly worse outcome (p = 0.02).[11] Long-term follow-up demonstrated that certain patient sub-groups—those with node involvement, negative CRMS, and/or low-lying tumors (within 5–10 cm of the anal verge)—obtained the greatest benefit from preoperative radiation.[12,13] These findings suggested that some sub-groups treated with multimodality therapy may benefit less from the addition of chemoradiation. Furthermore, neoadjuvant radiation did not improve overall survival.

Current data support the use of either single-agent 5-FU or oral capecitabine with concurrent radiation therapy. A recent large randomized study comparing infusional 5-FU to oral capecitabine showed equivalent efficacy.[14] This trial also demonstrated that concurrent use of oxaliplatin with radiation adds to toxicity but does not improve efficacy; therefore, this approach is not recommended.[14,15] Extrapolating from data on colon cancer, postoperative oxaliplatin-containing regimens such as FOLFOX are typically used in the setting of rectal cancer. Adjuvant chemotherapy begins 4 to 6 weeks after surgery and administration of 12 cycles is standard, although discontinuing oxaliplatin upon early signs of neuropathy is essential to prevent long-term impairment.

Although use of chemoradiation as initial management is now standard practice, there has been growing interest in the use of systemic oxaliplatin-containing chemotherapy first,

followed by chemoradiation, for locally advanced disease. Chau et al published data on an initial series of patients with locally advanced, poor-risk rectal cancer who were treated with CapeOx for 3 months, followed by capecitabine plus radiation therapy.[16] The radiologic response rate was 88%, and 86% of patients achieved symptomatic response at a median of 32 days. A recent single-center retrospective study on the use of initial induction FOLFOX chemotherapy in patients with locally advanced rectal cancer demonstrated high response rates. Notably, this treatment strategy enabled the delivery of virtually all planned systemic chemotherapy without limiting the ability to deliver the planned chemoradiotherapy.[17] Patients were routinely re-evaluated by their surgeons after approximately 8 weeks of chemotherapy to rule out local progression, and no patient in this series was reported to have local progression at the time of examination. All patients undergoing TME surgery achieved an R0 resection.

This concept of "chemotherapy first" with 4 months of FOLFOX or CapeOx, followed immediately by chemoradiotherapy and then TME, is a logical extrapolation from current practice. It is clear that there never will be an adequately powered, randomized phase III trial of "chemo first" versus the current routine of "chemo last"; however, there are several reasons for delivering all planned therapy before resection with the expectation that this would be advantageous. Advantages include introduction of the best systemic therapy as early as possible, thus maximally addressing concerns over distant micrometastatic disease and enabling the rapid initiation of chemotherapy to obtain symptomatic relief. Patients who are treated with chemotherapy as a first-line approach have a high likelihood of receiving all planned chemotherapy, which is less often the case when chemotherapy is planned postoperatively. Furthermore, diverting ostomies can be closed substantially earlier when no postoperative chemotherapy is required. This approach is especially attractive in the setting of bulky tumors and radiographic evidence of tumor involvement of the radial circumferential mesorectal margin, adjacent organs (prostate or vagina), or numerous locoregional lymph nodes.

Although the oncologic results of combined modality therapy for rectal cancer are impressive, trimodality treatment is difficult to endure. This has led many clinicians to question whether treatment can be simplified. Investigators have approached this by trying to tailor therapy and selectively omit one of the three major treatment modalities. For example, one suggested approach is elimination of systemic chemotherapy for patients who have favorable pathologic stage after neoadjuvant treatment. Another approach pioneered by Brazilian investigators is to selectively omit surgical resection for individuals with clinical complete response to neoadjuvant chemoradiation. Finally, in North America, there has been interest in using pelvic radiation selectively for those patients at greatest risk of pelvic recurrence.

The rationale for selective use of pelvic radiation stems from its short- and long-term morbidities. Neoadjuvant chemoradiation is taxing and time intensive, requiring daily treatment for 5 weeks, and compliance is frequently poor.[18]

KEY POINTS

- Combined modality therapy—including chemotherapy, radiation, and surgery—is the standard for locally advanced rectal cancer.
- Pelvic radiation reduces local recurrence but does not reduce distant relapse or improve overall survival.
- A noteworthy portion of patients are unable to complete the prescribed treatment for rectal cancer.
- Total neoadjuvant therapy attempts to deliver all therapy prior to surgery.
- PROSPECT is an international randomized trial attempting to individualize rectal cancer treatment.

Debilitating short-term toxicities have been reported in up to 50% of patients,[19] with up to 70% unable to complete the entire course of treatment.[18] Additionally, the long-term effects of radiation can lead to disabling complications. Radiation-related fibrosis and autonomic nerve injury are associated with increased fecal incontinence, urgency, and frequency, and higher rates of sexual and genitourinary dysfunction have also been observed. Overall quality of life is poor compared with that of patients who do not receive chemoradiation.[7,18,20-22] Finally, chemoradiation may impair bone marrow reserve, which complicates the ability to deliver systemic chemotherapy in the metastatic setting.

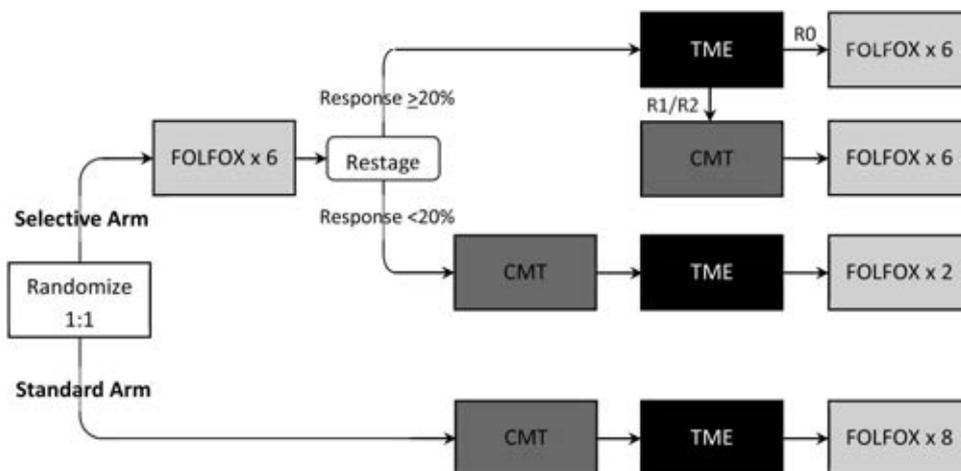
The current paradigm treats all patients with stage II and III rectal cancer alike. However, many experts question whether all of these patients should be treated as a homogeneous group. There is growing evidence that not all patients with stage II and III disease are high risk, and a more individualized approach has been advocated. The rationale for change is based on (1) treatment-related toxicities, (2) concerns regarding a delay in systemic chemotherapy, and (3) the potential for unnecessary overtreatment.

Gunderson et al demonstrated that the risk of local recurrence in patients with rectal cancer can be stratified by T and N stage using an aggregation of data from several phase III North American rectal cancer adjuvant trials (NCCTG 794751, NCCTG 864751, and U.S. GI Intergroup 0114).[23] TN stage was categorized according to risk of recurrence: low (T1/2N0), intermediate (T1/2N1, T3N0), moderately high (T1/2N2, T3N1, T4N0), and high (T3N2, T4N1/2). Patients with intermediate-risk tumors had better outcomes than patients with moderately high and high-risk tumors, including lower rates of local recurrence (6 to 8% vs. 8 to 15% and 15 to 22%, respectively) and improved overall survival (74 to 81% vs. 61 to 69% and 33 to 48%).[23] These data suggest that routine adjuvant radiation therapy may not be required for intermediate-risk tumors (T1/2N1 or T3N0) when TME with negative radial margins has been performed.

The final analysis of the Intergroup 0114 trial reported similar findings[24]; however, these are based on limited data and the conclusions are difficult to substantiate because all patients received radiation therapy. A second pooled analysis attempted to dissect the effect of treatment on outcome.[25] Data from five phase III North American rectal cancer trials conducted over a 13-year period (NSABP R01, NSABP R02, NCCTG 794751, NCCTG 864751, and U.S. GI Intergroup 0114) were aggregated, and the subsequent analysis of 3,791 patients compared outcomes according to TN stage and various treatment regimens: surgery alone (179 patients), surgery and radiation (281 patients), surgery and chemoradiotherapy (2,799 patients), or surgery and chemotherapy (532 patients). In the setting of intermediate-risk tumors (T1/2N1 and T3N0), no additional benefit in disease-free survival or overall survival was observed when adding radiation to chemotherapy after surgery. These analyses demonstrate heterogeneity in the risk of local recurrence, and provide a rationale for individualizing treatment.

A small pilot trial explored the use of initial therapy with FOLFOX-based chemotherapy, without planned radiation therapy, for locally advanced rectal cancer. The study cohort included 30% stage II and 70% stage III mid- to low rectal cancers. Of the 30 patients receiving chemotherapy alone, all had complete R0 resection and eight (27%) achieved a pathologic complete response with no viable tumor detected in the resection specimen.[26] All three patients who suffered recurrence had pulmonary metastasis, but no locally recurrent disease was observed. Nevertheless, delivery of preoperative chemotherapy without the routine use of radiation remains an experimental approach. It is currently being evaluated in the National Cancer Institute Cooperative Group PROSPECT trial, and at the present time should not be routinely used outside of a clinical trial.

PROSPECT (Fig. 1) is a large-scale, multi-institutional phase II/III randomized prospective trial comparing neoadjuvant FOLFOX with selective use of chemoradiation (NCCTG-N1048, NCT01515787). The study randomly and

FIGURE 1. Protocol Schema for NCCTG-N1048


This ongoing phase II/III trial investigates whether standard combined modality treatment (CMT: 5-FU or capecitabine-based chemoradiation) can be replaced with selective use of neoadjuvant FOLFOX.

equally assigns patients with T1/2N1, T3N0, and T3N1 rectal cancer with tumors that are amenable to sphincter-preserving procedures, and without at-risk radial CRM, to either the "standard" or "selective" arm. Treatment in the standard arm consists of preoperative 5-FU or capecitabine-based chemoradiation, followed by TME and eight cycles of FOLFOX. Patients assigned to the selection arm receive six cycles of neoadjuvant FOLFOX and are then restaged. If clinical response to chemotherapy is observed in 20% or more of patients, the patients immediately proceed to surgical resection and adjuvant FOLFOX (6 cycles); however, if tumor response is less than 20%, the patients receive conventional combined-modality therapy before surgical resection and adjuvant FOLFOX (2 additional cycles). Patients in the selective arm who are found to have positive CRMs on final pathology undergo chemoradiation because of the increased risk for local recurrence. This study will determine whether neoadjuvant FOLFOX with selective use of chemoradiation can be safely used as an alternative to standard chemoradiation without compromising the ability to perform a margin-negative surgical resection, achieve local control, and improve overall disease-free survival.

In summary, there has been substantial progress in rectal cancer therapy in the past decade. Now, the field is ready for precision medicine, with tailoring of treatment to individual patient risk. Advances in chemotherapy, surgery, radiation, and imaging have each enabled tailoring of treatment. Although some patients still do not receive beneficial adjuvant and neoadjuvant treatments, at the same time the neoadjuvant paradigm means that others receive too much treatment. Current trials, including PROSPECT, are attempting to meet these challenges and develop individualized treatment based on personal risk, thus maximizing oncologic outcome and quality of life while limiting treatment-related toxicity.

Biologic Therapies in Colorectal Cancer: Indications and Contraindications

Marwan Fakih, MD

OVERVIEW

The role of antiangiogenic and anti-epidermal growth factor receptor (EGFR) agents has been investigated extensively in colorectal cancer in the palliative, adjuvant, and neoadjuvant settings. Although the role of biologic agents has become well-defined in the first, second, and subsequent lines of treatment of metastatic colorectal cancer (mCRC), considerable debate continues around the optimal sequencing and around optimal patient selection. The benefits from integrating bevacizumab or cetuximab in the adjuvant setting have been investigated in several randomized phase III clinical trials in stage II/III disease, all with disappointing results. Neoadjuvant approaches incorporating biologic therapy in patients with liver metastatic disease have led to mixed results. Although the current evidence does suggest increased down-staging and increased resectability with the addition of cetuximab in patients with initially unresectable or borderline resectable liver metastases, a positive effect of anti-EGFR therapy on the overall survival (OS) in this setting is not conclusive. Patients with resectable liver metastases derive no benefit and may experience potential harm from the addition of cetuximab to neoadjuvant chemotherapy. Similarly, there is neither rationale nor adequate data to support the addition of bevacizumab to neoadjuvant chemotherapy in patients with resectable liver metastases. In this review, we examine the role of antiangiogenesis and anti-EGFR therapies across the spectrum of adjuvant, neoadjuvant, and metastatic disease.

Significant progress has been made in the last decade in the management of mCRC, with median OS of patients with mCRC now at or exceeding 30 months.[1,2] The improvements in outcome are at least partially credited to the integration of biologic therapies, whether antiangiogenic or anti-EGFR, in the mainstream treatment of metastatic disease. Although significant progress has been made with the addition of these classes in advanced noncurable disease, their role has been disappointing in the adjuvant setting and continues to evolve in the neoadjuvant setting. In this review, we will summarize the current clinical data for biologic and targeted agents in adjuvant CRC, neoadjuvant, and nonresectable mCRC.

BIOLOGIC THERAPY IN THE ADJUVANT TREATMENT OF COLORECTAL CANCER

Bevacizumab in Stage II and III Colon Cancer

Several randomized phase III clinical trials have evaluated bevacizumab in combination with systemic chemotherapy in the adjuvant treatment of colorectal cancer. The NSABP C-08 clinical trial randomized 2,710 patients with stage II or III colon cancer to receive 6 months (12 cycles) of modified FOLFOX6 regimen with or without 1 year of bevacizumab.[3,4] No significant effect on disease-free survival (DFS) or OS was noted in the study population or within the stage II or stage III subgroups. Interestingly, the effect of bevacizumab on DFS was different before and after the 15-month time point from study treatment. The hazard ratio (HR) for recurrence within 15 months from start of study treatment was 0.61 (95% CI, 0.48 to 0.78) in favor of bevacizumab. In contrast, a trend toward increased recurrence rate was noted after 15 months on the bevacizumab arm. A post hoc analysis of the NSABP-CO8 population by mismatch repair status suggested a benefit from bevacizumab in the mismatch deficient cohort (HR 0.52; 95% CI, 0.29 to 0.94).[5] The AVANT phase III clinical trial randomized patients with stage II or III colon cancer to receive 6 months of oxaliplatin plus a fluoropyrimidine with or without bevacizumab.[6] Patients were randomly assigned in a 1:1:1 ratio to three arms of treatment: FOLFOX4, FOLFOX4 plus 1 year of bevacizumab, XELOX plus 1 year of bevacizumab. No benefits in DFS were noted with the addition of bevacizumab to chemotherapy. The HR for DFS for bevacizumab/FOLFOX4 and bevacizumab/XELOX compared with FOLFOX4 were 1.17 (95% CI, 0.98 to 1.39) and 1.07 (95% CI, 0.9 to 1.28), respectively. Similar to the NSABP-C08 study, bevacizumab was associated with an improved DFS in the initial period of follow-up. In the first year of the study, the HR for DFS was 0.63 and 0.61 on the bevacizumab/FOLFOX4 and bevacizumab/XELOX arms in comparison with FOLFOX4. This initial improvement in DFS

was offset by a detrimental effect of bevacizumab in DFS in years 2 and 3, leading to an overall trend to increased recurrences on the bevacizumab arms. This rebound increase in recurrences in the bevacizumab arms translated into a trend toward a detriment in OS in both the bevacizumab/FOLFOX4 and bevacizumab/XELOX arms when compared with FOLFOX4. Finally, the QUASAR2 study randomized 1,941 patients with stage III or high-risk stage II colorectal cancer to receive eight cycles of capecitabine (24 weeks) with or without 16 cycles of every 3-week bevacizumab (48 weeks).[7] An initial trend in improvement in DFS was noted in the bevacizumab arm in the first 2 years of follow-up. However, further follow-up after 2 years was associated with an increased recurrence rate in the bevacizumab arm, leading to a final HR for DFS of 1.06 in the bevacizumab arm compared with the control arm. Subgroup analysis in the microsatellite stable (MSS) and microsatellite instability (MSI) groups showed a significant detriment with bevacizumab in the MSS group (HR 1.43, $p = 0.0005$), whereas no significant difference in outcomes was noted in the MSI group (HR 0.74, $p = 0.42$).

No benefit is expected from the addition of bevacizumab to adjuvant cytotoxic chemotherapy in patients with stage II or III disease. To the contrary, worrisome trends toward increased recurrence rate after completion of bevacizumab therapy have been noted and have translated in a trend toward a worsened OS. The favorable trends noted with bevacizumab in tumors with MSI are hypothesis generating and may warrant further investigation in this subgroup of patients.

KEY POINTS

- There is no role for biologic therapy in the adjuvant treatment of colorectal cancer.
- In the setting of resectable metastatic disease to the liver, there is no evidence to suggest a benefit from adding either antiangiogenic or anti-epidermal growth factor receptor (EGFR) therapy. The addition of anti-EGFR therapy to chemotherapy in the neoadjuvant treatment of KRAS-wild type (WT) resectable liver metastases has been associated with a detrimental effect on disease-free survival.
- In patients with unresectable but potentially resectable disease, consideration for neoadjuvant FOLFOXIRI/bevacizumab (good performance status) or combination chemotherapy plus anti-EGFR agents (RAS-WT) should be made to increase the chances of curative-intent surgery.
- In RAS-mutant type or BRAF-MT metastatic colorectal cancer (mCRC), the continuum of angiogenesis targeting during the first two lines of treatment is recommended.
- Bevacizumab or anti-EGFR therapy in the first-line therapy of RAS-WT and BRAF-WT mCRC is acceptable with no clear evidence of superiority of one approach compared with another.

Cetuximab in the Adjuvant Treatment of Colorectal Cancer

The role of anti-EGFR therapy in the adjuvant treatment setting has been investigated through the N0147 and PETACC-8 clinical trials.[8,9] The initial design of the N0147 included a randomization to 6 months of FOLFOX, FOLFIRI, or sequential FOLFOX followed by FOLFIRI, with or without cetuximab in patients with stage III colon cancer. Subsequent protocol amendments resulted in the closure of the FOLFIRI and sequential FOLFOX/FOLFIRI arms, as well as the limitation of enrollment to patients with KRAS-wild type (WT) tumors.[8] The study accrued 2,070 patients with KRAS-WT tumors. No benefit in 3-year DFS in the cetuximab/FOLFOX compared with the FOLFOX arm was noted in the KRAS-WT (HR 1.21; 95% CI, 0.98 to 1.49) or KRAS/BRAF-WT populations. No advantage to the addition of cetuximab was noted in any of the subgroup analyses. Of note, no definitive conclusions could be deduced from the FOLFIRI cohorts on N0147 because of the small sample size. However, a trend toward improved DFS and OS was noted in the cetuximab/FOLFIRI compared with FOLFIRI in an exploratory analysis.[10] The PETACC-8 clinical trial randomized patients with stage III colon cancer to 6 months of FOLFOX4 chemotherapy with our without cetuximab.[9] Similar to N0147, the study was subsequently amended to include only patients with KRAS-WT tumors. No benefit from cetuximab was noted in terms of DFS in the KRAS-WT (HR 1.05; 95% CI, 0.85 to 1.29; $p = 0.66$) or in the KRAS/BRAF-WT (HR 0.99; 95% CI, 0.76 to 1.28; $p = 0.92$) populations. Interestingly, and in a preplanned subgroup analysis, patients with T4N2 tumors derived a significant benefit from the addition of cetuximab, whereas, women and patients with right colonic tumors experienced a significant improvement in DFS in the chemotherapy only arm.

Based on the N0147 and PETACC-8 studies, there is no current role for cetuximab in the adjuvant treatment of colon cancer. Although subgroup analyses of PETACC-8 suggest a benefit in more advanced T4N2 disease, this can be considered, at best, hypothesis generating. Clearly, a more predictive signature of response beyond RAS and BRAF mutations will be needed to revisit the role of anti-EGFR in the adjuvant treatment of mCRC. The reason for disconnect in benefits from anti-EGFR therapy between adjuvant and metastatic disease studies is not clear but could be explained by a failure to induce complete pathologic sterilization despite an increased antitumor down-staging in metastatic settings.

BIOLOGIC THERAPIES IN THE NEOADJUVANT TREATMENT OF MCRC
Biologic Therapies in the Neoadjuvant Treatment of Resectable mCRC

When considering neoadjuvant treatment in the management of metastatic colorectal cancer, one has to define the goal of therapy. The main indications for neoadjuvant treatment for metastatic colorectal cancer are: (1) decrease in the risk for recurrence of disease in the setting of resectable liver

metastases and (2) down-staging for resection in patients with potentially resectable disease. The EORTC 40983 study randomized patients with four or less hepatic colorectal metastases to perioperative FOLFOX chemotherapy or observation.[11] This study met its primary endpoint of 3-year DFS improvement in favor of FOLFOX. No significant improvement in OS was confirmed.[11,12] Since the EORTC control arm did not include postoperative chemotherapy, the benefits of perioperative chemotherapy compared with adjuvant postoperative chemotherapy are currently not substantiated.

Bevacizumab addition to neoadjuvant CAPOX, FOLFOX, FOLFIRI, and FOLFOXIRI has been shown to be feasible in patients with resectable liver mCRC.[13-15] Retrospective analyses suggest an increased likelihood of complete pathologic responses of liver metastases and a lower incidence of sinusoidal damage with the integration of bevacizumab in the preoperative chemotherapy treatment of liver mCRC.[16-18] However, there is no strong evidence to date to support an improvement in DFS or OS with the addition of bevacizumab to preoperative chemotherapy in these settings. Given the discouraging DFS and OS data with bevacizumab in stage III colorectal clinical trials, there is no strong rationale to incorporate bevacizumab in the neoadjuvant or postoperative therapy in patients with resectable mCRC. Indeed, a recent retrospective analysis of patients undergoing hepatectomy with adjuvant chemotherapy with or without bevacizumab failed to show any additional benefit in the bevacizumab arm.[19]

The role of cetuximab as part of a neoadjuvant chemotherapy regimen in resectable mCRC to the liver was investigated through the New EPOC trial.[20] In this randomized phase III clinical trial, patients with resectable or suboptimally resectable *KRAS*-WT metastatic colorectal cancer to the liver were randomly assigned to perioperative chemotherapy with or without cetuximab. The progression-free survival (PFS) was significantly shorter in the chemotherapy/cetuximab compared with the chemotherapy arm (14.1 vs. 20.5 months; HR 1.48; 95% CI, 1.04 to 2.12; p = 0.03). Chemotherapy consisted predominantly of oxaliplatin-based therapy (FOLFOX or XELOX), although, 11% of the patient population received FOLFIRI. Given the small number of patients on the irinotecan arm, no definitive conclusions can be extrapolated from this subgroup.[20] This study was criticized for lack of adequate surgical quality control, imbalance in patient characteristics, variations in chemotherapy backbones, and increased rate of early death without clear attribution.[21]

The detrimental effect of cetuximab on the New EPOC trial and the lack of benefit from adjuvant cetuximab treatment in stage III disease suggest that the addition of cetuximab to chemotherapy in *KRAS*-WT tumors does not improve the rate of microscopic disease eradication and, hence, does not decrease the risk for disease relapse. This strategy should be avoided in patients with resectable liver metastases.

Biologic Therapy in the Management of Potentially Resectable mCRC

Down-staging for resection in the setting of metastatic disease that is deemed unresectable at the time of presentation but potentially resectable after a major clinical response should be considered a standard approach. Patients who are converted to resectable disease with chemotherapy achieve a 5-year OS of 30% to 50%, far exceeding any 5-year survival reported with palliative chemotherapy.[22,23] Therefore, it is imperative that the most effective combination chemotherapy is considered in patients with advanced, potentially resectable, mCRC.

Since no randomized studies have evaluated the combination cytotoxic chemotherapy compared with cytotoxic chemotherapy/bevacizumab in such settings, one cannot conclusively determine the role of angiogenesis inhibition in down-staging for resection. However, since many of the patients with potentially-resectable disease do not achieve resectability, and given the positive effect of bevacizumab on PFS and OS, the routine implementation of bevacizumab in this setting is considered an acceptable practice, particularly when anti-EGFR therapy is not considered or advisable. Additional considerations for the addition of bevacizumab in this setting include retrospective analyses suggesting increased complete pathologic responses and decreased sinusoidal damage to the liver with the addition of bevacizumab to chemotherapy.[16-18] When considering bevacizumab in the management of potentially resectable mCRC, it is important to consider the most effective chemotherapy backbones. To that end, the OLIVIA clinical trial randomized patients with initially unresectable colorectal liver metastases to FOLFOX plus bevacizumab or FOLFOXIRI plus bevacizumab.[15] The FOLFOXIRI arm was associated with an improved response rate, a higher resection rate, higher R0 resection rate, and improved PFS (Table 1).

Although the addition of cetuximab to chemotherapy in the setting of resectable hepatic metastatic disease has resulted in disappointing results, the value of cetuximab in unresectable-potentially resectable hepatic metastatic disease has been supported by several studies. A phase III clinical trial randomized patients with *KRAS*-WT tumors with unresectable hepatic mCRC to receive first-line FOLFOX or FOLFOX/cetuximab.[24] Patients assigned cetuximab achieved a higher response rate, R0 hepatic resection rates, and OS (Table 1). Additional support to this strategy comes from several other phase II clinical trials describing a high response rate and resection rates with cetuximab-based combinations.[25,26] In addition, a recent update from CALGB 80405 reported that 15.7% of 1,137 patients with *KRAS*-WT tumors underwent resection after 1:1 randomization to chemotherapy with bevacizumab or chemotherapy plus cetuximab.[27] A higher percentage of patients underwent resection (with no evidence of disease) in the cetuximab arm in comparison with bevacizumab (62% vs. 38%). No OS difference in outcome was noted between arms after resection, suggesting that preoperative cetuximab does not worsen postoperative outlook when compared with a bevacizumab backbone (Table 1).

Both bevacizumab and cetuximab are justified in the setting of unresectable, potentially-resectable mCRC. Since the majority of these patients do not attain resectability, the integration of biologic therapy in the first-line setting is recom-

TABLE 1. Biologicals in Initially Non-Resectable CRC Liver Metastases

	Study Design	Treatment Arm	Comparator Arm	RR and Resection Rate	PFS/OS
Gruenberge et al[15] 2015	Randomized phase II clinical trial 80 patients Primary endpoint: overall resection rate	FOLFOX/BV	FOLFOXIRI/BV	Favors FOLFOXIRI arm RR: 81% vs. 62% Resection rate: 61% vs. 49% R0: 49% vs. 23%	Favors FOLFOXIRI arm PFS 18.6 vs. 11.5 months
Ye et al[24] 2013	Randomized phase III trial of 138 patients (*KRAS*-WT) Primary endpoint: conversion rate to radical resection	FOLFOX	FOLFOX/Cmab	Favors Cmab arm Resection rate: 29% vs. 13% R0: 26% vs. 7%	Favors Cmab arm PFS (HR 0.6, p = 0.04) OS (HR 0.54, p = 0.013)

Abbreviations: RR, response rate; PFS, median progression-free survival; OS, median overall survival; HR, hazard ratio; BV, bevacizumab; Cmab, cetuximab; WT, wild type.

mended in view of its positive effect on PFS and OS. In the setting of *RAS*-mutant type (MT) or *BRAF*-MT tumors, one would favor the use of FOLFOXIRI/bevacizumab in younger good performance status (PS) cases. In the setting where a doublet chemotherapy is chosen (more limited PS, older, etc.), an anti-EGFR addition is a reasonable choice in *RAS*-WT tumors given its more pronounced effect on downstaging compared with bevacizumab.

BIOLOGIC THERAPY IN NON-RESECTABLE MCRC

The choice of biologic therapies in mCRC is often considered in view of the genetic profile of the tumor. In this review, we will consider the pros and cons for angiogenesis targeting or EGFR targeting based on RAS and BRAF status.

Biologic Therapies in *RAS*-MT and *BRAF*-MT Tumors

Tumors with *RAS* mutations (exon 2, 3, and 4 of *KRAS* and *NRAS*) constitute approximately 50% of tumors; whereas, patients with *BRAF* mutations constitute 5% to 10% of patients with colorectal cancer.[28,29] Patients with *RAS*-MT tumors derive no benefit from the addition of anti-EGFR therapy to chemotherapy.[30] To the contrary, the addition of cetuximab to oxaliplatin-based chemotherapy has been associated with worsening in multiple outcome parameters.[28,29,31] The benefits of bevacizumab in mCRC have been shown to transcend *RAS* or *BRAF* mutational status and, therefore, the benefits reported on from phase III clinical trials from molecularly unselected patients with mCRC can be extrapolated to both *RAS*-WT and *RAS*-MT tumors.[32,33]

Targeted Therapy in the First-Line Treatment

The only angiogenesis-targeting agent to show improvement in PFS and OS in the first-line treatment of mCRC is bevacizumab. These studies were performed in *RAS* and *BRAF* unselected patients but can be extrapolated to the *RAS*-MT population.[32,33] The only phase III study to report a significant improvement in OS was the AVF2107 study. AVF2107 randomized patients to irinotecan and 5-FU/leucovorin with or without bevacizumab.[34] Subsequent first-line phase III

studies have consistently confirmed an advantage to the addition of bevacizumab to several fluoropyrimidine-based backbones, albeit with a PFS primary endpoint.[35-37] The advantage of the incorporation of bevacizumab in first-line treatment of mCRC has been particularly notable in the setting of fluoropyrimidine monotherapy.[37] The addition of bevacizumab to FOLFOX or XELOX has resulted in a clinically modest improvement in PFS and insignificant improvement in OS.[35] Given the favorable toxicity profile of bevacizumab and its reproducible positive effect on PFS, it is recommended that this agent is considered in the first-line treatment of patients with *RAS*-MT or *BRAF*-MT cancer (and as an option for *RAS*-WT as discussed below). Since anti-EGFR therapy is not an option in this setting, this is considered the only viable option for targeted therapy in this population. The reader is directed to our recent review on targeted therapy for further details on this topic.

There is no convincing evidence that patients with *BRAF*-MT mCRC derive a clinically significant benefit from anti-EGFR therapy.[35,38] Significant progress is being made through the concurrent targeting of EGFR and BRAF (with or without MEK) in this population.[39,40] However, such strategies are still considered investigational. Therefore, consideration of front-line addition of bevacizumab should be made in this subgroup of patients. However, the outlook of these patients continues to be dismal. Recent subgroup analysis from the TRIBE clinical trial has suggested a benefit from FOLFOXIRI/bevacizumab in comparison with FOLFIRI in patients with *BRAF*-MT disease.[1] Given the aggressive biology of *BRAF*-MT cancers, consideration for up-front FOLFOXIRI/bevacizumab should be considered in the younger fit individuals.

Targeted Therapy in the Second-Line Treatment

The value of bevacizumab in the second-line treatment of patients with previously bevacizumab-naive disease who progressed on a first-line therapy of irinotecan plus 5-FU has been confirmed through the ECOG 3200 clinical trial.[41] In this study, patients receiving FOLFOX/bevacizumab experienced a superior response rate, PFS, and OS than the

FOLFOX control arm (Table 2). However, in clinical practice, most patients who proceed to second-line treatment have had prior bevacizumab exposure. Three randomized phase III clinical trials have now reported on angiogenesis targeting post-bevacizumab progression.[41-43] The results of these studies are summarized in Table 2. Both the ML18147 and RAISE clinical trials mandated prior progression on a bevacizumab-based therapy and resulted in significant improvements in PFS and OS in favor of bevacizumab and ramucirumab.[44] The VELOUR clinical trial included both patients with bevacizumab-naive and bevacizumab pretreated disease and resulted in significant improvement in PFS and OS in the overall population. None of the three trials showed an improvement in response rate in the patients who were bevacizumab-pretreated. The three agents investigated are different biologically with bevacizumab being directed toward VEGF-A, aflibercept toward VEGF-A, VEGF-B and PlGF, and ramucirumab toward VEGFR-2. Although no head-to-head comparison among these agents have been performed to date, bevacizumab has been associated with the most favorable safety profile, whereas, concerns have been raised regarding the increased toxicity of aflibercept when combined with chemotherapy.[43] All three antiangiogenic agents are considered acceptable options for second-line treatment, with a preference toward bevacizumab given its more established safety profile. Although bevacizumab can be considered across different backbones in the second-line treatment, aflibercept and ramucirumab should only be considered with FOLFIRI. No clinical or biologic biomarkers have been identified to direct treatment toward any of these three biologicals in the setting of second-line FOLFIRI.

Targeted Therapy in Chemotherapy-Refractory or Resistant Colorectal Cancer

The CORRECT clinical trial[45] enrolled patients with mCRC who progressed after or were intolerant of fluoropyrimidines, oxaliplatin, irinotecan, and anti-EGFR therapy (in *KRAS*-WT). All patients had received prior bevacizumab. The study showed a significant clinically modest improvement in OS (median OS 6.4 vs. 5 months; HR 0.77; 95% CI, 0.64 to 0.94; one-sided p = 0.0052). Consideration for single-agent regorafenib can therefore be made after progression on all standard chemotherapy.

Biologic and Targeted Therapies in *RAS*-WT Tumors

It is important to note that the recommendations regarding antiangiogenesis therapies reported above for the *RAS* or *BRAF*-MT populations apply equally to the *RAS/BRAF*-WT population. On the other hand, the management of the *RAS/BRAF*-WT population is complicated by the proven effectiveness of anti-EGFR therapy across all lines of treatment. Therefore, treatment decisions in patients with *RAS/BRAF*-WT disease have to factor in efficacy and toxicity data with both classes of targeted agents. In this section we address the effect of anti-EGFR agents in this group of patients, and when feasible, put it in context of antiangiogenic therapies.

Targeted Therapies in the First-Line Treatment of *RAS*-WT mCRC

The CRYSTAL clinical trial evaluated the combination of FOLFIRI with cetuximab compared with FOLFIRI alone in the first-line treatment of mCRC.[46] No benefit was noted in the *KRAS*-MT (exon-2) population, whereas, a significant

TABLE 2. Angiogenesis Targeting in the Second-Line Treatment of mCRC

Abbreviations: mCRC, metastatic colorectal cancer; OS, overall survival; Cmab, cetuximab; Pmab, panitumumab; RR, response rate; PFS, progression-free survival; HR, hazard ratio; EGFR, epidermal growth factor receptor; OR, odds ratio; WT, wild type.

improvement in response rate, PFS, and OS was noted in the *KRAS*-WT subgroup.[46] Subsequent analysis based on *RAS*-WT (no *KRAS* or *NRAS* exon 2–4 mutations) showed even more robust improvements in PFS and OS than the *KRAS*-WT population (Table 3).[47] Similar benefits were noted with panitumumab with a FOLFOX backbone on the PRIME clinical trial (Table 3).[28] Two other phase III clinical trials failed to show a survival advantage for cetuximab in *KRAS*-WT tumors in the first-line setting (Table 3).[29,48] The NORDIC trial used a nonconventional bolus fluoropyrimidine-oxaliplatin regimen.[48] The COIN trial included XELOX as a chemotherapy backbone, which was associated with increased toxicities when combined with cetuximab and, therefore, potentially confounding cetuximab efficacy.[29] In addition, the lack of benefit on the NORDIC trial may have been confounded by a detrimental effect for cetuximab in the patients with *KRAS* (exon 3 and 4) and *NRAS* mutations who were included in the study analysis.

Three randomized first-line studies investigated bevacizumab compared with anti-EGFR therapy in the first-line treatment of *KRAS*-WT tumors (Table 4).[2,31,49] All three studies have reported efficacy data based on *RAS*-MT. The FIRE-3 and CALGB 80405 studies confirmed an improved response rate in favor of anti-EGFR therapy, no difference in PFS among arms, but diverted in the OS results. The FIRE-3 clinical trial showed an improvement in OS in *RAS*-WT tumors favoring cetuximab, whereas, no difference was noted in the CALGB 80405 study (Table 4).[2,49,50] The reason behind this difference in OS is unclear. A difference in postprogres-sion salvage rate with anti-EGFR therapy in the bevacizumab arms could very well have contributed to these variations in outcome. Other contributing factors could be variations in treatment compliance, dose intensity, and early treatment discontinuation because of toxicity, all of which are yet to be reported on CAALGB 80405. The PEAK clinical trial is a smaller randomized phase II clinical trial of FOLFOX/pani-tumumab compared with FOLFOX/bevacizumab.[31] The results from this study were somewhat consistent with the FIRE-3 clinical trial (Table 4). For further review, please refer to our recent review on this topic.

Both bevacizumab and anti-EGFR therapy are considered appropriate options in the first-line treatment of metastatic cancer. Given the increased down-staging potential of anti-EGFR therapy in the first-line setting compared with bevacizumab, this may be the more preferable biologic agent in the potentially resectable cases, especially when FOLFOXIRI (with or without bevacizumab) is contraindicated. In addition, anti-EGFR therapy is preferred in patients with higher risk for perforation (bulky primary, significant carcinomatosis) or with known risk factors for arterial thrombotic events. Bevacizumab is more preferable in patients who want to avoid skin toxicity.

Targeted Therapies in the Second-Line Treatment of *RAS*-WT mCRC

Although anti-EGFR therapy clearly increases the response rate and PFS in patients with *RAS*-WT mCRC, no studies have reported an improvement in OS in this setting (Table 5).[38,51,52] Two studies

evaluated cetuximab and panitumumab in the setting of single-agent irinotecan.[38,51] The EPIC trial did not select patients based on *RAS* status but reported improvements in response rate and PFS.[51] The PICCOLO study excluded patients with *KRAS* codon 12, 13, and 61 mutations and showed an improvement in response rate and PFS, but no benefit in OS.[38] The 20050181 study randomized patients to FOLFIRI plus panitumumab compared with FOLFIRI in patients with *KRAS* (exon-2) WT disease.[52] A significant improvement in response rate and PFS was noted on the panitumumab arm. A recent update on this study showed further accentuation of benefit in favor of panitumumab in the *RAS*-WT population (Table 5).[53]

It is unclear at this time what the best strategy is for a biologic therapy in the second-line setting of *RAS*-WT tumors after progression on first-line bevacizumab-based combinations. The continuation of bevacizumab or a switch to anti-EGFR– based therapy (in the setting of irinotecan-based backbone) is acceptable. However, in the setting where down-staging is important, anti-EGFR therapy is more appropriate.

Targeted Therapies in the Third-Line Treatment of *RAS*-WT mCRC

There is no current data to support the continuation of bevacizumab in the third-line treatment in mCRC. In patients who have progressed on all cytotoxic chemotherapies, the combination of anti-EGFR plus irinotecan is considered the most appropriate choice in patients with good PS who are irinotecan tolerant.[54] The use of cetuximab or panitumumab monotherapy in this setting is also considered appropriate based on the C017 and the ASPECCT trials (Table 6).[55,56] Regorafenib should only be considered after failure (or intoler-

ance) of all cytotoxic and anti-EGFR therapy. It is important to note that no randomized data have reported on anti-EGFR recycling and that the above recommendations in the second- and third-line treatment with anti-EGFR therapy are based on clinical trials of patients with anti-EGFR naive disease. The question of recycling is an important research question given the *RAS*-mutation emergence in the setting of anti-EGFR therapy. It is possible that prolonged breaks after anti-EGFR progression allow for tumor reconstitution with anti-EGFR sensitive clones resulting in further benefit from anti-EGFR rechallenge. A small phase II clinical trial supports this concept; however, more studies are needed to confirm these findings and to identify the patients who would best benefit from this strategy.[57]

Systemic Treatment: Maintenance Compared with Holiday

Cornelis J.A. Punt, MD, PhD, Lieke H.J. Simkens, MD, and Miriam Koopman, MD, PhD

OVERVIEW

With the currently available cytotoxic and targeted drugs, metastatic colorectal cancer (mCRC) may be controlled by systemic treatment for a substantial period of time. However, many questions remain about the optimal use of drugs and duration of treatment. The feasibility of chemotherapy-free intervals has been studied in patients with mCRC treated with chemotherapy alone, but the results are conflicting. Current data show that oxaliplatin may be safely interrupted, but they do not allow a firm conclusion on the safety of a full treatment break of chemotherapy. For targeted therapy, continuous inhibition of intracellular signaling by prolonged administration would theoretically be beneficial for efficacy of treatment. Recent data support the use of maintenance treatment with chemotherapy and bevacizumab. No data on the optimal duration of treatment with anti-epidermal growth factor receptor (EGFR) agents are currently available.

Colorectal cancer is the second most common cause of cancer deaths worldwide, and its incidence is still increasing. Approximately 50% of the patients will eventually develop distant metastases, which may be treated with surgical resection and/or systemic treatment. The systemic treatment for mCRC has changed substantially over the past 20 years. Currently available drugs with proven efficacy can be classified as cytotoxic (i.e., classic chemotherapy) and targeted drugs (e.g., antibodies, small molecules). A large number of patients respond well to treatment, and many patients often ask for drug holidays. If this would not compromise survival, a drug holiday could increase quality of life (QoL) and would reduce health care costs. This paper will review the data on the optimal duration of treatment.[1]

CHEMOTHERAPY

Effective cytotoxic drugs in mCRC include the fluoropyrimidines, irinotecan, and oxaliplatin. These drugs are the backbone of systemic treatment of mCRC. There is no outright preference for either oxaliplatin or irinotecan in first-line combination schedules.[2] Retrospective studies have shown that the exposure to these three cytotoxics during the course of disease appears more important than their up-front combined use.[3-5] This has been confirmed by the results of subsequent prospective studies, of which the results showed no benefit for up-front combination treatment over sequential treatment starting with fluoropyrimidine monotherapy.[6,7] The choice between combination or sequential therapy may depend on several factors, such as tumor-related symptoms, potential resectability of metastases, and performance sta-

tus.[8] As a result of the improved outcome of treatment, an increasing number of patients continue to do well on chemotherapy. Objective responses are usually achieved within the first 4 to 6 months of treatment.

Optimal Duration of Chemotherapy

The optimal duration of treatment is still a matter of debate, with no consensus on whether chemotherapy should be continued until disease progression or that a chemotherapy break is justified after the maximum response has been achieved. Furthermore, in case of intermittent treatment, it is unknown whether treatment should be resumed after a predefined interval or at disease progression. The feasibility of chemotherapy-free intervals has been studied, but the results are conflicting. In a Medical Research Council study, patients with stable disease or better after initial 12 weeks of chemotherapy were randomly selected to receive continuous or intermittent treatment, with resumption of the initial treatment on progression.[9] No survival difference was observed between the continuous and intermittent treatment arm. However, a large number of eligible patients refused to be randomly assigned or received unplanned treatment on progression. The availability of oxaliplatin introduced the problem of handling its most relevant toxic effect: the sensory neuropathy. The question arose whether intermittent treatment with oxaliplatin could reduce neurotoxicity without a detrimental effect on efficacy. The OPTIMOX1 study randomly selected previously untreated patients with mCRC to receive oxaliplatin in combination with 5-fluorouracil (5-FU)/leucovorin (LV; FOLFOX4) until progression or six cycles of FOLFOX7, followed by maintenance treatment with

5-FU/LV for 12 cycles and then reintroduction of FOLFOX7 until progression.[10] There was no significant difference in median progression-free survival (9.0 vs. 8.7 months, hazard ratio [HR] 1.06, p = 0.47) or overall survival (19.3 vs. 21.2 months, HR 0.93, p = 0.49). In the intermittent treatment arm, a decreased incidence of toxicity was observed. Oxaliplatin was reintroduced in this treatment arm in 40% of the patients, in whom disease control was achieved in 70%. The authors concluded that oxaliplatin can be safely discontinued after six cycles. Next, the OPTIMOX2 trial was conducted to evaluate the strategy of discontinuation of all oxaliplatin-based chemotherapy compared with maintenance with 5-FU/LV after induction treatment with FOLFOX7.[11] In both arms, FOLFOX was reintroduced on disease progression, which, different from RECIST criteria, was defined as the time point at which tumors had regained their initial pretreatment size. The median progression-free survival was significantly prolonged in the maintenance arm as compared to the chemotherapy-free interval arm (8.6 vs. 6.6 months, respectively; HR 0.61, p = 0.017), but there was no significant difference in median overall survival (23.8 vs. 19.5 months; HR 0.88, p = 0.42). However, the trial was discontinued early because of the registration of bevacizumab, and therefore, no definite conclusions could be drawn. QoL was not evaluated in either OPTIMOX1 or OPTIMOX2.

The COIN trial also investigated intermittent compared with continuous chemotherapy.[12] Patients were randomly assigned to continuous oxaliplatin plus 5-FU/LV (FOLFOX) or capecitabine (CAPOX) or the same regimen given for 12 weeks with resumption of treatment on disease progression. Patients on intermittent treatment did spend less time on treatment, had substantially less toxicity, and scored better on several QoL symptom scales (but not on QoL global scales). Median overall survival in the continuous and the intermittent group was 15.8 and 14.4 months, respectively (HR 1.08, p = 0.60). Patients with elevated baseline platelet counts did perform poorly on intermittent treatment. The authors concluded that although noninferiority was not shown for intermittent treatment, chemotherapy-free intervals may be a treatment option for selected patients.

For irinotecan-based chemotherapy, two studies investigated whether continuous treatment was superior to a defined period of treatment. In a study by Lal et al, patients with stable disease or better after eight cycles of irinotecan in second line were randomly assigned to continuation or discontinuation of irinotecan until disease progression.[13] Only 17% of the patients who received second-line irinotecan were eligible for randomization, leaving 55 evaluable patients. There was no difference in median progression-free survival or overall survival between the two treatment arms. Furthermore, QoL was comparable in both arms. Although these results suggest that irinotecan can be safely discontinued after eight cycles, this study was underpowered. In the GISCAD study,[14] a total of 337 patients were randomly selected to receive intermittent treatment with FOLFIRI given in a 2-months-on 2-months-off schedule or continuous treatment with FOLFIRI—both until disease progression. The intermittent schedule was not inferior to continuous treatment for the primary endpoint of overall survival nor for progression-free survival or response rate. Furthermore, toxicity profiles were comparable, which is not surprising, as the toxicities of irinotecan are usually not cumulative. QoL was not evaluated in this study. The authors concluded that the intermittent use of FOLFIRI does not decrease its efficacy compared to its continued use.

These data show that QoL has been investigated in only a few studies that address the benefit of intermittent compared with continuous treatment. Although palliative chemotherapy by definition should primarily strive for the relief or the delay of symptoms, it has been shown that patients' main incentive to accept palliative chemotherapy in advanced CRC trials is prolongation of life rather than improvement of QoL.[15,16] With the observed small or absent differences between the treatment strategies in the aforementioned trials, data on QoL would therefore be helpful to discuss these strategies with patients.

TARGETED THERAPY

Targeted drugs with efficacy in mCRC include bevacizumab—an antibody against vascular endothelial growth factor A (VEGF)—and cetuximab and panitumumab—antibodies against the EGFR.[17] More recently, aflibercept—a recombinant fusion protein that blocks the activity of VEGF and placental growth factor[18]—and regorafenib—a multikinase inhibitor that blocks the activity of several protein kinases involved in tumor angiogenesis, oncogenesis, and the tumor microenvironment— have shown efficacy in patients with mCRC.[19] Bevacizumab and aflibercept are used in combination with chemotherapy, and the anti-EGFR antibodies may also be used as monotherapy. The currently available data support use of regorafenib only as monotherapy. Bevacizumab has shown survival benefits with fluoropyrimidine-containing chemotherapy and is currently considered as a standard first-line treatment option for patients with mCRC.[20-24] In second line, bevacizumab also improved progression-free survival and overall survival in combination with FOLFOX chemotherapy.[25] This latter study showed no benefit for bevacizumab monotherapy. The benefit of the anti-EGFR antibodies panitumumab and cetuximab is restricted to patients with a *RAS* wild-type tumor.[26] These antibodies have shown survival benefits with chemotherapy in first line[27-29] and

---

KEY POINTS

- Maintenance treatment with capecitabine plus bevacizumab is effective.
- Current data do not support the use of bevacizumab monotherapy.
- The optimal treatment duration of anti-EGFR therapy is unknown.
- For chemotherapy, current data do not allow a firm conclusion on the safety of a full treatment break.
- Oxaliplatin can be safely discontinued and re-introduced at progression of disease.

second line,[30] as well as monotherapy in late line.[31,32] Bevacizumab should not be combined with an anti-EGFR antibody.[33,34] In patients with *RAS* wild-type tumors, there appears no outright benefit for either bevacizumab or anti-EGFR antibody treatment in combination with first-line chemotherapy, although some studies show a yet unexplained survival benefit for starting with anti-EGFR treatment.[35-37] Aflibercept has shown efficacy in combination with FOLFIRI for patients with mCRC previously treated with an oxaliplatin-containing regimen, with or without bevacizumab.[18] For patients with mCRC whose disease progressed on these standard therapies, regorafenib increased overall survival compared with best supportive care.[19]

Optimal Duration of Targeted Therapy

Targeted therapy is characterized by the inhibition of intracellular signal transduction pathways that are relevant for tumor growth. RECIST criteria appear to be less suitable to evaluate its effects.[38,39] Theoretically, discontinuation of a drug that inhibits growth signals could result in tumor regrowth. This would favor its prolonged administration, which is, however, associated with a higher risk for toxicity and increased health care costs. The first data that supported the prolonged use of bevacizumab came from the NO16966 study.[22] In this study, first-line bevacizumab in combination with oxaliplatin-based chemotherapy showed only a modest increase in the primary endpoint of progression-free survival compared to chemotherapy alone (9.4 vs. 8.0 months; HR 0.83, p = 0.0023). However, compared to the initial registration study,[20] in the NO16966 study, a much lower percentage of patients received bevacizumab until disease progression or death. The relevance of this was shown by the results of a planned subset analysis of NO16966, taking into account only progression or death events occurring within 28 days from the last dose of any component of the study. In this analysis, the results of the chemotherapy-alone treatment were comparable with the overall analysis, but the median progression-free survival for chemotherapy plus bevacizumab was increased (HR 0.63). Further support for the benefit of prolonged use of bevacizumab comes from observational studies in which investigators could decide whether or not to continue bevacizumab after disease progression on first-line treatment, with a switch in the chemotherapy regimen.[40] Patients who continued bevacizumab beyond progression had increased overall survival. In an experimental model, bevacizumab beyond progression resulted in measurable changes in the tumor proliferation and microenvironment compared to discontinuation of bevacizumab.[41] The clinical observation was confirmed, albeit with a smaller benefit, in a prospective randomized study.[42] In this study, patients with mCRC with disease progression up to 3 months after discontinuing first-line chemotherapy plus bevacizumab were randomly assigned to second-line chemotherapy with or without bevacizumab. Median overall survival (primary endpoint) was significantly better in patients treated with bevacizumab (HR 0.81, p = 0.0062). The MACRO trial prospectively investigated the use of maintenance treatment of bevacizumab monotherapy in first line.[43] After six cycles of capecitabine, oxaliplatin, and bevacizumab, patients were randomly selected to receive either the continuous administration of this schedule or bevacizumab monotherapy. Noninferiority was not confirmed. The primary endpoint—median progression-free survival—was 10.4 compared with 9.7 months for the continuous and the monotherapy bevacizumab arm, respectively (HR 1.10, p = 0.38). Of note, patients were randomly selected at the start of first-line treatment, and therefore, the inclusion of patients who did not complete the first six cycles of induction therapy may have influenced the outcome. Furthermore, the efficacy of bevacizumab monotherapy may be questioned.[25,44] The SAKK 41/06 study assessed the efficacy of continuing treatment with single-agent bevacizumab after induction therapy with chemotherapy and bevacizumab.[45] In this phase III trial, patients with mCRC without disease progression after 4 to 6 months of standard first-line chemotherapy plus bevacizumab were randomly assigned to bevacizumab monotherapy or observation. Noninferiority of the primary endpoint time to progression (TTP) could not be demonstrated for treatment holidays compared with continuation of bevacizumab. Median TTP was 4.1 months for bevacizumab continuation compared with 2.9 months for no continuation (HR 0.74; 95% CI, 0.58 to 0.96). There was no difference in median OS between the treatment arms (HR 0.83, p = 0.2).

The CAIRO3 study of the Dutch Colorectal Cancer Group provided prospectively collected data on the optimal duration of treatment with chemotherapy and bevacizumab.[46] This study randomly selected patients with stable disease or better after six cycles of initial therapy to receive capecitabine, oxaliplatin, and bevacizumab and observation or maintenance therapy with continuous low-dose capecitabine and bevacizumab. Maintenance treatment significantly improved the first TTP (HR 0.43, p < 0.0001), the second TTP (primary endpoint) after reintroduction of capecitabine, oxaliplatin, and bevacizumab (HR 0.67, p < 0.0001), and the second TTP after any treatment following first progression (HR 0.68, p < 0.001). Toxicity of maintenance treatment was acceptable, and QoL did not deteriorate. Median overall survival was also improved by 3.5 months with maintenance treatment, but this was not statistically significant (HR 0.83, p = 0.06). However, the trial was not powered to demonstrate a benefit in overall survival. Notable survival benefits were observed in selected patient subgroups (e.g., patients with a complete or partial response as best response to induction treatment, and patients with synchronous metastatic disease and resected primary tumor). The main conclusion of CAIRO3 is that maintenance treatment with capecitabine plus bevacizumab is effective. The AIO 207 trial compared (1) maintenance treatment with a fluoropyrimidine plus bevacizumab, (2) bevacizumab alone, and (3) observation after induction treatment of 6 months with a fluoropyrimidine, oxaliplatin, and bevacizumab.[47] Maintenance treatment with bevacizumab alone was noninferior compared to chemotherapy plus bevacizumab for the primary endpoint: time to failure of treatment strategy. Noninferiority could not be demonstrated for no treatment. The main characteristics of

TABLE 1. Main Differences in Design of CAIRO3 and AIO 207 Trials

	CAIRO3	AIO 207
Patients	556	476
Design	Two-arm superiority	Three-arm noninferiority
Primary Endpoint	PFS2	TFS
Treatment Period Prior to Randomization	4.5 mo	6 mo
Exclusion of Patients Who Did Not Tolerate (Part of) Induction Treatment	Yes	No
Reintroduction of Oxaliplatin (%)	47%-60%	21%-45%

Abbreviations: PFS2, progression-free survival as measured by disease progression or death after reintroduction of capecitabine, oxaliplatin, and bevacizumab following either maintenance treatment with capecitabine plus bevacizumab or observation; TFS, time to failure of strategy, progression, or death after reintroduction of fluoropyrimidine, oxaliplatin, and bevacizumab following either maintenance treatment with fluoropyrimidine plus bevacizumab, bevacizumab alone, or observation.

CAIRO3 and AIO 207 are shown in Table 1. Although the design of AIO 207 was less straightforward than CAIRO3, the AIO 207 data support the use of fluoropyrimidine plus bevacizumab maintenance treatment.

For anti-EGFR treatment, only data from the NORDIC trial provide some insight on its optimal duration of treatment. This trial investigated treatment with first-line cetuximab with continuous or intermittent chemotherapy (fluorouracil, leucovorin, and oxaliplatin [FLOX]) compared with FLOX alone.[48] Cetuximab did not add a notable benefit to FLOX chemotherapy, neither given continuously nor given intermittently. No difference was found within subsets of patients with KRAS wild-type or mutant tumors; however, the study was not sufficiently powered for these subgroup analyses. The GERCOR DREAM study showed positive results for maintenance treatment with erlotinib—an EGFR tyrosine kinase inhibitor—in combination with bevacizumab.[49] After initial treatment with chemotherapy (FOLFOX, CAPOX, or FOLFIRI) and bevacizumab, patients with mCRC were randomly assigned to maintenance treatment with bevacizumab with or without erlotinib. The primary endpoint was progression-free survival on maintenance treatment, which was significantly better for patients treated with both drugs. However, the absolute benefit in median progression-free survival was only 1.1 month (HR 0.76, p = 0.010). Median OS was also significantly better for patients treated with maintenance treatment with bevacizumab plus erlotinib compared to bevacizumab monotherapy, 24.9 compared with 22.1 months, respectively (HR 0.79, p = 0.035). The NORDIC ACT trial had a similar design, randomly selecting patients to receive maintenance treatment with bevacizumab with or without erlotinib after induction treatment with chemotherapy (CAPIRI, CAPOX, FOLFIRI, OR FOLFOX).[50] The primary endpoint progression-free survival was not significantly different between the two arms, 5.7 compared with 4.2 months, respectively (HR 0.79, p = 0.12). Also median overall survival was comparable in both arms (HR 0.88, p = 0.51). Given the fact that the value of erlotinib has not been demonstrated in mCRC and that the efficacy of bevacizumab monotherapy is not supported by results of other trials, the implications of the DREAM and NORDIC ACT trial results for general practice are difficult to assess.

CONCLUSION

For the palliative treatment of patients with mCRC with chemotherapy alone, current data do not allow a firm conclusion on the safety of a full treatment break. The benefit of a drug holiday with a possible detrimental effect on outcome must be weighed against the toxicity and possibly decreased QoL that is associated with continuous treatment. In case of the use of combination chemotherapy with oxaliplatin, the chemotherapy may be reduced to fluoropyrimidine monotherapy during the maintenance phase, with reintroduction of oxaliplatin on progression. As to the use of targeted therapy, current data do not support the use of maintenance treatment with bevacizumab monotherapy. No data are available on the optimal duration of anti-EGFR antibody treatment. Data from the CAIRO3 and AIO 207 study support the use of maintenance treatment with chemotherapy and bevacizumab. Therefore, with bevacizumab being part of standard first-line treatment schedules, current data support the use of maintenance treatment with bevacizumab in combination with chemotherapy. Further studies should provide data on specific subgroups in which maintenance treatment is most effective.

Treatment of Peritoneal Carcinomatosis of Colorectal Origin

Andrea Cercek, MD, James C. Cusack Jr, MD, and David P. Ryan, MD

OVERVIEW

The management of peritoneal carcinomatosis from colon cancer remains a controversial issue. Peritoneal carcinomatosis is associated with worse survival and has led to an aggressive treatment that combines surgery and intraperitoneal chemotherapy (IPC). This review will describe the rationale behind this treatment and the current controversy surrounding it.

Metastatic colon cancer is generally considered incurable except for the setting of metastases that are isolated to the liver or lung and can be resected. During the last 20 years, there has been a marked improvement in the survival of patients with metastatic colon cancer because of the development of multiple anticancer drugs such as irinotecan, oxaliplatin, antivascular endothelial growth factor therapy, and anti-epidermal growth factor receptor therapy. When fluorouracil (5-FU) was the only available chemotherapy, the median survival and 5-year survival were 12 months and 1%, respectively.[1] With the advent of combination chemotherapy and multiple lines of therapy, the median survival is now approximately 2 years and the 5-year survival is greater than 20%.[2] Moreover, for those patients with disease isolated to the liver or lung that can be surgically resected, 20% to 40% of patients can be cured by complete resection of these metastases.

METASTATIC COLORECTAL CANCER AND PERITONEAL CARCINOMATOSIS

Peritoneal carcinomatosis is regarded by the patient and physician as one of the most feared ways that colon cancer metastasizes. From a patient's perspective, the presence of peritoneal metastases is not considered curable unlike resectable liver or lung metastases. Additionally, the presence of peritoneal carcinomatosis is associated with a worse overall survival compared with patients who lack any peritoneal carcinomatosis.[3] Additionally, peritoneal carcinomatosis is associated with a high symptom burden including nausea, vomiting, abdominal pain, bloating, and intestinal obstruction. From the doctor's perspective, these symptoms are often very difficult to control because of carcinomatosis and lead to frequent hospitalizations.[4] The degree of symptom burden often precludes the use of standard chemotherapy regimens because of the poor performance status of the patient.[5]

In response to these challenges, investigators have attempted to treat patients with isolated peritoneal carcinomatosis using cytoreductive surgery (CRS) and hyperthermic intraperitoneal chemotherapy (HIPEC). Earlier studies estimated that peritoneal carcinomatosis occurs as the sole site of disease in as many as 25% of patients, but a recent study evaluating the subset of patients with peritoneal carcinomatosis in the North Central Cancer Treatment Group studies 9741 and 9841 demonstrated that 17% of patients (364 of 2,101) enrolled in these two studies had peritoneal carcinomatosis as a component of multisite disease, and only 2.1% of patients (44 of 2,101) had peritoneal carcinomatosis as the sole site of disease.[3] Although the topic of CRS and HIPEC is often debated, the applicability to the management of metastatic colon cancer is uncommon.

CYTOREDUCTIVE SURGERY AND INTRAPERITONEAL CHEMOTHERAPY

CRS was introduced with the goal of removing all gross disease and, thus, prolonging survival.[6] CRS involves surgical resection of visible disease in the abdomen and pelvis (including visceral organs if involved by tumor). The extent of disease is assessed at initial exploration by the surgeon using a peritoneal cancer index (PCI), as initially described by Sugarbaker et al.[7] The abdominal cavity is divided into a grid of nine squares and the small bowel mesentery is separated into four quadrants; each grid or quadrant is scored, based on disease burden, on a scale of zero (no gross disease) to three (extensive disease). Therefore, the extent of disease can range from zero to 39; patients with a PCI of greater than 30 are generally thought to have a low likelihood of having a complete gross cytoreduction. After cytoreduction, a completeness of cytoreduction score (CCR) is then assigned. A CCR of zero signifies that no gross disease remains after CRS, whereas,

Corresponding author: Andrea Cercek, MD, Memorial Sloan Kettering Cancer Center, 505 E. 79th St., New York, NY 10075; email: cerceka@mskcc.org.

a score of one indicates that tumor nodules remain but are all 2.5 mm or less in diameter. Residual disease that is greater than 2.5 mm in diameter is assigned a CCR of two or three depending on the size and extent of the tumor left behind. Cytoreduction is considered to be therapeutic when a CCR of zero or one is obtained, and has been shown to be independently associated with improved survival.[8] However, even with optimal cytoreduction, microscopic disease may be left behind. IPC was, therefore, developed to deliver regional chemotherapy into the peritoneal cavity, thereby attempting to eradicate the remaining microscopic disease.

The initial use of IPC was delivered in the postoperative setting and is known as EPIC (early postoperative IPC). In this approach, a catheter is placed intraoperatively and chemotherapy is administered into the peritoneum on several subsequent postoperative days. The drug most commonly used is floxuridine, which is a fluorinated pyrimidine analog of 5-FU. Although initial reports were promising, there were theoretical concerns of EPIC being unable to perfuse all peritoneal surfaces because of the onset of fibrosis and adhesions. Indeed, after a few cycles, many patients developed nausea, abdominal distension, and pain thought to be related to adhesions.

The advantage of IPC is that it enables the delivery of much higher doses of chemotherapy directly to the cancer cells than could be achieved systemically. First pass hepatic extraction of floxuridine is high, and, thus, high concentrations of floxuridine can be delivered into the peritoneum without substantial systemic absorption and toxicity.[8] For these reasons, many centers have explored and utilized IPC with EPIC after CRS since the early 1990s. To date, however, there are no randomized clinical trials that support its benefit.[9]

In an attempt to improve upon delivery of IPC, intraoperative delivery of heated chemotherapy was developed. HIPEC offers several theoretical advantages. First, it is given during the time of surgery, which minimizes the risk for adhesions. Second, the heated chemotherapy is thought to have

increased cytotoxicity based on animal and preclinical data.[10-12] Of note, a recent study using a rat model showed no benefit to HIPEC.[13]

There were two randomized studies of HIPEC compared with systemic chemotherapy. In the first, Verwall and colleagues randomly assigned 105 patients younger than age 71 to CRS plus HIPEC (using mitomycin C) or systemic therapy (using 5-FU/leucovorin) alone. The patients treated with CRS plus HIPEC had an improved median survival of 22.4 months compared with 12.6 months (p = 0.032).[14] Unfortunately, this study was conducted in the era of 5-FU therapy alone. The incremental survival benefit of 10 months is equivalent to what would be expected with modern systemic chemotherapy using oxaliplatin and irinotecan. Furthermore, the patients were not stratified based on prior 5-FU exposure, so it is not known whether they benefitted or progressed on 5-FU alone. Of the 105 patients, 18 (17%) had appendiceal tumors, which have variable histologies and can at times be more indolent than typical colorectal adenocarcinomas. Second- or third-line chemotherapy with oxaliplatin or irinotecan was not recorded, thus, we cannot learn if these subsequent regimens had an effect on outcome. Additionally, an important difference is noted between median survival of patients in the surgical arm between those who had limited peritoneal disease (29 months) and those with extensive disease (5 months). In the surgical group, 8% of patients died from postoperative complications. In a follow-up publication by Verwall et al with a median follow-up of 8 years, four out of 51 patients were alive in the systemic arm and five out of 54 in the CRS plus HIPEC arm.[15]

The second randomized study was attempted by the French group, Elias and colleagues. Unfortunately, it was terminated early before reaching the target accrual of 90 patients because of poor accrual. Thirty-five patients were randomly selected to receive CRS plus EPIC or CRS alone. EPIC did not appear to improve outcomes, but patients with CCR0 had a 60% 2-year survival.[16]

There are no randomized trials comparing HIPEC with EPIC. Elias et al reported a large retrospective cohort study of 523 patients from 23 centers who were treated with CRS and either HIPEC or EPIC.[17] The median survival was 30.1 months. The overall 1-year, 3-year, and 5-year survival rates were 81%, 41%, and 27%, respectively with a median follow-up of 45 months. The rate of grade 3 to 4 complications was 31% and the death rate was 3.3%. Multivariate analyses revealed that the only factor that correlated significantly with overall survival was the PCI index (p < 0.0001). The use of adjuvant systemic chemotherapy and lymph node status (p = 0.02) were noted but did not reach statistical significance.

In a systematic review of CRS IPC studies and case reports before March 2006, Yan and colleagues reported that 5-year survival rates varied from 11% to 19%. Patients who received complete cytoreduction benefitted most with median survivals between 28 months to 60 months and 5-year survival ranging from 23% to 44%.[18] Interestingly, Chua and col-

KEY POINTS

- Isolated peritoneal carcinomatosis related to colorectal cancer occurs infrequently and is associated with a poor prognosis.
- Therapeutic cytoreduction may be achieved using systemic chemotherapy and/or cytoredcutive surgery (CRS) and intraperitoneal heated chemotherapy (HIPEC).
- Optimal management of peritoneal carcinomatosis is determined by a multidisciplinary care team (medical oncologist and surgeon).
- Stringent selection criteria for patients undergoing CRS/HIPEC may reduce associated morbidity and mortality.
- The timing of CRS/HIPEC should be coordinated by the multidisciplinary care team.

leagues performed a meta-analysis of all CRS HIPEC cases performed between 1995 to 2009. In patients with complete cytoreduction (722 patients) the median overall survival was 33 months (range, 20 months to 63 months) and the median 5-year survival rate was 43% (range 20% to 51%).[19] In contrast, the patients with incomplete cytoreduction had a much poorer outcome with a median overall survival of only 8 months and a 5-year survival of 0%. These findings strongly suggest that appropriate patient selection is key in the success of CRS and IPC.

It is evident that surgically rendering patients free of all disease is associated with an increased chance of cure for patients with isolated liver or lung metastases. Therefore, it is reasonable to conjecture that some patients with isolated and/or limited peritoneal metastases can be resected for cure. Although the surgical series suggest that this may be the case, it is difficult to tease out the independent effects of CRS from IPC since they are given concurrently. A well-designed multicenter randomized controlled trial by the Walter Reed Army Medical Center and the American College of Surgeons (ACOSOG-Z6091) attempted to answer this question, but unfortunately, closed to accrual 1 year after opening in 2011. The primary reason for failure to accrue was patients' perception that randomization to an arm without IPC was unacceptable.

A second French multicenter randomized controlled trial (Prodige 7) recently completed accrual. In this trial, 280 patients with colorectal carcinoma underwent CRS and were randomly selected to receive HIPEC with oxaliplatin over 30 minutes at a minimum of 42°C and preceding intravenous 5-FU/leucovorin bolus or no HIPEC). Data analysis is ongoing. The primary endpoint is 3-year and 5-year overall survival. It is noteworthy that most investigators use mitomycin C as the HIPEC regimen and not oxaliplatin. Thus, the results of this trial might not change their clinical practice. Nevertheless, the results, which are expected to be reported this spring, are eagerly awaited.

MORBIDITY AND MORTALITY

The morbidity and mortality of CRS plus IPC are substantially higher than those of either systemic chemotherapy or CRS alone and should be addressed. In retrospective reviews, the range of postoperative mortality has been reported to range from 0% to 12%.[18] In the two largest studies, including the Dutch randomized study, the range was 3% to 8%.[15,17] Grades 3 and 4 toxicities have been reported in between 23% to 55.6% of patients, including respiratory complications, septic shock, and pulmonary embolism. Hematologic toxicity including hemorrhage, fistulae, peritonitis, cerebral stroke, and renal insufficiency were the most common complications.[15,17,18] In addition, there is a steep learning curve associated with performing CRS/HIPEC, requiring approximately 140 procedures to develop expertise.[20] Similarly, a more recent study found that approximately 180 and 90 CRS/HIPEC procedures

are required to improve operative and oncologic outcomes, respectively.[21] These data exemplify the importance of developing well-organized, multidisciplinary teams that consists of surgeons, perfusionists, anesthesiologists, intensivists, nutritionists, oncologists, and nurse specialists to work together in lowering the associated morbidity and mortality of CRS/HIPEC procedures.

Stringent patient selection is also critical to optimizing operative and oncologic outcomes of patients undergoing CRS/HIPEC. Patients older than 70 and those with significant comorbidities have higher rates of perioperative morbidity and mortality after CRS/HIPEC.[22] To avoid treatment-related morbidity and mortality associated with CRS/HIPEC, high-risk patients may be offered alternative treatments such as systemic therapy alone or CRS alone, particularly in the absence of prospective data that demonstrates the superiority of CRS/HIPEC. The timing of surgery also affects patient outcomes. To coordinate the timing of CRS/HIPEC, patients with metastatic disease confined to the peritoneal cavity should be seen by both the experienced CRS/HIPEC surgeon and the medical oncologist at the time of diagnosis of carcinomatosis or isolated peritoneal disease recurrence. Considerations that influence the timing of CRS/HIPEC include response to systemic chemotherapy, availability of chemotherapy options, and the emergence of treatment-related toxicities. Treatment with effective systemic chemotherapy prior to CRS/HIPEC provides the advantage of reducing the bulk of disease identified at surgery, and, thereby, potentially lowering the initial PCI at the time of CRS/HIPEC.

CONCLUSIONS AND FUTURE DIRECTIONS

Although the data are difficult to interpret because of the lack of large randomized studies and the presence of numerous institutional series, CRS and IPC may provide a benefit to a certain subset of patients with peritoneal carcinomatosis of colorectal origin. The data available do demonstrate that the extent of peritoneal disease greatly affects outcomes. It is conceivable that patients with limited peritoneal disease that can be completely resected (CCR0) may experience a cure, but it is more likely that they will at least achieve better control of disease. The question remains whether the benefit is derived from CRS alone or the addition of IPC. Moreover, if IPC is helpful, it remains debatable whether HIPEC or EPIC is the best route. The French Prodige study will hopefully provide insight into the benefit of adding IPC to CRS. An ongoing study at Memorial Sloan Kettering Cancer Center is evaluating CRS plus HIPEC compared with EPIC in patients with peritoneal carcinomatosis of colorectal or appendiceal origin. As is the case with most therapies, molecular and genetic profiling may identify patients who would benefit from regional therapies. Until these predictive profiles are identified, the optimal approach for patients with peritoneal carcinomatosis will remain controversial.

Hepatocellular Carcinoma Tumor Board: Making Sense of the Technologies

Ghassan K. Abou-Alfa, MD, Jorge Marrero, MD, John Renz, MD, PhD, and Riccardo Lencioni, MD, PhD

OVERVIEW

Hepatocellular carcinoma (HCC) is a leading cause of cancer-related death, with a rising global incidence. The vast majority of HCC cases occur in the setting of liver cirrhosis, mainly due to chronic hepatitis C (HCV) or hepatitis B (HBV) viral infections, alcohol consumption, and nonalcoholic fatty liver disease. The new approval of curative therapy with two NS5A inhibitors, ledipasvir and sofosbuvir, for the treatment of HCV will no doubt affect HCC incidence and outcome. No studies have evaluated the use of the new antivirals in patients with HCC. Staging and scoring remain an integral part of the management of patients with advanced HCC. Curative therapies for the treatment of HCC are evolving. Improvements in surgical techniques and risk stratification for orthotopic liver transplantation (OLT) have expanded access and improved the outlook for patients suffering from HCC. Interventional locoregional treatments continue to play a key role in the management of HCC. Transarterial chemoembolization is considered the standard of care for patients with noninvasive multinodular tumors at the intermediate stage. Bland embolization appears to have similar virtues in some studies. Y90 radioembolization represents a promising treatment option for patients unfit or refractory to transarterial chemoembolization. The advent of sorafenib as a standard of care with an improvement in survival sadly remain the only major breakthrough in the treatment of advanced HCC, with mounting negative data from multiple clinical trials. Advances in immunotherapy and customized therapy may hopefully help reverse this tide.

Hepatocellular carcinoma is a leading cause of cancer-related death, with a rising global incidence.[1] The vast majority of HCC cases occur in the setting of liver cirrhosis, usually because of chronic HCV or HBV, alcohol consumption, nonalcoholic fatty liver disease, among others. Because the majority of patients with HCC have cirrhosis, it is important to understand it and its complications, while we focus on the recent advancements in prevention of cirrhosis-causing etiologies, specifically HCV. This manuscript also addresses the recent developments in the curative and palliative whole treatment armamentarium for HCC from surgery and transplant through local therapies, up to systemic treatment including targeted and immunotherapies.

CIRRHOSIS AND LIVER DYSFUNCTION

Cirrhosis is the outcome of a relentless inflammatory event that ultimately leads to hepatic fibrosis in response to a chronic liver disease (e.g., HCV), to the point where most of the liver parenchyma is replaced by scar. This starts a steady hepatic decompensation phenomenon, along with a risk of developing HCC. Hepatic decompensation includes the development of jaundice, ascites, variceal hemorrhage, hepatic encephalopathy, hepatopulmonary syndrome, or portopul-

monary hypertension. Cirrhosis can be compensated or decompensated, with a 2-year survival of 90% compared with 54%, respectively.[2] HCC is the other important complication of cirrhosis and occurs at an annual incidence rate of 2% to 3%.[3] The presence of cirrhosis and its complications will affect the prognosis and management of patients with HCC. Multidisciplinary management including hepatology is critical in the care for patients with advanced HCC.

The Child-Turcotte classification system was developed in 1964 to risk-stratify patients undergoing shunt surgery for portal decompression at the University of Michigan. In 1972, Pugh modified the Child-Turcotte system, and it became known as the Child-Turcotte-Pugh score, also known for short as the Child-Pugh score. The Child-Pugh score is composed of levels of albumin, prothrombin time, and total bilirubin and also with the presence or absence of clinical hepatic encephalopathy and ascites. Based on these variables, points are assigned and patients are classified as A, B, or C. Although empirically derived, the Child-Pugh has been shown to accurately predict outcomes in patients with cirrhosis and portal hypertension, and it continues to be used today. Because it is simple and does not require complicated calculation, this tool is widely used by clinicians to assess the risk of mortality in patients with cirrhosis. Another important system to as-

---

sess liver function is the Model for End-Stage Liver Disease (MELD)— composed of serum total bilirubin, serum creatinine, and international normalized ratio—and it has been shown to be better at predicting mortality in patients with cirrhosis when compared to the Child-Pugh score.[4] This combined with its purely measurable parameters made the MELD score instrumental in helping to allocate donated livers for transplant based on the immediate need of the receiving patient. The Child-Pugh continues to be a reference scoring system for the assessment of liver function, and it is included in many HCC clinical trials as a reference. There have been an endless number of prognostic scoring systems for HCC with a continued debate over their validity.[5] However, a measure of hepatic function is important in the assessment of patients with HCC.

ADVANCEMENTS IN THE TREATMENT OF HEPATITIS C

HCV still lacks a preventative vaccine like that of HBV, which has helped decrease the incidence of HCC in high-risk countries. However, recent developments in direct-acting antiviral agents for HCV infection have shown potential to alter the natural history of the infection and, ultimately, affect the incidence of HCC.

Certain antiviral agents act directly on HCV targets, whereas others target host proteins that are vital for the replication of HCV. Among the viral targets are the NS3/4A serine protease, which cleaves the HCV polyprotein, and the NS5B RNA-dependent RNA polymerase. However, another target, the nonstructural protein 5A (NS5A), has claimed success as a therapeutic target for HCV because of its importance in the assembly of the cytoplasmic membrane-bound replication complex and the high potency of its inhibitors both clinically and preclinically.[6]

The US Food and Drug Administration (FDA) approved the combination of two NS5A inhibitors, ledipasvir and sofosbuvir, a fixed, single pill combination for the treatment of HCV.[7] A 12-week course of treatment has shown a sustained virologic response of 90% for genotype 1. When patients with compensated cirrhosis were treated for 12 weeks, there had a sustained response rate of 96%.[8] The ledipasvir and sofosbuvir combination appears to be very well tolerated, with fatigue and headaches as the most common side effects. Another new agent recently approved by the FDA for the treatment of HCV is a pack containing a combination of a protease inhibitor ABT-450 (ritonavir, ABT-450/r), an NS5A inhibitor (ombitasvir), and a nonnucleoside polymerase inhibitor (dasabuvir) plus ribavirin.[9] A 12-week course showed a sustained virologic response of 96.2% (95% CI, 94.5 to 97.9) in genotype 1 infection. The pack was used in compensated cirrhosis, and 12 weeks of treatment led to a sustained virologic response of 92%.[10] This treatment has shown to be well tolerated, with fatigue, nausea, pruritus, and insomnia as the most common reactions.

With the advent of new curative anti-HCV therapy, it is still unclear how this will affect HCC incidence and outcome. No studies have evaluated the use of the new antivirals in patients with HCC.

CURATIVE THERAPIES

Curative therapies for the treatment of HCC are evolving. Improvements in surgical techniques and risk stratification for orthotopic liver transplantation (OLT) have expanded access and improved the outlook for patients suffering from HCC.

Liver Transplantation

HCC was one of the earliest recognized indications for OLT and remains a leading indication for OLT in adults and children today.[11] The proposal of the Milan Criteria by Mazzaferro et al in 1996 was a sentinel event within the transplant community as it was the first successful attempt to stratify disease burden at OLT with post-OLT outcomes.[12] The limits of the Milan criteria are a single lesion of 5 cm or less in diameter or no more than three lesions, none of which are more than 3 cm in diameter. When the Milan criteria are fulfilled, the post-OLT survival of recipients transplanted because of HCC was not significantly different than OLT recipients, with no diagnosis of HCC. This observation led to the subsequent stratification of OLT candidates into those within or outside Milan criteria. The distinction is significant, as candidates within Milan criteria receive prioritization for OLT and are eligible for automatic progression toward OLT that is not dependent on a decline in their physiology.[13] All other wait list candidates progress toward OLT based on their risk of isolated liver failure as determined by their individual MELD scores.

KEY POINTS

- Hepatocellular carcinoma (HCC) continues to have a rising global incidence.
- A 12-week course of treatement with NS5A inhibitors ledipasvir and sofosbuvir has shown a sustained virologic response up to 96% for patients with hepatitis C viral infection genotype 1.
- The Metro Ticket algorithm asserts that the further one deviates from the Milan criteria with respect to tumor burden in applying liver transplant, the higher the "price" one pays with long-term disease recurrence.
- Despite the theoretical potential synergies between locoregional and systemic therapies with antiangiogenic properties such as sorafenib all clinical trials completed so far have failed to provide evidence of a clinical benefit in that setting.
- Sorafenib remains the sole standard of care for advanced HCC with an improvement in survival to 10.7 months compared to 7.9 months for placebo (0.69; 95% CI, 0.55 to 0.87).

When considering OLT for HCC, transplantation is not restricted to patients within Milan criteria. Indeed, there are no limits to the tumor burden that can be addressed by OLT. The only requirements are identification of a recipient, availability of a donor allograft, and a stable mechanism to pay for services and post-OLT immunosuppressive medications. Two groups widely recognized as performing well after OLT who do not meet Milan criteria are patients without cirrhosis with a larger tumor burden and patients who are subsequently downstaged to within Milan criteria by locoregional therapy.[14] Few long-term data exist on the outcomes of down-staging; however, at the present time, down-staging HCC to within Milan criteria is recognized within the transplant community as an indication to resume automatic prioritization toward OLT.

Other institutions, including the University of Chicago, have specific programs to address OLT for patients with cirrhosis with disease burden exceeding the Milan criteria. These programs typically employ aggressive locoregional therapy to obtain local control, with a period of watchful waiting to exclude extra-hepatic disease. Locoregional therapy typically includes transarterial chemoembolization (TACE) or yttrium-90 (Y90) microsphere embolization in conjunction with percutaneous or laparoscopic radio frequency ablation (RFA). Patients who tolerate therapy and demonstrate no evidence disease progression qualify for OLT utilizing extended-criteria donor allografts. Multiple centers have reported excellent long-term survival based on the Metro Ticket algorithm for management of HCC.[15]

The Metro Ticket algorithm, initially proposed by Mazzaferro, simply asserts that the further one deviates from the Milan criteria with respect to tumor burden in applying OLT for HCC, the higher the "price" one pays with long-term disease recurrence.[16] Several groups have proposed alternative classification strategies for HCC. The most notable is the University of California San Francisco criteria that represents a modest expansion of the Milan criteria but lacks long-term follow-up data.[17]

Additional information outside the total number of lesions and their maximal diameter that are valuable in assessing the applicability of OLT to HCC include alpha-fetoprotein, tumor differentiation, and evidence of vascular invasion. Alpha-fetoprotein levels in excess of 1,000 ng/mL at presentation are a poor prognostic indicator for maturation to OLT and should trigger triage to a high-risk protocol.[18] Although not formally a component of an OLT evaluation for HCC, histology consistent with poorly differentiated HCC is also a negative prognostic indicator for maturation to OLT. Our practice does not mandate histology during the evaluation process but to routinely obtain histology at the time of RFA therapy if indicated. Similarly, the observance of vascular invasion, either macroscopically as venous thrombosis/invasion or microscopically on histology, should direct the patient to a high-risk protocol.[18,19]

The UCSF group reported a large series of long-term outcomes among patients who underwent downstaging for potential liver transplantation compared with patients within Milan criteria. Patients outside Milan were categorized as a large single mass (5 cm < diameter ≤ 8 cm), 2 or 3 lesions (3 cm < one mass ≤ 5 cm with total tumor diameter ≤ 8 cm), and > 3 lesions (each ≤3 cm with total tumor volume ≤ 8 cm). Overall results were excellent, with over half of the downstaging group maturing to liver transplantation. The 1- and 2-year cumulative probabilities for dropout were 24.1% and 34.2% in the down-staging group versus 20.3% and 25.6% in the within Milan group (p = 0.04); however, Kaplan-Meier 5-year post-transplant survival and recurrence-free probabilities were not significantly different. In the multivariate analysis, only pretreatment alpha-fetoprotein ≥ 1,000 ng/mL, Child's class cirrhosis significantly predicted dropout.[15,19,20]

Surgical Resection

Surgical resection remains the standard of care for the treatment of HCC. Traditionally, surgical resectability has been a function of disease burden as well as estimation of functional hepatic reserve as determined by the Child-Pugh score. New surgical techniques combined with improved understanding of disease progression in patients with cirrhosis are now challenging this traditional rationale. The surgical technique of associating liver partition with portal vein ligation for staged hepatectomy as advocated by Schadde and others offers the potential to expand surgical resection to a larger tumor burden within the liver.[22] Their data demonstrate that this technique may allow a larger amount of multifocal disease within the liver to be surgically approached and may enhance regeneration. Promising early data suggest efficacy among patients with cirrhosis who are not candidates for OLT. The current donor shortage and the psychosocial/medical/insurance restrictions placed upon candidacy for liver transplantation precludes this from ever displacing surgical resection as the standard of care.

Salvage Transplantation

Improved understanding of the limitations of salvage transplantation has significantly advanced triage of patients between surgical resection and OLT. Salvage transplantation is the practice of OLT following curative surgical resection. Early data supporting the practice of salvage transplantation re-enforced the traditional mantra of exhausting all surgical options before progressing to OLT. However, recent data examining the role of salvage transplantation stratified by indication for cirrhosis is challenging conventional wisdom. When the indication for cirrhosis has been removed from the patient's physiology, as in abstinence from alcohol or eradication of a viral hepatitis, the benefits of salvage transplantation are preserved. However, attempting salvage transplantation in the setting of patients who have ongoing liver injury, as in hemachromatosis, primary biliary cirrhosis, or an untreated viral hepatitis, has very low efficacy. Therefore, a thorough understanding of the patient's underlying liver disease and recognition of continuing liver injury are essential to appropriate selection of therapy. Patients without con-

tinuing liver injury should be triaged to maximally aggressive surgical resection with salvage transplantation reserved for therapeutic failures. Conversely, surgical resection has very little efficacy in all but the most minimal disease burden in the presence of continuing liver injury. As these patients have a low probability of maturing to salvage transplantation, they will benefit from early referral for OLT.[23]

Ablation

Ablation techniques have evolved considerably over the past 20 years and are increasingly used to definitively treat small HCC tumors. Several methods for focal tumor destruction have been developed and clinically tested. Although RFA has been the most popular technique to date, several alternate technologies—including thermal and nonthermal methods— have recently been adopted, as they seem to overcome some of the specific limitations of RFA.[24]

Several studies have reported long-term outcomes of RFA in patients with small, unresectable tumors and Child-Pugh class A liver disease, and they demonstrate 5-year survival rates as high as 50% to 70%.[25] The question remains whether RFA can compete with surgical resection as a first-line treatment for HCC. Randomized clinical trials of RFA and surgery reported to date have failed to provide an unequivocal answer to this question.

Recurrence after surgery or ablation remains a serious concern. A randomized phase III study comparing adjuvant sorafenib to placebo after curative resection or ablation showed no difference in recurrence-free survival (33.4 for sorafenib versus 33.8 months for placebo, hazard ratio [HR] 0.940; 95% CI, 0.780 to 1.134; p = 0.26).[26]

Although 18F-FDG PET-CT is not part of current routine diagnostic work-up for patients with HCC, studies have suggested that uptake of 18F-FDG is associated with poor tumor differentiation and may be a predictor of recurrence and worse outcomes following surgical or locoregional treatment.[27,28] These results will need to be validated in larger prospective cohorts.

PALLIATIVE LOCAL THERAPIES

Interventional locoregional treatments play a key role in the management of HCC. TACE is considered the standard of care for patients with noninvasive multinodular tumors at the intermediate stage. Bland embolization appears to have similar virtues in some studies. Y90 radioembolization represents a promising treatment option for patients unfit or refractory to TACE.

Transarterial Treatments

TACE is the most widely used treatment for patients with HCC unsuitable for radical therapies worldwide.[29] The most important advance in TACE therapy has been the drug-eluting beads for transarterial administration, which have been shown to reduce liver toxicity and systemic drug exposure compared to standard TACE.[30]

Conventional TACE regimens are based on the administration of an anticancer-in-oil emulsion followed by embolic agents. The key component of this procedure is lipiodol, which is used both as a vehicle to carry and localize the chemotherapeutic agent inside the tumor and as an embolic agent for tiny tumor vessels. Randomized, controlled trials and meta-analyses have shown that TACE improves survival with respect to best supportive care, extending the median survival from 16 to 19–20 months.

However, such trials were performed more than a decade ago. Distinct technical advances in the performance of TACE and improved patient selection and management have taken place since the completion of these studies.[31] In a randomized phase II study comparing TACE using LC Bead loaded with 150 mg of doxorubicin to bland transarterial embolization (TAE) with Bead Block microspheres, there was no difference in median progression-free survival (6.2 vs. 2.8 months; p = 0.11) or overall survival (19.6 versus 20.8 months; p = 0.40) for Bead Block and LC Bead, respectively.[32] Given a comparable safety profile, and similar outcomes, the advancement in technology and super selectivity in arterial blockade place the role of added doxorubicin into question.

An unsettled issue in the management of patients treated with embolization is the assessment of tumor response and the criteria for treatment discontinuation. Several recent investigations conducted in the United States, Europe, and Asia have shown that the assessment of tumor response by modified Response Evaluation Criteria in Solid Tumors predicts overall survival in patients with HCC treated with TACE.[33] It has been suggested that TACE should be discontinued in patients in whom an objective response in the treated tumor has not been achieved after two treatment cycles.[34]

Radioembolization

Radioembolization is a form of intra-arterial radiation therapy that was developed to capitalize on the arterial perfusion of HCC, with the aim of delivering radiation tumoricidal doses to liver tumors.[35] Radioembolization with Y90 is challenging the current paradigm of HCC treatment. Multiple centers around the world have provided compelling data that suggest a clinical role in patients with portal vein thrombosis as well as in downstaging to transplantation or conversion of patients with surgically inoperable disease (because of small liver remnant) to potential cure with resection. This approach, however, still lacks randomized, controlled study data.

Combination of Locoregional and Systemic Therapies

The key downside to locoregional treatment is the high rate of tumor recurrence, which exceeds 70% at 5 years after local ablation of early-stage HCC.[36] Several experimental studies have suggested potential synergies between locoregional and systemic therapies with antiangiogenic properties, such as sorafenib. Unfortunately, the clinical trials completed so far failed to provide evidence of a clinical benefit. Such an ap-

proach failed to provide a clinically meaningful improvement in time-to-progression (TTP) compared with drug-eluting bead TACE alone in the randomized phase II SPACE study.[37] Median TTP was 169 days in the sorafenib group and 166 days in the placebo group, (HR 0.797; 95% CI, 0.588 to 1.080; p = 0.072). The phase III trial that compared the efficacy and safety of brivanib with placebo as adjuvant therapy to TACE in patients with unresectable HCC has similarly disappointing results: the median overall survival was 26.4 compared with 26.1 month, respectively (HR 0.90; 95% CI, 0.66 to 1.23; log-rank p = 0.5280).[38]

The combination of locoregional and systemic therapy has so far been investigated mostly in patients with limited tumor burden, for whom antiangiogenic treatment was administered on top of the standard locoregional approach. Another developing idea views systemic and interventional therapies as complimentary modalities, which allows patients with advanced-stage disease to be candidates for locoregional treatments.[39]

SYSTEMIC THERAPY

The advent of sorafenib as a standard of care with an improvement in survival to 10.7 months compared to 7.9 months for placebo (0.69; 95% CI, 0.55 to 0.87; p < 0.001)[40] was a major breakthrough in the treatment of advanced HCC, after decades of disappointing attempts to identify a standard of care therapeutic agent.[41] The past 8 years, however, have been disappointing with mounting negative data from multiple clinical trials. Few studies with promising early robust results may turn the tide around.

First-Line Therapy

A phase II study compared doxorubicin plus sorafenib to doxorubicin plus placebo in 96 patients with advanced HCC and Child-Pugh A.[42] The primary endpoint, median TTP, was 9 months for the doxorubicin and sorafenib arm compared with 5 months for the doxorubicin and placebo arm. An exploratory comparison of overall survival between the two arms showed a significant difference of 13.7 months in favor of doxorubicin and sorafenib compared with 6.5 months for doxorubicin and placebo (p = 0.0049, HR 0.45). A potential synergistic effect between doxorubicin and sorafenib that is based on the dissolve of an inhibitory dimer of ASk-1 and Raf, plus other putative mechanisms, may explain the improved outcome.[43] A large randomized phase III trial comparing the combination of sorafenib and doxorubicin with sorafenib alone in the first-line setting[44] and a phase II study of this regimen in the second-line setting after sorafenib failure[45] are currently underway.

Second-Line Therapy

Several studies evaluating novel therapeutics in the second-line setting have been met with disappointment. These include brivanib[46] and otherwise known active therapies such as everolimus[47] and ramucirumab.[48] The perception of low-hanging fruit when comparing to a placebo in the second-line setting is a reminder of the continued advancement in the total care of patients with HCC who generally are living longer than previously perceived.

The biosynthesis of the nonessential amino acid arginine occurs as part of the urea cycle and is dependent on the enzymes argininosuccinate synthetase and argininosuccinate lyase. Messenger RNA encoding argininosuccinate synthetase is not present in subsets of HCCs; therefore, arginine must be extracted from the circulation. Pegylated arginine deiminase (ADI-PEG 20) is an arginine-degrading enzyme isolated from *Mycoplasma* that is formulated with polyethylene glycol (molecular weight 20 kd). Based on encouraging phase II data,[49] ADI-PEG20 is currently being evaluated in a phase III trial in comparison to placebo with patients with advanced HCC in the second-line setting.[50]

Overexpression of c-MET and its ligand HGF occur in up to 80% of human HCC tumors.[51] Tivantinib, a selective MET receptor tyrosine kinase inhibitor, was evaluated at two doses in a randomized, placebo-controlled phase II trial for patients with advanced HCC in the second-line setting. It was found that patients with high MET-expressing tumors, tivantinib therapy resulted in a median overall survival of 7.2 months compared with 3.8 months for placebo (HR 0.38; 95% CI, 0.18 to 0.81). Considering that high tumoral MET expression was associated with an improved overall survival when compared with low tumoral MET expression (3.8 months versus 9 months, HR 2.94; 95% CI, 1.16 to 7.43), a randomized phase III study of patients with advanced HCC and high MET-expressing tumors only in the second-line setting followed and is currently underway.[52] Cabozantinib, an inhibitor of MET and vascular endothelial growth factor receptor 2, has also shown promising efficacy data in a cohort of 41 patients with advanced HCC.[53] Median progression-free survival for the cohort was estimated at 4.2 months. A phase III study cabozantinib is underway.[54] Because tivantinib and cabozantinib are both multitargeted tyrosine kinases, their antitumor activity is not solely dependent on MET pathway inhibition, and selection for MET overexpressing tumors, such as for tivantinib, may not be warranted when using such class of drug.

Immunotherapy

Immune escapes have been identified to carry a poor outcome with a high likelihood of metastatic spread.[55] Tremelimumab, a monoclonal antibody to cytotoxic T-lymphocyte antigen-4, has demonstrated antitumor activity in patients with heavy pretreated unresectable and metastatic hepatitis C–related HCC.[56] Partial response rate was 17.6% and TTP was 6.48 months (95% CI, 3.95 to 9.14). Similarly data have suggested that program death receptor-1 and program death receptor-1 ligand (PDL-1) can suppress HCC,[57] and several studies are investigating these agents in HCC as monotherapy.[58,59] Preliminary data from a multiarm expansion study of MEDI4736, an anti-PDL-1 antibody in patients with advanced solid tu-

mors including HCC, has shown promise.[60] An expansion study of MEDI4736 was initiated in multiple cancer types including HCC. The study continues to enroll patients and generate more mature follow-up data.

CUSTOMIZED THERAPY

Recent work by many groups has attempted to recognize the key drivers and potential targets for advanced HCC.[61,62] No clear patterns have evolved so far, short of recognizing certain genetic variation in select cohort of patients. A more global approach that attempts to evaluate cohorts of patients with HCC with specific ethnicity and etiology and that correlates genetic findings with clinical outcomes may make headway toward custom-made therapy for patients with advanced HCC. One of such current global efforts led by Memorial Sloan Kettering Cancer Center is also attempting to interrogate the genetic profile of each patient into specific clusters that are yet to be discovered.

Making Sense of Current and Emerging Therapies in Pancreatic Cancer: Balancing Benefit and Value

Daniel H. Ahn, DO, Andrew H. Ko, MD, Neal J. Meropol, MD, and Tanios S. Bekaii-Saab, MD

OVERVIEW

Pancreatic cancer remains the fourth leading cause of cancer deaths in the United States with a dismal prognosis and a 5-year survival of less than 5% across all stages.[1] In 2014, there were approximately 46,420 new cases of pancreatic cancer with only 9% of patients having localized disease.[2] Given that the vast majority of patients present with advanced disease, much of the focus for drug development has been in the metastatic setting, which is evident with the advent of two combination chemotherapy regimens for this indication. Although conventional cytotoxic chemotherapy remains the standard of care, an ongoing search for novel therapeutic approaches continues. We will highlight several new approaches here, with a particular emphasis on immunotherapeutic strategies. We will also introduce concepts regarding the potential economic effects associated with the development and implementation of new treatments in pancreatic cancer.

Conventional cytotoxic chemotherapy remains the standard of care for pancreatic cancer. Table 1 highlights major findings from key clinical trials in advanced pancreatic cancer. Before recent advances, the last significant therapy approved for pancreatic cancer was erlotinib in 2007, based on a phase III randomized control trial showing that this agent when added to gemcitabine improved survival.[3] However, because the degree of survival improvement was of questionable clinical significance and at the expense of significant toxicities (62% grade 3 to 4 adverse events), the combination has never found significant traction in the treatment of pancreatic cancer. During the past several years, two chemotherapy regimens, FOLFIRINOX and gemcitabine/nab-paclitaxel, have emerged as new standards of care for the first-line treatment of metastatic pancreatic cancer, both based on randomized phase III trials that show more clinically meaningful benefits when compared with gemcitabine.

Despite these recent advances, the median survival for patients with metastatic disease remains less than a year, highlighting a desperate need to continue the developmental therapeutic path in pancreatic cancer.

RECENT DEVELOPMENTS WITH TARGETED THERAPEUTIC AGENTS

Beyond conventional cytotoxic chemotherapy, the modern trend in developing novel therapeutic approaches offers promise for improving the outlook of patients with advanced pancreatic cancer.

TARGETING TUMOR MICROENVIRONMENT

The stromal compartment in pancreatic cancer is dense and contributes to the aggressive nature of this tumor by fostering tumor growth and enhancing drug resistance by inhibiting effective penetration of chemotherapy. With an increased understanding of the importance of the role of the tumor microenvironment and its role in tumor proliferation, agents aimed at targeting the tumor microenvironment is an area of increased interest in pancreatic cancer.[4-9] However, previous attempts to target the tumor microenvironment, in particular with Hedgehog signaling inhibitors, have proved unsuccessful.[10,11]

Recent early phase studies have shown promising results in targeting tumor stroma in pancreatic cancer with PEGPH20. PEGPH20, a pegylated form of recombinant hyaluronidase, has been shown to successfully degraded hyaluronic acid (HA), a primary component of tumor peristroma, leading to the re-expansion of tumor microvasculature and improving the delivery of gemcitabine.[12] Early studies of PEGPH20 in combination with gemcitabine have demonstrated provocative progression-free survival and overall survival (OS) in patients with elevated levels of hyaluronic acid,[13] which has resulted in two ongoing randomized phase II trials in meta-

TABLE 1. Standard Chemotherapy Regimens in Metastatic Adenocarcinoma of the Pancreas

Chemotherapy Regimen	Sample Size	Survival, Median (Months)	Hazard Ratio	Objective Response Rate	Toxicities (Grade 3 to 4)	Author
Gemcitabine vs. 5-FU	126	5.65 vs. 4.41	Not reported	5.4	Neutropenia 25.9%	Buris III et al 1997[44]
Gemcitabine/erlotinib vs. gemcitabine	569	6.24 vs. 5.9	0.82	8.6	62% (fatigue 15%, infection 17%)	Moore et al 2007[3]
FOLFIRINOX vs. gemcitabine	342	11.1 vs. 6.8	0.57	31.6	Fatigue 23.6% neutropenia 45.7%	Conroy et al 2011[45]
Gemcitabine/nab-paclitaxel vs. gemcitabine	861	8.5 vs. 6.7	0.72	23	Fatigue 17% neutropenia 38%	Von Hoff et al 2013[46]
5-FU/leucovorin + MM-398 vs. 5-FU	417	6.1 vs. 4.2	0.57	16	Fatigue 14% neutropenia 20% diarrhea 13% vomiting 11%	Von Hoff et al 2014[47]

static pancreatic cancer (ClinicalTrials.gov NCT01959139 and NCT01839487).

TARGETING THE RAS PATHWAY

Targeting signaling pathways in cancer remains an attractive therapy in pancreatic cancer. Given the nearly universal presence of activating *KRAS* mutations in pancreatic cancer and its key function in cell survival and proliferation, *KRAS* represents an ideal target; although, its relevance as a therapeutic target is not fully established.[14-16] Targeting *RAS* directly is a challenge; one approach using oncolytic viruses is described below. Attempts have been made to inhibit downstream effector molecules to *RAS,* although cross-talk between parallel downstream signaling pathways and negative loop feedback inhibition have been indicated as potential mechanisms for resistance and highlight the need to inhibit multiple pathways simultaneously.[17]

TAKING ADVANTAGE OF SYNTHETIC LETHALITY

For a distinct group of patients with pancreatic cancer, the concept of synthetic lethality may afford a specific treatment strategy. Synthetic lethality occurs when a combination of mutations in two or more genes leads to cell death, whereas, a single mutation does not and by itself remains viable. Tumors harboring defective DNA repair mechanisms render them vulnerable to synthetic-lethality approaches, leading to the use of targeted agents that induced the death of tumor cells while sparing normal cells. Mutations in genes, including tumor suppressor genes (*BRCA 1/2, ATM*), may confer an increased sensitivity to DNA-damaging cytotoxic chemotherapy including platinum analogs and PARP inhibitors because of the associated defective homologous recombination and an inability to mount efficient DNA repair.[18,19] In specific subgroups of patients, including those of Ashkenazi Jewish descent and individuals with a family history of pancreatic cancer, the prevalence of germ-line mutations of *BRCA1* and *BRCA2* has been reported in as many as 19%.[20,21] For patients with germ-line *BRCA1/BRCA2* mutations, a phase III randomized, double-blind study, the POLO trial, is investigating the use of the PARP inhibitor olaparib in patients with metastatic pancreatic cancer whose disease has not progressed on first-line platinum-based chemotherapy (ClinicalTrials.gov NCT02184195).

KEY POINTS

- Pancreatic cancer remains a devastating disease with an increasing prevalence and the highest mortality rate of any malignancy.
- Cytotoxic chemotherapy remains the primary treatment for advanced pancreatic cancer, with several new combination regimens emerging as first-line standards.
- New agents targeting the tumor microenvironment and cancer-signaling pathways are being investigated in pancreatic cancer.
- Although pancreatic cancer has been mostly considered an immunosuppressive malignancy, developments have renewed interest in immunotherapy as a treatment option in this disease.
- Attention to the value of new therapeutics is critical to prioritizing efforts and selecting treatment for individual patients.

IMMUNOTHERAPEUTIC APPROACHES IN PANCREAS CANCER
Targeting PD-1/PD-L1

Except for melanoma, renal cell carcinoma, and prostate cancer, immunotherapy for solid tumors remains experimental. Tumors resist an immune response by inducing tolerance in tumor-specific T cells and by expressing ligands that bind to inhibitory receptors, or immune checkpoints on T cells, which dampen their immune response against tumors. Immunotherapeutic approaches, notably agents targeting negative regulatory molecules on activated T cells, such as cytotoxic T lymphocyte antigen-4 (CTLA-4), programmed death-1 (PD-1), and its binding ligand, programmed death ligand 1 (PD-L1), are showing promise in a number of malignancies. Antagonism of these immune checkpoints can augment the nascent antitumor response from the immune system.

Pancreatic cancer has been mostly considered an immunosuppressive malignancy, with pancreatic cancer cells producing cytokines (transforming growth factor-beta) and surface molecules that mediate immunosuppression (FAsL, PDL-1). Moreover, it has been mostly considered a nonimmunogenic malignancy, since tumor-infiltrating effector T lymphocytes do not represent a histopathologic hallmark for this disease. Therapeutic approaches focusing on overcoming T-cell immunologic checkpoints with anti-CTLA-4 and anti-PD1 monoclonal antibodies alone have failed to demonstrate any meaningful activity in pancreatic cancer to date.[22,23] However, studies investigating the combination of checkpoint inhibitors with "immune resensitizing" agents are currently in development in this disease, as described below.

VACCINE THERAPIES

With molecular identification of human tumor antigens, antitumor vaccine therapies specifically sensitize immune cells against tumor antigens. Several types of vaccinations are under investigation against pancreatic cancer, including whole-cell, peptide, DNA, and vaccines with microorganisms.

GVAX

GVAX is an irradiated whole-cell modified vaccine composed of two irradiated pancreatic cancer cell lines (PANC 6.03 and PANC 10.05) engineered to express granulocyte-macrophage colony-stimulating factor (GM-CSF), a growth factor that plays a key role in stimulating the immune system response by inducing dendritic cell differentiation. Administration of GVAX in addition to standard 5-FU-based chemoradiation as part of adjuvant therapy after pancreatic cancer resection demonstrated promising results in a single-institution phase II trial.[24] Moreover, several studies investigating the immunologic effects of GVAX have demonstrated its ability to create an inflammatory reaction causing an upregulation of PD-L1, suggesting the potential utility of combining this vaccine with immune checkpoint inhibitors.[25,26]

CRS-207

An alternative immune-based strategy undergoing clinical investigation in pancreatic cancer is CRS-207, a live-attenuated *Listeria* monocytogenes (LM) vaccine (CRS-207, Aduro Biosciences, Berkeley, CA) genetically modified to express mesothelin, which is often overexpressed in pancreatic cancer. A recent randomized phase II trial in patients with chemotherapy-refractory metastatic pancreatic cancer suggested a significant improvement in overall survival when sequential treatment with GVAX/CRS-207 was administered, as compared with GVAX alone (median OS, 6.1 vs. 3.9 months; hazard ratio

[HR] 0.59, p = 0.02).[27] These findings have led to an ongoing phase IIB randomized control trial comparing CRS-207 alone to CRS-207 in combination with GVAX or to chemotherapy in previously treated metastatic pancreatic cancer (ClinicalTrials.gov NCT02004262). Another phase II study is investigating the use of GVAX in combination with CRS-207 with or without nivolumab, an anti-PD-1 monoclonal antibody, in previously treated metastatic pancreatic cancer (ClinicalTrials.gov NCT02243371).

ALGENPANTUCEL-L

Algenpantucel-L (NewLink Genetics Corporation, Ames, Iowa) is a whole-cell vaccine made of two human pancreatic cancer cell lines (HAPa-1 and HAPa-2) that are genetically modified to express alpha^{1,3}-galactosyl epitopes (alphaGAL), a carbohydrate present in the cells of most mammals except humans, which have developed pre-existing immunity. On injection, algenpantucel-L induces an immune response that parallels the hyperacute rejection that can occur postorgan transplant. An open-label phase II trial of this vaccine in combination with adjuvant chemotherapy and chemoradiation in resected pancreatic cancer demonstrated promising 1-year disease-free survival and OS rates (62% and 86%, respectively).[28] On this basis, a large phase III trial was recently completed in the United States, evaluating standard adjuvant chemotherapy or chemoradiation with or without algenpantucel-L in resected pancreatic cancer (ClinicalTrials.gov NCT01072981).

ONCOLYTIC VIROTHERAPY

Because of their tumor selectivity and ability to cause cancer cell lysis, oncolytic viruses continue to represent an area of considerable interest in cancer treatment. These viruses selectively target tumor cells through engineered mutations that prevent the binding and replication of the virus in normal, healthy cells and attack specific tumor epitopes that lead to cancer cell death.

Reovirus is a family of naturally occurring, ubiquitous nonenveloped human virus whose replication is dependent on cellular activity of *RAS*; specifically, it is cytopathic in transformed cells possessing an activated *RAS* signaling pathway.[29-32] Given the prevalence of *KRAS* mutations in pancreatic cancer, reovirus has represented a promising and attractive candidate as an oncolytic virus in this disease. Bekaii-Saab et al reported the results of a phase II randomized trial in which 73 patients with metastatic pancreatic adenocarcinoma were randomly assigned to receive carboplatin/paclitaxel alone or in combination with Reolysin.[33] Although this agent was well tolerated overall, it failed to show an improvement in outcomes, including in those patients with *KRAS* mutations. Investigation into other oncolytic viruses (adenovirus, parvovirus, pox virus, measles virus) continues in patients with pancreatic cancer.

TABLE 2. Cost of First-Line Standard Chemotherapy Regimens in Metastatic Pancreatic Cancer*[48]

Regimen	Monthly Costs of Drugs	Monthly Cost of Administration	Monthly Cost of Toxicities**	Total Monthly Cost†
Gemcitabine	$188	$143	$1,032[2]	$1,363
Gemcitabine/ nab-paclitaxel	$9,008	$522	$2,692	$12,221
FOLFIRINOX	$763	$531	$5,940	$7,234
Gemcitabine/ erlotinib	$6,831	$143	$1,032[2]	$8,007

*All costs were calculated in U.S. dollars ($). The unit price of each drug was determined from the 2013 average sales price from the Centers for Medicare & Medicaid Services. Fees for administration and toxicities were calculated according to the 2013 physician fee schedule.[49]
**The cost of growth factor is included.
†The cost of growth factor is based on data extrapolated from the gemcitabine arm in the MPACT trial.[46]

THE JAK/STAT PATHWAY

Recent studies have indicated that *JAK2*/signal transducers and activators of transcription 3 (STAT3) signaling pathways are important for the initiation and progression of pancreatic cancer.[34] In addition to its contribution to tumorigenesis, the clinical symptoms associated with pancreatic cancer, including cachexia and weight loss, reflect a chronic inflammatory state likely related in part to the *JAK*/STAT pathway.[35] Based on these findings, ruxolitinib, a *JAK1/JAK2* inhibitor, is currently under investigation in metastatic pancreatic cancer. A randomized phase II study (RECAP trial) compared the addition of ruxolitinib to capecitabine with capecitabine alone in patients after progression on gemcitabine-based therapy.[36] Although no survival difference was observed in the overall study population, a preplanned analysis in the subgroup of patients with elevated levels of C-reactive protein (CRP) revealed a significant survival benefit in favor of the ruxolitinib-containing arm (HR 0.47, p = 0.01). Based on these findings, two phase III trials, JANUS-1 and JANUS-2, investigating the use of capecitabine with or without ruxolitinib in the first and second-line of therapy, respectively, are ongoing for patients with metastatic pancreatic cancer with elevated CRP, a biomarker of an inflammatory state (ClinicalTrials.gov NCT02117479 and NCT02119663).

CHIMERIC ANTIGEN RECEPTOR T CELLS

Last, albeit in its early stages, the role of autologous T cells manufactured to express chimeric antigen receptors, known as CAR T cells, is under active investigation in a variety of tumor types, including pancreatic cancer. These CARs can recognize specific membrane proteins expressed on tumor cells, such as mesothelin in pancreatic cancer.[37] This adoptive cell transfer approach has produced sustained remissions in hematologic malignancies,[38] but its safety and efficacy in solid tumors requires further study.

THE VALUE OF CURRENT AND EMERGING THERAPIES

Concern has been raised regarding the high costs of new innovations in oncology from a variety of perspectives, including society, payer, and patient.[39] From the patient perspective, high out-of-pocket expenses can affect personal finances and treatment adherence (Table 2). Given the increasing number of treatment options available for patients with advanced pancreatic cancer, coupled with the fact that the benefits of each recent advance have been incrementally modest, it is important to systematically compare the benefits and costs (i.e., the value) of each option. This will allow oncologists to help patients optimize treatment decisions, and payers and policymakers to rationally address resource allocations. The American Society of Clinical Oncology has stressed the importance of recognizing financial implications for patients,[40] and is developing a user-friendly framework for the assessment of value.

Pancreatic cancer treatments highlight the importance of not only considering anticancer drug costs in such analyses, but also supportive care and management of complications that may differ substantially between regimens. For example, recent economic analyses have indicated that although the drug costs associated with gemcitabine/nab-paclitaxel are much higher than those with FOLFIRINOX, the costs associated with supportive measures (including hematopoietic growth factors and hospitalization) are greater with FOLFIRINOX.[41,42] Despite the higher costs associated with administration and toxicities with FOLFIRINOX, the monthly cost of gemcitabine/nab-paclitaxel remains higher. Although cost is one important factor in determining treatment, other factors not limited to quality of life and survival benefit should be considered in any treatment decision. As new treatments are developed, including a number of the newer (and likely very costly) agents discussed above, the inclusion of economic analyses in phase III clinical trials, supplemented by analyses of administrative data, will be essential for prioritizing and applying these various treatment approaches in a thoughtful way. This information will be useful both for our individual patients and for society at large.

CONCLUSION AND FUTURE DIRECTIONS

Despite advances in cancer care and research, pancreatic cancer remains very challenging, with standard treatment regimens providing modest gains at a significant cost. A variety of novel therapeutic approaches, including several targeting the immune system in different ways, have produced promising results and spurred further investigation in both early- and later-phase studies. As these innovations continue to be developed, it is important that we set a high bar to ensure that we bring the greatest value to our patients.[43]

Current and Future Care of Patients with the Cancer Anorexia-Cachexia Syndrome

Egidio Del Fabbro, MD

OVERVIEW

Many important advances have occurred in the field of cancer cachexia over the past decade, including progress in understanding the mechanisms of the cancer anorexia-cachexia syndrome (CACS) and the development of promising pharmacologic and supportive care interventions. However, no approved agents for cancer cachexia currently exist, emphasizing the unmet need for an effective pharmacologic therapy. This article reviews the key elements of CACS assessment in daily practice, the contribution of nutritional impact symptoms (NIS), the evidence for current pharmacologic options, and promising anticachexia agents in perclinical and clinical trials. It also proposes a model for multimodality therapy and highlights issues pertinent to CACS in patients with pancreatic, gastric, and esophageal cancer.

Many important advances have occurred in the field of cancer cachexia over the past decade, including progress in understanding the mechanisms of CACS and the development of promising pharmacologic and supportive care interventions. However, no approved agents for cancer cachexia currently exist, emphasizing the unmet need for an effective pharmacologic therapy. Patients with CACS may have different priorities; for many, preserving lean body mass (LBM) and function may be important, while for others, maintaining appetite to enjoy meals with their family may be the primary goal. Appetite and weight loss are also associated with important clinical outcomes such as decreased survival, fewer completed cycles of chemotherapy, more treatment side effects, and poorer health-related quality of life.[1-3]

CACHEXIA AND UPPER GASTROINTESTINAL CANCERS

A study by DeWys[4] in 1980, of more than 3,000 patients enrolled in Eastern Cooperative Oncology Group chemotherapy trials, identified the high prevalence of weight loss in cancer and its association with decreased survival. The survival of patients with gastric and pancreatic cancer did not correlate with weight loss (even though 85% of these patients experienced weight loss, and one-third lost more than 10%). Possibly, weight loss may have lost its powerful predictive value in these patients because of their very poor prognosis.[5] A subsequent retrospective study found weight loss in pancreatic and gastric cancer at presentation was associated with poorer quality of life and increased chemotherapy toxicity,

even at lower doses.[6] Outpatients with esophageal or pancreatic cancer have the highest nutritional risk scores, and more than 80% experience anorexia and weight loss even when they have a performance status (PS) of 1.[7]

ASSESSMENT OF PATIENTS

A consensus definition of cancer cachexia is important for clinical trial design and for identifying patients with the syndrome in clinical practice. Ideally, patients who are at risk should be identified early to provide the greatest opportunity for effective intervention. A delay could result in uncontrolled symptoms, poorer quality of life, and more rapid entry into the refractory stage of cachexia. A recent study of body composition imaging by CT of 368 patients shows 5% or less of patients gained muscle within 90 days of death, suggesting the anabolic opportunity for intervention probably exists early in the disease trajectory.[8]

Definition

Cancer cachexia is defined as a multifactorial syndrome characterized by ongoing loss of skeletal muscle mass (with or without loss of fat) leading to progressive functional impairment, which cannot be fully reversed by conventional nutritional support.[9] Based on the current definition, detection of cancer cachexia centers on involuntary weight loss of more than 5% over 6 months (or 2% when evidence of sarcopenia is present).[9,10] Recently, attempts have been made to incorporate anorexia severity, PS, and markers of inflammation, such as C-reactive protein, into staging criteria for the identifica-

tion of precachexia, cachexia, and refractory cachexia. A simple, objective, systemic inflammation–based approach using C-reactive protein and albumin has prognostic value independent of tumor stage, PS, and treatment in a variety of advanced tumors, but it has yet to be incorporated into the screening or staging of cancer cachexia.[11,12] More research is required to identify simple patient-reported outcomes or biomarkers that could help classify patients into early and late stages of cachexia.

Assessment Tools

A brief standardized assessment that includes NIS such as nausea, depression, and severe pain should be performed on all oncology patients who are at risk for CACS (Fig. 1). Unfortunately, the American Society of Clinical Oncology's Quality Oncology Practice Initiative does not currently include any specific questions about appetite,[13] and without systematic inquiry, symptoms such as anorexia may not be identified by oncologists, since patients volunteer few symptoms relative to their total symptom experience.[14]

The 10-item Edmonton Symptom Assessment Scale (ESAS) has shown a high prevalence of multiple symptoms in ambulatory patients with cancer, similar to the symptom burden reported in palliative care populations.[15] The ESAS assesses symptom severity, including appetite, but does not include other CACS-relevant symptoms such as constipation, early satiety, or dysgeusia. A more comprehensive evaluation requires an additional assessment measure such as the Patient-Generated Subjective Global Assessment (PG-SGA): an American Dietetic Society–endorsed questionnaire that identifies additional reversible factors contributing to poor oral intake. A recently validated brief version, the a-PG-SGA, can be completed in less than 5 minutes and provides additional diagnostic and prognostic value for patients with cancer.[16] Using these simple tools for symptom and nutritional assessment, along with a history of 5% or more weight loss during the past 6 months would identify many patients with CACS.

KEY POINTS

- The cancer anorexia-cachexia syndrome (CACS) is common in patients with upper gastrointestinal cancers and is associated with decreased survival and poor tolerance to chemotherapy.
- No approved drugs currently exist for CACS, suggesting an unmet need.
- Preliminary studies using multimodality therapy with pharmacologic and nonpharmacologic interventions have demonstrated improved clinical outcomes.
- A brief standardized assessment to identify CACS and the symptoms contributing to decreased caloric intake is necessary.
- Recent phase II trials have shown improved clinical outcomes for a number of single agents.

Role of Body Composition

Because of the high prevalence of obesity in the general population, many patients may have a normal or elevated body mass index even though they report weight loss and experience profound muscle wasting. Body composition assessment by dual-energy x-ray absorptiometry (DEXA) scan[17] or CT scan may identify patients with occult muscle wasting, consistent with sarcopenia. Patients with the combination of sarcopenia and obesity have a worse prognosis[18] and a higher risk of chemotherapy-related adverse effects.[19] The information derived from routine CT images can provide potentially clinically relevant information beyond assessment of tumor size and response.[20]

Several studies using routine CT imaging in patients with pancreatic cancer have demonstrated relationships between body composition, LBM,[16] impaired lung function,[21] and clinical outcomes. For patients entering a palliative care program, sarcopenia in patients who were overweight was an independent adverse prognostic indicator.[22] Another longitudinal study in patients with locally advanced pancreatic cancer showed that baseline obesity and loss of visceral adipose tissue (VAT) were associated with worse survival.[23] In particular, patients with diabetes who have pancreatic cancer experience accelerated VAT loss and reduced survival compared to those patients without diabetes.[24] In patients receiving neoadjuvant chemotherapy for potentially resectable pancreatic cancer, skeletal muscle loss and VAT loss were correlated with disease-free and progression-free survival, respectively.[25] Although quantification of LBM or fat is not yet conducted in daily clinical practice, CT imaging is emerging as a useful measure of body composition[16] and could influence clinical decision making and chemotherapy dosing in future.

Other modalities have been used for body composition analysis, including bioimpedance (BIA),[26] which relies on the different electrical properties of fat and muscle and—although not as accurate as CT imaging or DEXA—is relatively easy to use and nonburdensome for patients. Additional information provided by BIA such as the ratio of resistance and reactance (phase angle) may be useful for prognostication in several tumor types including pancreatic cancer.[27-29]

CURRENT MANAGEMENT

The clinical assessment and management should focus on nutrition (quantity and composition), symptoms contributing to poor oral intake, weight and body composition, and identification of any reversible metabolic abnormalities (Figs. 2 and 3).

Symptom Management

NIS such as nausea, depression, severe pain, dysgeusia, gastroparesis, and constipation can contribute to decreased caloric intake and weight loss in patients with CACS (Fig. 3). In addition, comorbid metabolic abnormalities such as hypogo-

FIGURE 1. CACS Assessment in Daily Practice

Goal of CACS assessment	• Identifying those at risk • Identifying early signs • Monitoring outcomes of interventions
Type of assessment tool	• Numeric scale for symptoms, includes appetite (ESAS) • Additional checklist for nutritional impact factors, e.g. abbreviated PG-SGA
Individual administering assessment	• Patient (self) or caregiver (ESAS), <5 minutes • Staff, e.g. dietitian (aPG-SGA), <5 minutes
Monitor key outcomes	• Weight change Optional: labs, body composition • Appetite • Fatigue, Physical Activity • Quality of life

CACS: Cancer Anorexia Cachexia Syndrome;
ESAS: Edmonton Symptom Assessment Scale;
aPG-SGA: Abridged Patient-Generated Subjective Global Assessment

nadism, thyroid dysfunction, and vitamin B12 and D deficiencies may contribute to fatigue, muscle weakness, and poor appetite. Other causes of weight loss that have a predominant starvation component such as gastrointestinal obstruction should be identified, especially if they are reversible and respond to endoscopic or surgical treatment

(e.g., stent placement or endoscopic dilation for esophageal obstruction).

A retrospective study of 151 patients with solid tumors referred to a specialized cachexia clinic found a median of three NIS and five or more NIS in 15% of patients.[30] Early satiety was the most common symptom, and it improved in many

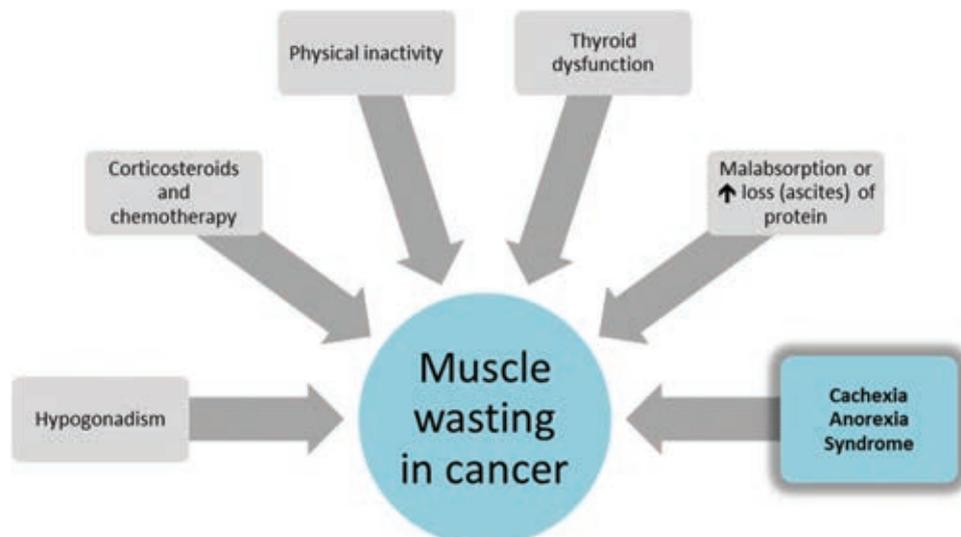
FIGURE 2. Muscle Wasting in Cancer


FIGURE 3. Mechanisms of Anorexia in Cancer
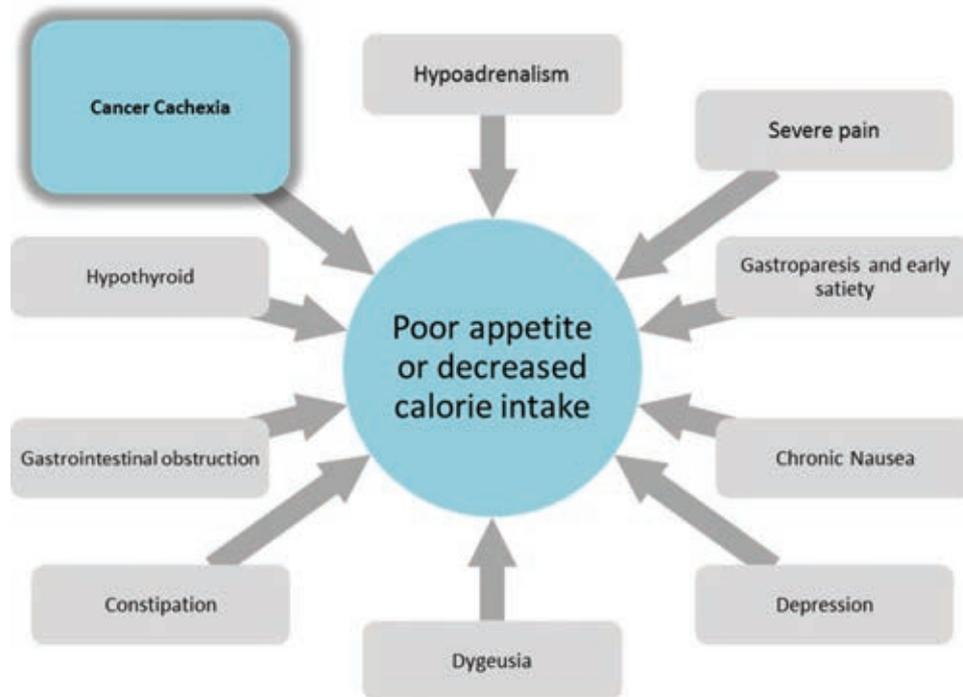


with 10 mg metoclopramide every 4 hours orally. Patients with advanced cancer often have gastroparesis and dysmotility; metoclopramide enables the stomach to accommodate more food and improves motility.[31,32] Although rare, tardive dyskinesia is an irreversible side effect, so the benefits of treatment beyond 3 months should be considered carefully since the duration and total cumulative dose of metoclopramide increase the risk of tardive dyskinesia.

Other NIS can also be effectively managed with readily available inexpensive medications. Constipation, often exacerbated by medications such as opioids and ondansetron may contribute to early satiety and can be effectively managed with laxatives, although few published trials compare bowel regimens.[33] Depressed mood may decrease appetite and should be managed with counseling and antidepressants if indicated. Mirtazapine and olanzapine are useful agents for both depression and nausea.[34] A small single-arm trial of mirtazapine in nondepressed patients with CACS produced weight gain of 1 kg or greater in about one-quarter of participants within 4 weeks.[35,36] There are no consistently effective therapies for dysgeusia; however, a trial of zinc sulfate may be justified[37,38] because this supplement has few side effects in comparison to dronabinol, which is also shown to have benefit for chemosensory perception.

PHARMACOLOGIC INTERVENTIONS
Current Agents
Progestational agents. Systematic reviews indicate that megestrol acetate (MA) plays a role in CACS by increasing appetite and body weight compared to placebo.[39-41] However, these improved outcomes found in a minority of patients should be weighed against potentially serious side effects and a failure to show better quality of life compared to other interventions.[42] In addition, the weight gain MA-induced weight gain may be predominantly fat or fluid, rather than muscle.[43]

An updated Cochrane review in 2013[42] evaluated 35 trials (23 with cancer), including 928 patients with gastrointestinal or pancreatic cancer. Approximately one in four patients taking MA for cachexia (e.g., to treat cancer or AIDS) had an increase in appetite, while one in 12 experienced weight increase. Safety was evaluated in 3,180 patients. Dyspnea, edema, impotence, and thromboembolic phenomena were more common in patients taking MA, and deaths were increased, especially with higher doses. Since the median treatment duration was 8 weeks and follow-up length was short, the authors suggest adverse events may become even more relevant with prolonged use. Although some earlier studies showed improvement in fatigue as a secondary endpoint,[44,45] there are concerns prolonged suppression of gonadal and adrenal function by MA could exacerbate symptoms such as fatigue and poor libido.[46] Symptomatic adrenal suppression may be particularly problematic in pediatric patients with cancer, and stress-dose hydrocortisone is suggested for patients with acute illness or undergoing surgery.[47]

Because of the increased risk for mortality and thromboembolism, patients should be informed of the potentially serious side effects. MA should be reserved for patients placing a high priority on improved appetite, since MA may have an

antianabolic effect by decreasing muscle size.[48] Given that increased mortality is associated with higher doses of MA, it may be prudent to start at lower doses and monitor response. The optimal dose for weight gain is more than 400 mg/day, although improvements in appetite have been reported at 160 mg/day[4].

Corticosteroids. Although small randomized trials have shown corticosteroids improve symptoms of anorexia and fatigue,[49,50] only recently have two randomized, placebo-controlled trials confirmed their efficacy. In patients with advanced cancer (predominantly head and neck or gastrointestinal tumors), 4 mg dexamethasone twice daily for 14 days significantly improved fatigue (p = 0.008) and anorexia (p = 0.013) compared to placebo, with similar adverse events.[51] Notably, the physical domain of health-related, rather than the psychologic, quality of life improved. A prior positive trial in advanced gastrointestinal cancers had speculated the benefits of corticosteroids were largely caused by mood elevation.[17] A second recent study compared 7 days of 16 mg methylprednisolone twice daily to placebo and similarly showed improvements in fatigue and anorexia but no difference in the primary outcome of pain intensity.[52]

Despite improvement in appetite and fatigue in the short term, no studies have demonstrated any benefit on LBM, and prolonged use can cause proximal myopathy.[53] Although dexamethasone is considered preferable over other corticosteroids because of its lower mineralocorticoid effect, common toxicities include candidiasis, edema, cushingoid changes, depression, and anxiety.[54] Based on recent placebo-controlled clinical trials and the rapid onset of effect, dexamethasone seems most appropriate for short-term use in patients near the end of life.

Cannabinoids. Cannabinoids such as dronabinol and nabilone are approved for chemotherapy-related nausea in patients not responding to conventional antiemetics.[55] Dronabinol is also approved for treatment of anorexia in patients with AIDS,[56] but unfortunately, the evidence for any benefit in cancer cachexia is very limited. A multicenter randomized trial of 289 patients with advanced cancer compared the effects of cannabis extract delta-9-tetrahydrocannabinol (2.5 mg twice daily) and placebo on appetite and quality of life.[57] Consistent with other symptom intervention studies, there was a significant placebo effect and improved appetite in all three groups but no differences between the groups (p > 0.15). A lack of intrapatient dose escalation may be considered a limitation; however, the dose was based an earlier phase II study showing a higher risk of adverse psychotropic effects and dropouts in patients taking higher doses of dronabinol (5 vs. 2.5 mg).[58]

A multicenter randomized controlled trial (RCT) of 469 patients compared MA and dronabinol combination therapy to either agent alone for appetite stimulation in patients with lung or gastrointestinal cancer.[59] MA was superior to dronabinol alone, and combination therapy did not provide any additional benefit. Despite the consistently negative results in large trials, a recent single RCT showed that dronabinol improved taste and protein consumption in patients with cancer who had dysgeusia.[60]

Fish oil or eicosapentanoic acid. Despite eicosapentanoic acid (EPA) showing initial benefits for CACS and fatigue in patients with pancreatic cancer,[61] three systematic reviews found insufficient evidence for EPA in the management of cancer cachexia.[62-64] Although no serious adverse effects were reported, abdominal discomfort, belching, nausea, and diarrhea often affected quality of life. More recently, there is renewed interest in fish oil after two small RCTs showed improved weight and muscle mass in patients with non–small cell lung cancer (NSCLC) at initiation of first-line chemotherapy.[65,66]

Thalidomide. A recent Cochrane review of thalidomide in cancer cachexia found insufficient evidence for clinical practice.[67] Unfortunately, the review follows a study in patients with esophageal cancer showing no benefit and poor tolerability to thalidomide,[68] despite earlier trials in pancreatic[69] and esophageal cancer[70] that found improvements in LBM and minimal side effects after 4 weeks of 200 mg/day. More recently a phase II trial found improved appetite and minimal side effects with doses of 50 and 100 mg.[71] More trials are probably warranted; however, other studies of thalidomide have experienced difficulty in patient accrual.[72]

New Agents
Despite a number of promising interventions on the horizon, enobosarm and anamorelin are the only agents completing phase III RCTs.

Androgens. Hypogonadism is common in male patients with cancer and is associated with increased symptom burden including fatigue, anorexia, and diminished libido.[41-45] Although testosterone replacement has improved muscle mass and strength in HIV-positive men,[46] it has not been studied in large, RCTs for patients with cancer. A preliminary, double-blind, placebo-controlled trial of testosterone replacement in men with advanced cancer who had hypogonadism showed significant improvement in fatigue after 10 weeks (p = 0.003) but no effect on appetite or weight.[47]

Selective androgen receptor modulators theoretically produce greater anabolic effects with fewer side effects such as prostatic hypertrophy. A phase II RCT of enobosarm for patients with advanced cancer who had cachexia found increased LBM and physical function compared to baseline with minimal side effects.[73] Preliminary results from a phase III placebo-controlled trial showed an increase in LBM (p = 0.036) in patients with NSCLC on enobosarm treated with platinum plus taxane.[74] Physical function as assessed by stair-climb power was not significantly better in patients receiving enobosarm. Final results are awaited.

Ghrelin and ghrelin mimetics. Ghrelin, an orexigenic hormone, enhances appetite and food intake in humans. A phase

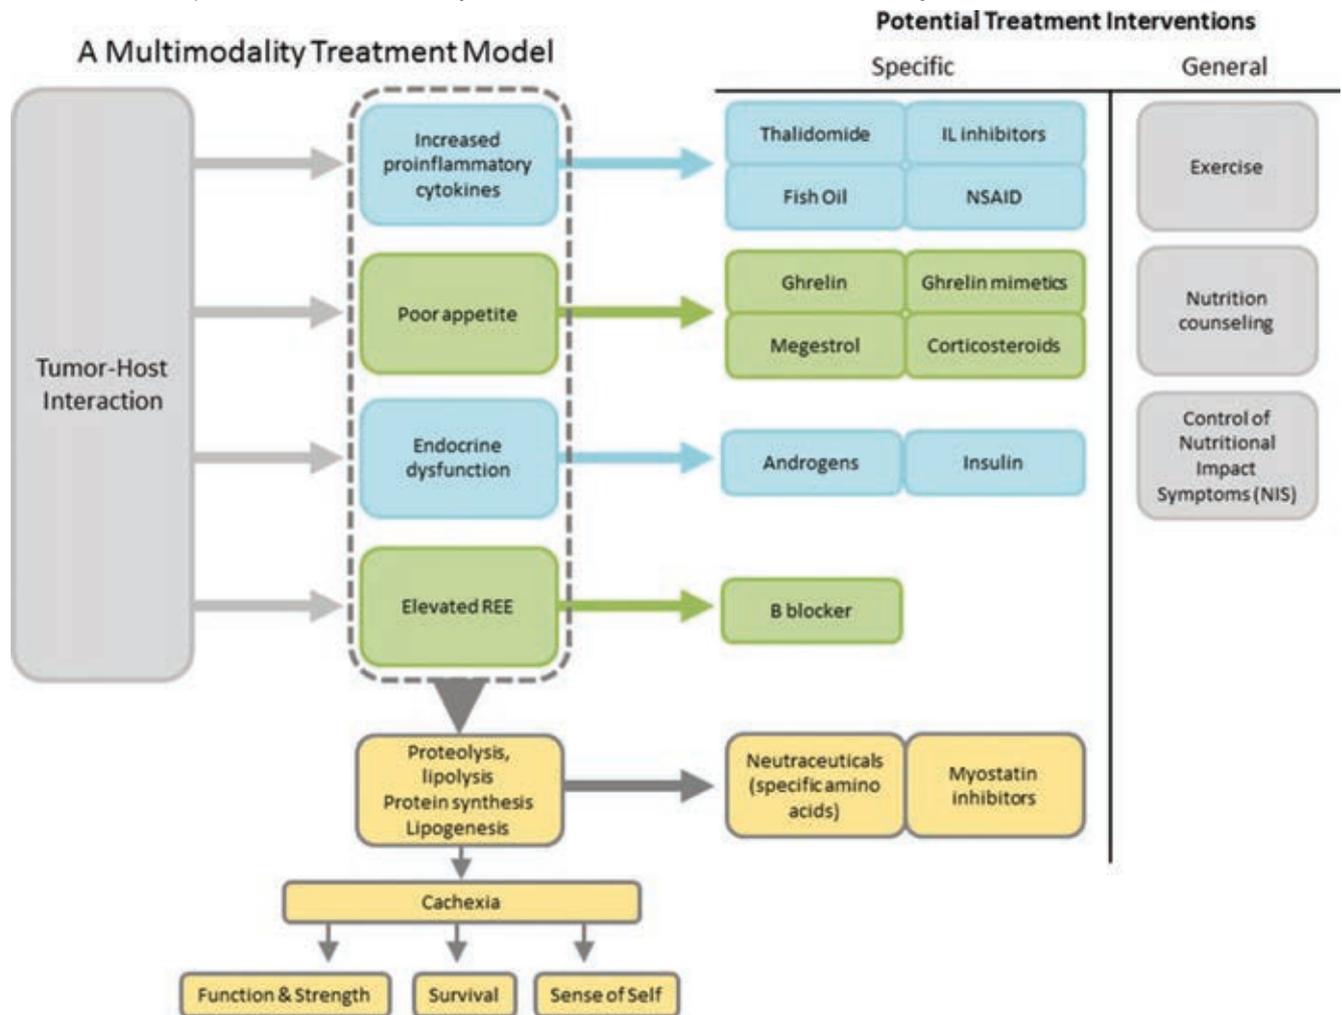
II RCT of ghrelin in patients with advanced cancer showed improved appetite and decreased fat loss with higher doses[50]; however, its development for CACS is hindered by the subcutaneous mode of administration and daily frequency. Because ghrelin has the potential for increasing insulin-like growth factor 1,[75] which could theoretically cause tumor progression, the initial efficacy and safety from early studies should be confirmed in large RCTs. An oral ghrelin mimetic anamorelin has made the furthest progress toward approval thus far, after early-phase trials showed increased food intake, appetite, and LBM in patients with cancer.[76] In addition, a pooled analysis of two phase II trials confirmed the benefits and few adverse effects of 12-week therapy. An encouraging preliminary report from the multicenter phase III trials suggests muscle mass (p = 0.0001) and appetite are improved in NSCLC.[77]

Myostatin and proinflammatory cytokine inhibitors. Myostatin is an extracellular cytokine that negatively regulates muscle mass.[54] The results of early-phase clinical trials are awaited following promising animal studies that showed tar-geting the myostatin pathway reversed muscle wasting, increased grip strength, stimulated appetite, and prolonged survival, independently of tumor progression.[78,79]

Few recent clinical trials have targeted proinflammatory cytokines, except for a phase I trial of a mAB against interleukin alfa-1 that showed a median weight gain of 1 kg from baseline and no dose-limiting toxicities.[80]

Multimodal therapy for the cancer anorexia-cachexia syndrome. Even though new single agents show potential for improving outcomes, a more effective approach might be simultaneous, multifaceted therapy targeting the different mechanisms contributing to CACS (Fig. 4).[81] Several studies have used a combination of pharmacologic agents for CACS.

A progestin in combination with an EPA, L-carnitine, and thalidomide significantly increased appetite, LBM (p = 0.007), and spontaneous physical activity, although there was no placebo arm.[82] Beta blockers[83] and insulin[84] have also been used as multimodality therapy in combination with nonsteroidal anti-inflammatories (NSAIDs), showing bene-

FIGURE 4. A Proposed Model for Management of Cancer Anorexia-Cachexia Syndrome


Abbreviations: REE, rested energy expenditure; NSAID, nonsteroidal anti-inflammatory.

fits in reducing elevated resting energy expenditure and attenuation of weight loss and also improvements in survival (p = 0.03). Although NSAIDs have been combined with other agents and have demonstrated improvement in some clinical outcomes, a systematic review concluded that the risk of side effects and insufficient evidence suggest NSAIDs should be restricted to clinical trials.[85]

CONCLUSION

Because the causes of muscle wasting and poor caloric intake in patients with CACS are multifactorial, a comprehensive multidimensional approach using pharmacologic and non-pharmacologic interventions is most likely to be effective in reversing or stabilizing weight loss and muscle wasting. Ideally, treatment should be individualized, taking into account the patient's overall condition, the principal mechanisms of their weight loss, and their goals of care. New anticachexia agents have shown promise in preclinical and early-phase studies, but their efficacy and safety need to be confirmed in larger phase III RCTs. Clearly there is an unmet need for an effective pharmacologic agent, and even though we now have several promising candidates, any specific anticachexia intervention would still need to be incorporated into a multimodality approach.

The Spectrum of Neuroendocrine Tumors: Histologic Classification, Unique Features and Areas of Overlap

David S. Klimstra, MD, Himisha Beltran, MD, Rogerio Lilenbaum, MD, and Emily Bergsland, MD

OVERVIEW

Neuroendocrine neoplasms are diverse in terms of sites of origin, functional status, and degrees of aggressiveness. This review will introduce some of the common features of neuroendocrine neoplasms and will explore the differences in pathology, classification, biology, and clinical management between tumors of different anatomic sites, specifically, the lung, pancreas, and prostate. Despite sharing neuroendocrine differentiation and histologic evidence of the neuroendocrine phenotype in most organs, well-differentiated neuroendocrine tumors (WD-NETs) and poorly differentiated neuroendocrine carcinomas (PD-NECs) are two very different families of neoplasms. WD-NETs (grade 1 and 2) are relatively indolent (with a natural history that can evolve over many years or decades), closely resemble non-neoplastic neuroendocrine cells, and demonstrate production of neurosecretory proteins, such as chromogranin A. They arise in the lungs and throughout the gastrointestinal tract and pancreas, but WD-NETs of the prostate gland are uncommon. Surgical resection is the mainstay of therapy, but treatment of unresectable disease depends on the site of origin. In contrast, PD-NECs (grade 3, small cell or large cell) of all sites often demonstrate alterations in P53 and Rb, exhibit an aggressive clinical course, and are treated with platinum-based chemotherapy. Only WD-NETs arise in patients with inherited neuroendocrine neoplasia syndromes (e.g., multiple endocrine neoplasia type 1), and some common genetic alterations are site-specific (e.g., *TMPRSS2-ERG* gene rearrangement in PD-NECs arising in the prostate gland). Advances in our understanding of the molecular basis of NETs should lead to new diagnostic and therapeutic strategies and is an area of active investigation.

Neuroendocrine neoplasms are a diverse group of neoplasms. Although these share certain pathologic features regardless of where they arise, they have largely been studied and classified in an organ-specific manner (which has led to a variety of different terminological variations) and their grading and staging remain site specific. Nonetheless, conceptual commonalities cross organ boundaries. This review will introduce some of the common features of neuroendocrine neoplasms and will also explore the differences in pathology, classification, biology, and clinical management between tumors of different anatomic sites, specifically the lungs, pancreas, and prostate.

PATHOLOGIC CONCEPTS IN NEUROENDOCRINE TUMORS

The concept of neuroendocrine differentiation in tumors can be defined as the secretion into the bloodstream of bioactive substances, usually peptide hormones or bioamines, by the neoplastic cells. The histologic similarity of the cells composing many neuroendocrine neoplasms and non-neoplastic neuroendocrine cells suggests that the tumors may arise from these mature counterparts. Although this concept is likely

overly simplistic even in the case of WD-NETs, which bear the closest resemblance to their normal cell counterparts. Pathologically, neuroendocrine differentiation has come to be defined as architectural and cytological patterns reminiscent of non-neoplastic neuroendocrine cells (such as a nesting or trabecular growth pattern and coarsely stippled nuclear chromatin) and the production of characteristic neurosecretory proteins that can be detected by immunohistochemistry. These include most importantly chromogranin A and synaptophysin, although some authorities accept the expression of CD56 (neural cell adhesion molecule or even neuron specific enolase (NSE) as adequate evidence of neuroendocrine differentiation.[1-3] However, NSE has been widely questioned as a neuroendocrine marker, based on the lack of specificity. Thus, in practice, WD-NETs are usually readily recognizable as having neuroendocrine differentiation based on their routine histologic features, and proof can be obtained with universally available immunohistochemical stains. The historic terms for WD-NETs was a carcinoid tumor or, in the pancreas, an islet cell tumor, although recent practice in the gastroenteropancreatic system has been to replace these terms with NET to avoid the connotation that a carcinoid tumor is a benign neoplasm.[1-3]

In addition to WD-NETs, which closely resemble non-neoplastic neuroendocrine cells, there also exist poorly differentiated neuroendocrine neoplasms, which are high grade carcinomas that exhibit neuroendocrine differentiation. These neoplasms also have characteristic histologic features (some of which are shared with WD-NETs) and they typically express the same general neuroendocrine markers described above, albeit less intensely and in fewer of the tumor cells. PD-NECs are usually classified as a small cell carcinoma or large cell neuroendocrine carcinoma (LCNEC), variants which are distinguished based on the cell size and specific nuclear morphology.[4] The histologic features of small cell carcinoma are sufficiently distinctive and can often be diagnosed without the need to demonstrate neuroendocrine differentiation by immunohistochemistry, whereas LCNEC must demonstrate immunexpression in at least one neuroendocrine marker to distinguish them from poorly differentiated carcinomas of an exocrine type (e.g., poorly differentiated adenocarcinoma or large cell undifferentiated carcinoma). PD-NECs are primarily distinguished from WD-NETs by having a substantially higher proliferative rate, although there are many other differences.

Despite sharing neuroendocrine differentiation and certain histologic features associated with the neuroendocrine phenotype, accumulating evidence demonstrates that, in most organs, WD-NETs and PD-NECs are actually two very different families of neoplasms.[4] They are etiologically different in some organs, and only the WD-NETs typically arise in patients with neuroendocrine neoplasia syndromes, such as MEN1 or von Hippel Lindau syndrome. The WD-NETs are variably aggressive, but most are relatively indolent with a

natural history that can evolve over many years or decades, whereas PD-NECs are uniformly highly aggressive.[5] PD-NECs, especially small cell carcinomas, exhibit marked but transient sensitivity to platinum-based chemotherapy, whereas WD-NETs are usually unresponsive to platinum and other cytotoxic chemotherapy regimens.[6,7] Also, PD-NECs often arise in association with exocrine-type precursor lesions or are combined with elements of adenocarcinoma or squamous cell carcinoma, though these associations are extremely rare in WD-NETs. Furthermore, individual tumors containing a combination of both WD-NET and PD-NEC are nearly nonexistent. Finally, emerging genetic data generally demonstrate distinct molecular alterations in these two neuroendocrine neoplasm families. Although some alterations are specific to the site of origin (discussed later), WD-NETs lack alterations in genes such as *Rb* and *TP53* that are commonly found in PD-NECs.

Although terminology and classification systems vary by organ (Table 1), the distinction between WD-NETs and PD-NECs applies in most organs.[2,8] Prognostic stratification based on grading has also been developed for most anatomic sites, and usually it is largely the proliferative rate that defines the grade.[9] Proliferative rate is determined by counting mitotic figures (usually expressed as the number 10 in high power microscopic fields or 2 mm^2) or, in some locations, by calculating the percent of tumor cells immunolabeling for the proliferation marker Ki67 (the Ki67 index). The entire group of neuroendocrine neoplasms is divided into three grades, with the low and intermediate grades (grade 1 and 2) being WD-NETs, and the high grade (grade 3) group generally consisting of PD-NECs.[2] Recently the grading parameters for neuroendocrine neoplasms of the entire gastrointestinal (GI) tract and pancreas have been unified, such that a single system proposed by the European Neuroendocrine Tumor Society (ENETS)[10,11] and endorsed by the World Health Organization (WHO)[12,13] is now widely used for this group of neoplasms (Table 2). In the thorax, a different WHO-accepted system has been in place for many years and is maintained for neuroendocrine neoplasms of the lung and thymus (Table 3).[14] For organs outside of these sites, various systems exist that largely draw on the thoracic or gastroenteropancreatic proposals. Details about each system are described later in the text. It should be emphasized that the classification and grading systems for all neuroendocrine neoplasms are being reviewed continuously, and new data are emerging that may suggest a need to modify the specific proliferation rate cut-points used for grading. Also, distinctive features specific to each site of origin are emerging, and many other potential prognostic factors are being evaluated. Thus, the ultimate assessment of prognosis will likely involve a grading scheme that will evolve with more experience and will be integrated with other prognostic data. A noteworthy advance was the inclusion of all neuroendocrine neoplasms in the American Joint Committee on Cancer (AJCC) staging system in 2009, some being staged using the same parameters as exocrine carcinomas of the same organ, others having unique NET-specific staging systems.[15]

KEY POINTS

- Neuroendocrine neoplasms are a diverse in terms of sites of origin, functional status, and degrees of aggressiveness.
- Despite sharing neuroendocrine differentiation and histologic evidence of the neuroendocrine phenotype, accumulating evidence suggests that in most organs, well-differentiated neuroendocrine tumors (WD-NETs)s (grade 1 and grade 2) and poorly differentiated neuroendocrine carcinomas PD-NECs (grade 3) are two very different families of neoplasms.
- WD-NETs arise in the lungs and throughout the gastrointestinal tract and pancreas; WD-NETs of the prostate gland are uncommon.
- Surgical resection is the mainstay of therapy for WD-NETs; treatment of unresectable disease depends on the site of origin.
- PD-NECs of all sites often demonstrate *P53* mutations and loss of *Rb*, exhibit an aggressive clinical course, and are treated with platinum-based chemotherapy.
- PD-NECs of the prostate should be suspected in patients who develop rapid progression in the setting of a disproportionately low prostate specific antigen; *TMPRSS2-ERG* gene rearrangement (present in 50% of patients) distinguishes PD-NECs of the prostate from small cell carcinomas of other primary sites.

TABLE 1. Classification of Neuroendocrine Neoplasms of the Lung, Pancreas, and Prostate

Differentiation	Grade	Lung	Pancreas	Prostate
Well differentiated	Low grade	Carcinoid tumor	Well-differentiated neuroendocrine tumor, grade 1	Carcinoid tumor*
	Intermediate grade	Atypical carcinoid tumor	Well-differentiated neuroendocrine tumor, grade 2	
Poorly differentiated	High grade	Small cell carcinoma	Poorly differentiated neuroendocrine carcinoma, grade 3; small cell carcinoma	Small cell carcinoma
		Large cell neuroendocrine carcinoma	Poorly differentiated neuroendocrine carcinoma, grade 3; large cell neuroendocrine carcinoma	Large cell neuroendocrine carcinoma
Combined	High grade	Combined small cell carcinoma (with adenocarcinoma or squamous cell carcinoma)	Mixed ductal neuroendocrine carcinoma (small cell carcinoma)	Mixed neuroendocrine carcinoma-acinar adenocarcinoma (small cell carcinoma)
		Combined large cell neuroendocrine carcinoma (with adenocarcinoma or squamous cell carcinoma)	Mixed ductal neuroendocrine carcinoma (large cell neuroendocrine carcinoma)	Mixed neuroendocrine carcinoma-acinar adenocarcinoma (large cell neuroendocrine carcinoma)
				Adenocarcinoma with Paneth cell-like neuroendocrine differentiation**

*Due to their rarity in the prostate, carcinoid tumors have not been divided into low and intermediate grades.

**Adenocarcinoma with Paneth cell-like neuroendocrine differentiation contains well-differentiated neuroendocrine cells, but the entity is included in the high-grade category because its biology is based on the adenocarcinoma component. These are not poorly differentiated neuroendocrine carcinomas in the family of small cell carcinomas or large cell neuroendocrine carcinomas.

An important subset of neuroendocrine neoplasms exhibits inappropriate secretion of one or more bioactive hormones, causing distinctive paraneoplastic syndromes, such as carcinoid syndrome, Cushing syndrome, and Zollinger-Ellison syndrome. The clinical picture of patients with these functional neuroendocrine tumors can be dominated by the paraneoplastic symptoms, which creates challenges in management unique to each tumor. Also, certain functional tumor types have a characteristic prognosis, such as the low rate of malignant behavior in pancreatic insulinomas. Although it is important to recognize functional tumors, the definition of these entities requires the presence of the corresponding clinical syndrome. Therefore, detection of specific hormones by immunohistochemistry is rarely useful in the pathologic characterization of neuroendocrine tumors.[1]

PATHOLOGIC APPROACH TO NEUROENDOCRINE TUMORS OF SPECIFIC ANATOMIC SITES
Pancreatic Neuroendocrine Tumors
Pancreatic neuroendocrine tumors (PanNETs) are well-differentiated NETs arising within the pancreas and include an array of functional types, including nonfunctional Pan-

TABLE 2. ENETS/WHO Grading System for Pancreatic Neuroendocrine Neoplasms

Tumor Grade	Definition
Low grade (grade 1)	< 2 mitoses/10 HPF, AND Ki67 index < 3%
Intermediate grade (grade 2)	2-20 mitoses/10 HPF, OR Ki67 index 3-20%
High grade (grade 3)	> 20 mitoses/10 HPF OR Ki67 index > 20%

Abbreviations: ENETS, European Neuroendocrine Tumor Society; WHO, World Health Organization; HPF, high power microscopic fields.

NETs, which are now the most prevalent type.[16] PD-NECs (small cell carcinoma and LCNEC) also arise in the pancreas but are rare. PanNETs can range from small (0.5 cm, by definition the size separating a PanNET from a neuroendocrine microadenoma), circumscribed, organ-confined tumors with a very low risk for aggressive behavior to large, necrotic, highly infiltrative malignancies.[17] The histologic patterns are usually typical of WD-NETs, but many morphologic variants exist that can cause confusion for other neoplasms. Such variants include, clear cell, oncocytic, glandular, pleomorphic, and rhabdoid morphologies.[18,19] The WHO classification system for PanNETs is the same for other neuroendocrine neoplasms of the GI tract (Table 2) and relies exclusively on the proliferative rate to separate grade 1, 2, and 3 neoplasms, the last group largely representing the PD-NECs.[8,20,21] A number of studies have validated the recommendation that both mitotic rate and Ki67 index be used to determine the grade, and that the region with the highest proliferative rate (hot spot) should be used to define the Ki67 index.[22] Also, in cases with grade discordance between the two proliferation measures, the higher grade should be assigned.[23,24] Grading based on biopsy samples remains complicated by heterogeneity within well-differentiated PanNETs, between the primary and metastases, and even among different metastatic sites.[22,25] Tumor stage and growth rate (for patients with distant metastases) observed on cross-sectional imaging are also helpful to predict the prognosis. A variety of other predictive markers have been evaluated, including immunohistochemical labeling for CD117, cytokeratin 19, CD99, CD44, p27, progesterone receptor, and PTEN, but none of these is routinely used in practice.[26]

The molecular alterations in PanNETs have been better characterized recently as a result of the completion of whole-

TABLE 3. IASLC/WHO Grading System for Pulmonary Neuroendocrine Neoplasms

Neoplasm	Morphology	Mitoses	Necrosis	Immunohistochemistry
Typical carcinoid tumor	Polygonal cells arranged in nested or trabecular patterns	< 2 per 10 HPF	Absent	Chromogranin, synaptophysin, CD56 (supportive, but not required)
Atypical carcinoid tumor	Polygonal cells arranged in nested or trabecular patterns	2-10 per 10 HPF	Present, usually punctate	Chromogranin, synaptophysin, CD56 (supportive, but not required)
Large cell neuroendocrine carcinoma	Large cells, moderate cytoplasm, round nuclei, frequent nucleoli	> 10 per HPF	Present, usually extensive	Chromogranin, synaptophysin, CD56 (at least one required)
Small cell carcinoma	Small cells, scant cytoplasm, fusiform nuclei, no nucleoli	> 10 per HPF	Present, usually extensive	Chromogranin, synaptophysin, CD56 (supportive, but not required)

Abbreviations: IASLC, International Association for the Study of Lung Cancer; WHO, World Health Organization; HPF, high power microscopic fields.

exome sequencing studies.[18] Well-differentiated PanNETs differ substantially from pancreatic ductal adenocarcinomas, which lack frequent alterations in *KRAS, TP53, CDKN2A*, and *SMAD4*. Instead, there are alterations in chromatin remodeling genes, such as *MEN1, DAXX*, and *ATRX*.[27] Additionally, alterations in members of the mTOR pathway are seen. Potential therapeutic targets can be proposed for PanNETs based on these alterations. Both *MEN1* and mTOR pathway alterations may be expected as a result of the occurrence of PanNETs in patients with *MEN1*, von Hippel-Lindau, neurofibromatosis-1, and tuberous sclerosis syndromes. PD-NECs of the pancreas have different molecular alterations from PanNETs, including common *TP53* and *Rb* mutations, as well as less frequent alterations in *KRAS* and *CDKN2A*.[28] These findings demonstrate the genetic distinction between the well differentiated and poorly differentiated families of pancreatic neuroendocrine neoplasms.

In terms of predicting response to specific therapy, there are few well-established biomarkers. Loss of expression of MGMT or methylation of its promoter can predict sensitivity to temozolomide.[29] In theory, inactivation of the mTOR pathway should also correlate in the response to mTOR inhibitor therapy, but this is a complex pathway with multiple positive and negative regulators, and a simple biomarker of pathway activation status has not been developed.[30,31]

Pulmonary Neuroendocrine Tumors

The classification of neuroendocrine neoplasms in the lung has been established for many years and, in many ways, represents the standard against which other neuroendocrine tumor families are judged (Table 3).[14] Well-differentiated NETs in the lung (and thymus) are still referred to as carcinoid tumors, with the designation of atypical carcinoid denoting the intermediate grade tumor. The high grade entities are the PD-NECs, small cell lung carcinoma (SCLC), and LCNEC.[32-34] Although a relatively new entry in the WHO classification, LCNEC received various designations in the past. In resected specimens, the morphology is typically neuroendocrine (trabecular pattern, rosettes, etc.), but the cells are larger than SCLC, with abundant cytoplasm and prominent nucleoli. Immunohistochemistry (IHC) confirmation with labeling for chromogranin, synaptophysin, or CD56 is required (Table 3). Important differential diagnostic consid-

erations include, large cell carcinoma with nuclear envelope (NE) morphology (which displays the typical NE morphology, but lacks IHC labeling for neuroendocrine markers) and large cell carcinoma with NE differentiation (which lacks NE morphology, but nonetheless expresses NE markers by IHC). Both of these entities should be approached clinically as a non–small cell lung cancer (NSCLC), as opposed to LCNEC, which is managed similarly to SCLC. Although the general concept of three grades and a separation between well-differentiated and poorly differentiated entities is the same as it is for the pancreas and GI tract, there are some subtle differences in the parameters for classification. Unlike in the GI and pancreatic NETs, the proliferative rate in the thoracic NETs is determined solely based on the mitotic rate. There are studies showing a positive correlation with the Ki67 index, and a formal classification of lung NETs that incorporates Ki67 has been proposed, but to date, the official WHO classification remains based only on mitotic rate.[35] However, the presence of necrosis is included, as either necrosis or an elevated mitotic rate can define a WD-NET as an atypical carcinoid tumor. Another difference is the threshold of the proliferative rate that separates intermediate grade (atypical carcinoid) from high grade (PD-NEC; small cell carcinoma or LCNEC). In the GI tract and pancreas, more than 20 mitoses per 10 high-power field (HPF) are needed, whereas in the lung, 10 mitoses per 10 HPF are sufficient to categorize a neoplasm as high grade.

As in other anatomic sites, pulmonary neuroendocrine neoplasms actually constitute two families that may not be closely related.[36] Carcinoid tumors, which can be central or peripheral in the lung, usually arise in nonsmokers and can occur in the setting of MEN1. They may also be associated with hyperplasia of pulmonary neuroendocrine cells, and they are usually not combined with adenocarcinoma or squamous cell carcinoma.[37] The PD-NECs, in contrast, are closely linked to tobacco use and commonly (up to 30%) contain elements of adenocarcinoma or squamous cell carcinoma. Such tumors are designated as combined neuroendocrine carcinomas. Finally, individual neoplasms containing both carcinoid tumor and PD-NEC are almost nonexistent. Molecular data further support the separation of carcinoids from PD-NECs. The latter commonly exhibit *TP53* and *Rb* mutations,[38,39] whereas carcinoid tumors lack these changes and instead (like pancreatic WD-NETs) have alterations in chro-

matin remodeling genes, such as *MEN1*, *PSIP1*, and *ARID1A*.[40]

Prostatic Neuroendocrine Tumors

In contrast to the lung and pancreas, where WD-NETs are relatively commonly encountered, the prostate almost never gives rise to true WD-NETs (carcinoid tumors). Individual case reports exist, but many such neoplasms may represent the more common manifestation of neuroendocrine differentiation in prostatic neoplasia and adenocarcinoma with neuroendocrine differentiation. A recent consensus group proposed a formal classification of prostatic neuroendocrine neoplasia.[41]

Conventional prostatic adenocarcinomas can exhibit neuroendocrine differentiation, but in the absence of a morphologically evident neuroendocrine component, focal immunohistochemically detected neuroendocrine differentiation is not thought to affect prognosis and it is not recommended to perform immunohistochemistry to search for it.[41] Prostatic adenocarcinoma with Paneth cell-like neuroendocrine differentiation is defined as a conventional prostatic adenocarcinoma containing morphologically evident neuroendocrine cells, which are typically highly granulated and resemble intestinal Paneth cells.[42] This phenomenon may be particularly marked following androgen deprivation therapy. The neuroendocrine cells lack an androgen receptor (AR) and have a well differentiated morphology, with bland nuclei and a low proliferative rate. When Paneth cell-like neuroendocrine differentiation is extensive, the tumor may resemble a true prostatic carcinoid tumor, but prostate specific antigen (PSA) expression is typically retained and elements of conventional adenocarcinoma are also usually identified. This pattern of differentiation is, if anything, a favorable prognostic sign, and the Gleason grade should be assigned based only on the pattern in the conventional adenocarcinoma elements. The rarest of all prostatic neuroendocrine neoplasms is a true carcinoid tumor, which can only be diagnosed when prostatic origin can be confirmed (as opposed to metastasis or direct extension from an adjacent organ) and Paneth cell-like neuroendocrine differentiation in a conventional prostatic adenocarcinoma is ruled out.[41] The absence of any adenocarcinoma component and negative immunostaining for PSA are required for the diagnosis.

The other types of prostate neuroendocrine neoplasms are PD-NECs, including small cell carcinoma[43,44] and LCNEC, the latter being very rare.[45] These tumors are often (but not always) positive for neuroendocrine markers (chromogranin, NSE, CD56, and/or synaptophysin) by IHC. As in other prostatic neuroendocrine neoplasms, AR expression is reduced or absent. Copy number loss of the tumor suppressors RB1 (85% to 90%)[46] and mutation of TP53 (50% to 60%) is shared with small cell carcinomas of other sites.[46,47] Notably, the combination of RB1 and TP53 alterations can drive small cell prostate cancer formation in mouse models.[48,49] In addition, PD-NEC of the prostate (NEPC) is associated with increased stem-like and neuronal signaling pathways (e.g., MYCN, ASCL1),[50] as evidenced by decreased expression of the master repressor of neuronal differentiation, RE1-silencing transcription factor (REST),[51] increased expression of cell cycle programs (e.g., AURKA, AURKB, PLK1),[47,50,52] and overexpression of the chromatin modifier DEK[53] and the polycomb complex gene, *EZH2*.[47,54] The role of these molecular alterations as diagnostic or predictive biomarkers remains to be determined.

These highly aggressive carcinomas can occur in pure form or—as in the lung, GI tract, and pancreas—they can be combined with elements of conventional adenocarcinoma. Mixed tumors are often heterogeneous with both AR positive and AR negative cells coexisting. Further demonstrating the relationship of these PD-NECs with conventional prostatic adenocarcinoma, some cases retain focal PSA immunoexpression. The prostate cancer-specific *TMPRSS2-ERG* gene rearrangement is detectable by fluorescence in situ hybridization (FISH) in approximately 50% of PD-NECs of the prostate (similar to the frequency in prostate adenocarcinomas) and distinguishes PD-NECs of the prostate from small cell carcinomas in other primary sites.[47,55]

Primary Site Determination in Neuroendocrine Neoplasms

In some clinical scenarios, it may be important to identify the site of origin of a neuroendocrine tumor presenting with metastatic disease. A variety of transcription factors can be helpful, although none are perfectly sensitive or specific on their own.[26] Thyroid transcription factor-1 (TTF1) labels pulmonary carcinoid tumors and is a good, if not insensitive, marker for WD-NETs provided a medullary thyroid carcinoma can be excluded. CDX2 is an intestinal lineage marker and generally stains only small bowel WD-NETs. Isl1 and PAX8 are positive in pancreatic WD-NETs and also, interestingly, label NETs of the rectum. A combination of these stains can supplement data from imaging studies in an attempt to identify the primary site. Defining the site of origin of a PD-NEC is more problematic, especially in the case of small cell carcinomas, which commonly express TTF1 as a primary in the lung, GI tract, pancreas, or prostate. In cases of small cell carcinoma of an unknown primary where prostate is suspected, *ERG* FISH is clinically indicated to support prostatic origin (though a negative test does not exclude it).

CLINICAL FEATURES AND MANAGEMENT OF PANCREATIC NEUROENDOCRINE TUMORS
Clinical Features

PanNETs arise in and around the pancreas and comprise approximately one-third of gastroenteropancreatic NETs (the remainder being traditional intestinal carcinoid tumors originating in the stomach and intestinal tract).[56] PanNETs account for approximately 1% to 2% of pancreatic tumors by incidence, but 10% by prevalence.[17,57,58] Interestingly, as with other NETs, the incidence of PanNETs is on the rise. It is unclear if this reflects improved diagnostic tools, an increased awareness of the disease, an aging population, or other factors.[59,60]

The majority of PanNETs (40% to 91%) are well-differentiated and nonfunctional, thus they are not associated with a clinical syndrome from hormone excess. Historically diagnosed at a late stage, advances in diagnostic imaging techniques (including endoscopic ultrasound) have facilitated detection of incidentally discovered small nonfunctional tumors, which now comprise up to 40% of newly diagnosed tumors.[61-63] Interestingly, asymptomatic secretion of peptides can be documented in 60% to 100% of nonfunctional tumors (e.g., chromogranin, pancreatic polypeptide, and others).[64] In contrast, a minority of patients (22% in a recent series) presents with a clinical syndrome stemming from hormone excess.[65] Insulin-producing tumors are the most common (90% of which exhibit benign behavior), followed by gastrinomas, glucagonomas, and other rarer syndromes.[64]

The initial work-up of a patient suspected to have a PanNET typically involves cross-sectional imaging with multiphasic CT or MRI to assess the primary tumor site and extent of disease. Endoscopic ultrasound, radiolabeled somatostatin receptor scintigraphy, and biochemical evaluations are recommended as clinically indicated.[64-66] Serum chromogranin A levels are elevated in 60% or more patients with a PanNET.[67]

Although indolent, PanNETs have malignant potential, as manifested by local invasion, lymph node involvement, and distant metastases. Most studies suggest that the risk of malignant behavior correlates with tumor size, as at least 50% of PanNETs recur or metastasize.[68] The presence of lymph node metastases also portends a worse prognosis in resected PanNETs (5-year survival is 49.4%).[69] Survival also depends on age, histologic grade, and functional status.[57] In contrast to other PanNETs, nearly all insulinomas are cured by complete resection.[64]

The etiology of PanNETs is largely unknown. Most tumors appear to be sporadic, but a small proportion of tumors arise in the setting of an inherited cancer syndrome (most commonly MEN1).[64] The potential for an accompanying inherited syndrome should always be considered, particularly if the patient has a compelling personal or family history, multifocal disease, a gastrinoma, or an insulinoma.[64]

Treatment

In addition to controlling tumor growth, it is critical to recognize the need for medical management of the hormone-excessive state in PanNETs. Somatostatin analogs (SSTa) are often employed for symptom control, but medications to control gastric acid hypersecretion and hypoglycemia are essential for patients with gastrinomas and insulinomas, respectively.[64,66] Of note, SSTa should generally be avoided in patients with insulinomas whose tumors test negative by somatostatin receptor scintigraphy.[66]

Patients with localized PanNETs are typically treated with surgical resection with regional lymph node dissection as there are no data to support neoadjuvant or adjuvant therapy. The optimal surgical technique depends on the location of the tumor. For some patients, enucleation may suffice (e.g., patients with insulinomas and incidentally detected small nonfunctional PanNETs).[70] The resultant lack of lymphadenectomy is a potential concern, however, as nonfunctional tumors that measure 10mm to 20 mm have a small but real risk of lymph node involvement.[66,70] On the other hand, several studies suggest that nonfunctional tumors that measure less than 10 mm may be safely observed in some cases.[66,71] Given the relatively indolent nature of the disease, patients with PanNET should be followed for recurrence for up to 10 years postresection.[66]

The treatment of advanced PanNETs has evolved dramatically in the last 5 years. Surgical resection of all known disease is recommended when feasible, although the data suggest that such operations are not curative.[66] The risk of recurrence after resection of NET liver metastases approaches 100% at 10 years in some series.[72,73] The role of cytoreductive surgery and/or ablation is more controversial, but is a consideration in select patients.

In patients with an unresectable disease, observation is an acceptable option in asymptomatic individuals with a low tumor burden and stable disease.[66] If systemic therapy is required, several targeted agents have proven cytostatic activity in PanNETs. Recent data suggest that biologically important subgroups may exist (e.g., those with *MEN1* or *DAXX/ATRX* mutations), but studies correlating mutations with a clinical outcome have been mixed.[74] Additional research is needed to identify valid biomarkers predictive of response to therapy in PanNETs. Octreotide delays progression in tumors of a midgut origin and is presumed to be active in PanNETs.[75] Patients with nonfunctional WD-NETs (including PanNETs) were included in the CLARINET study, in which patients were randomly selected to receive lanreotide or placebo.[76] Treatment with lanreotide improved progression-free survival (PFS; not reached vs. 18 months for placebo; hazard ratio 0.47; 95% CI, 0.30 to 0.73; p < 0.001), leading to approval for this indication. Peptide receptor radiotherapy with Lu^{177}- or Y^{90}-labeled SSTa also holds promise, but remains investigational for the treatment of PanNETs in the United States.[77]

The biologically targeted agents sunitinib and everolimus also delay tumor growth in progressive PanNETs and are approved for this indication.[30,78] Sunitinib is an oral multitargeted agent that inhibits vascular endothelial growth factor (VEGF) receptor signaling. In patients with progressive PanNET, treatment with sunitinib delays progression by approximately 6 months (median PFS 11.4 months vs. 5.5 months with placebo; p < 0.001).[78] The mTOR inhibitor everolimus also delays progression in patients with PanNETs (median PFS duration 11.0 months vs. 4.6 months with placebo, p < 0.001).[30] There are no data to guide the sequence of these agents, which have distinct side effect profiles and are characterized by stability, not shrinkage. Of note, although still considered investigational, preliminary results suggest that dual targeting of mTOR and VEGF signaling may be a means of inducing tumor regression, not just stability, in PanNET.[79]

The role of chemotherapy in PanNETs is evolving, but remains an option, particularly in patients with a progressive

disease and/or symptoms from tumor bulk. Streptozocin was approved for this indication more than 20 years ago.[80] However, subsequent studies have yielded conflicting results, raising questions about the optimal chemotherapy backbone in this disease.[81,82] Data from several small phase II studies have suggested that temozolomide-based regimens are active in PanNET, however, data from prospective randomized trials are lacking.[83] Combinations of targeted agents plus chemotherapy are also under study.[84]

In patients with PanNETs and a liver dominant disease, palliative liver-directed treatments (e.g., selective internal radiation therapy, hepatic arterial embolization, and hepatic arterial chemoembolization) are frequently employed.[85,86] The optimal timing and precise role of liver-directed therapy relative to the systemic agents that are U.S. Food and Drug Administration–approved is unclear.

PD-NECs of the pancreas are uncommon. When they occur, most are of the large cell type, metastatic at presentation, associated with a poor prognosis, and treated with platinum-based chemotherapy according to SCLC guidelines.[8]

CLINICAL FEATURES AND MANAGEMENT OF NEUROENDOCRINE TUMORS OF THE LUNG
Clinical Features

Carcinoid tumors, typical and atypical, account for approximately 1% to 2% of lung cancers and tend to have an indolent course.[59] Most lung carcinoids present with a central mass and symptoms secondary to airway involvement, such as cough, hemoptysis, dyspnea, or unresolved pneumonia. Carcinoid syndrome is rare in the absence of metastatic disease to the liver. A CT scan of the chest can suggest the diagnosis; and PET scans are usually not contributory. The diagnosis is typically made by bronchoscopy, except in peripheral lesions when a CT-guided biopsy is recommended.

On the other side of the NE spectrum, SCLC is more frequent (approximately 13% of all lung cancers), often advanced at presentation, and typically follows a more aggressive course.[87] A detailed discussion on the diagnosis and management of SCLC is beyond the scope of this article. Only one-fourth of patients present with limited stage SCLC (LD-SCLC) with disease confined to the chest and nodes (excluding contralateral hilar or contralateral supraclavicular nodes), whereas the majority of patients have extensive stage SCLC (ED-SCLC) or disease beyond the above definition at the time of the diagnosis.

The management of carcinoid tumors and SCLC across the NET spectrum has not changed appreciably in the past 2 decades. On the other hand, the diagnosis and treatment of LCNEC continues to generate considerable debate.[88] Important differences between SCLC and LCNEC include more frequent presentation of LCNEC as a peripheral mass and diagnoses in earlier stages.

Treatment
Carcinoid. The treatment of carcinoid tumors consists of surgical resection (including a nodal dissection) because of the frequent incidence of mediastinal involvement, particularly in atypical carcinoids.[89] The vast majority of patients with completely resected carcinoid tumors do not require adjuvant therapy. However, for patients with mediastinal node disease, the NCCN guidelines suggest consideration of treatment using chemotherapy and/or radiotherapy.[90] The efficacy of this intervention is unproven.[91] For patients with metastatic disease, chemotherapy with regimens used for SCLC is the mainstay of treatment. Unlike NE tumors of the GI tract, molecular-based therapies have not shown to be beneficial in carcinoid tumors, except for anecdotal case reports. The 5- and 10-year survival approaches 90% and 80% for typical carcinoids and approximately 70% and 50% for patients with atypical carcinoids, respectively.

SCLC. Combined chemotherapy and thoracic radiotherapy (TRT) followed by prophylactic cranial irradiation (PCI) is the recommended treatment for LD-SCLC and leads to a cure in approximately 15% to 25% of patients.[92] In ED-SCLC, chemotherapy is the primary treatment. PCI and consolidative chest radiotherapy prolong survival and should be discussed with patients who achieve a complete or a very good partial response to chemotherapy.[93] In contrast to NSCLC, targeted agents are not used in patients with SCLC, and immunotherapy is currently being explored.

LCNEC. The presence of a peripheral mass and discovery at an earlier stage contribute to the greater rate of surgical resection experienced by patients with LCNEC compared to those with SCLC, which rarely presents as a solitary peripheral nodule.[94] After resection, patients with LCNEC should receive adjuvant combined chemotherapy with platinum-etoposide regimens and TRT if the mediastinal nodes are positive. If unresectable at presentation, concurrent combined chemotherapy/TRT is the treatment of choice. Although little data exist to document the benefit of PCI in this disease, it should be considered in select patients.

CLINICAL FEATURES AND MANAGEMENT OF PROSTATIC NEUROENDOCRINE TUMORS
Clinical Features

In the majority of cases, neuroendocrine tumors of the prostate arise in the setting of concurrent or previously diagnosed conventional prostatic adenocarcinoma. Focal immunohistochemically detected neuroendocrine differentiation and Paneth cell morphology should be managed as prostate adenocarcinomas and carry a similar prognosis. PD-NEC, such as a small cell carcinoma, accounts for less than 1% of new prostate cancer diagnoses, but it more commonly arises as an androgen independent disease during clinical resistance to hormonal therapies.[95] Once NEPC develops, patients typically demonstrate an aggressive clinical course and poor overall survival.[95-97] Detection of patients developing NEPC is important, as these patients are less likely to respond to subsequent AR targeted therapies. However, diagnosis remains challenging because the clinical features associated

with AR independence and PD-NEC have only recently been recognized.

The incidence of NEPC is not well established because obtaining repeat biopsies in patients with metastatic prostate cancer has not been common practice. Autopsy series suggest PD-NEC may be present in up to 10% to 20% of men dying of metastatic castration-resistant prostate cancer (CRPC). Emerging data from the biopsies of metastases from patients with CRPC treated with the potent AR targeted therapies abiraterone or enzalutamide suggest the incidence may be rising.[98] This increased incidence could be a result of an increased recognition, patients living longer, or because of the effect of novel therapies. In a recent meta-analysis by Wang et al, which evaluated clinical outcomes of 123 patients with histologically confirmed NEPC that arose after a history of prostate adenocarcinoma, the median time of progression from adenocarcinoma to PD-NEC was 20 months and the median overall survival of patients with PD-NEC was 7 months.[99] Clinically, PD-NEC is associated with symptoms of accelerated disease progression often in the presence of visceral, lytic bone, or unusual sites of metastatic disease; a disproportionately low-serum PSA relative to the overall burden of disease; and a limited response to AR-targeted therapies.[52,96,97,100,101] Uncommonly, NEPC may be associated with an ectopic production of hormones (such as adrenocorticotrophic hormone [ADH], antidiuretic hormone, thyroxine, and with clinical manifestations of thyrotoxicosis), inappropriate ADH production, hypercalcemia, and/or adrenal hyperfunction. Elevated serum neuroendocrine markers (including chromogranin A, NSE, and/or carcinoembryonic antigen) may help support the diagnosis but can also sometimes be elevated in CRPC with adenocarcinoma histology.[102] If PD-NEC is suspected, a biopsy should be considered to confirm the diagnosis. The diagnosis and treatment of PD-NEC can be challenging, and assessment of the clinical context and additional pathologic review are often recommended before making treatment recommendations.

Treatment

Few patients with pure NEPC present with localized disease, and therefore there are limited data on treatment of patients with organ-confined disease. These patients are very likely to have occult metastatic disease not detected on a bone or CT scan, but PET scans may be useful in confirming localized disease.[103] For localized PD-NEC, a multimodality approach similar to SCLC should be considered, which consists of chemotherapy with concurrent or consolidative radiotherapy. Very limited data are available regarding the use of surgery in this clinical setting.

Chemotherapy is commonly used as front-line therapy for metastatic PD-NEC that either presents as de novo or occurs after therapy.[95,100] Since PD-NEC can show mixed or hybrid features (as described above with both PD-NEC and prostate adenocarcinoma components), androgen deprivation therapy is also often given either first or in combination with chemotherapy, depending on the clinical context. Platinum-based chemotherapy regimens (most often with cisplatin or carboplatin with either etoposide or taxane chemotherapy [docetaxel or paclitaxel]) are recommended for patients with aggressive clinical features and predominantly PD-NEC histology. In a phase II clinical trial of 38 patients with small cell prostate cancer treated with doxorubicin, cisplatin, and etoposide, Papandreou et al reported an objective response rate of 61%, although there were no complete responses.[104] This regimen was associated with greater toxicity as compared to cisplatin and etoposide alone, and there was no improvement in the median time to progression (5.8 months) and overall survival (10.8 months). Most recently, Aparicio et al defined a clinical diagnosis of anaplastic prostate cancer by one of seven aggressive clinical features (including PD-NEC) for inclusion into a phase II study of carboplatin and docetaxel (CD) followed by etoposide and cisplatin (EP) on progression.[105] In this study, 65.4% and 33.8% of patients were progression free after four cycles of CD and EP, respectively. Median overall survival was 16 months (95% CI, 13.6 to 19.0 months). There is no standard therapy after platinum chemotherapy, and patients are typically managed according to SCLC guidelines.

Special Considerations

Primary diagnostic challenge. Not all patients with aggressive androgen independent–CRPC demonstrate clear evidence of PD-NEC morphology on a metastatic biopsy.

Clinically aggressive tumors in the setting of a low PSA and poor clinical response to AR therapies (suggestive of AR independence) do not always demonstrate morphologic features of PD-NEC. This may be a result of disease heterogeneity and/or overlapping molecular features. Therefore, tumor morphology does not always predict clinical behavior. Chemotherapy including platinum is often considered, based on studies in anaplastic prostate cancer. The role of alternative AR therapies in this setting is not known.

Secondary diagnostic challenge. PD-NEC is not always androgen independent. At times, morphologic features or immunohistochemical profiles of metastatic tumors suggest PD-NEC, but AR expression and/or signaling are active.[106] These tumors are often either mixed or show hybrid features with both AR and neuroendocrine markers present. Clinically, these are less aggressive than most cases of PD-NEC, and patients are sometimes recommended for hormonal therapies. Future molecular markers to distinguish AR-driven CRPC from AR-independent disease will aid in patient selection for therapy.

CONCLUSION

Neuroendocrine neoplasms are a diverse group of neoplasms distinguished by site of origin, functional status, and degree of aggressiveness. Although a variety of pathologic features are shared, NETs have largely been classified in an organ-specific manner and their grading and staging remain site-specific. Nonetheless, several themes cross organ boundaries.

WD-NETs (grade 1 and 2) are relatively indolent (with a natural history that can evolve over many years or decades), closely resemble non-neoplastic neuroendocrine cells, and demonstrate production of neurosecretory proteins, such as chromogranin A and synaptophysin. Only WD-NETs arise in patients with inherited neuroendocrine neoplasia syndromes (e.g., MEN1). Surgery is the mainstay of therapy for WD-NETs, which are relatively unresponsive to chemotherapy (although several cytostatic agents have proven activity). In contrast, PD-NECs (grade 3) are uniformly highly aggressive, demonstrate a high proliferative rate, and are classified as small cell carcinoma or LCNEC. PD-NECs typically harbor molecular alterations distinctive from WD-NETs (leading to loss of Rb and P53 function), and some alterations are site-specific (e.g., *TMPRSS2-ERG* gene rearrangement in NEPC). PD-NECs exhibit marked but transient sensitivity to platinum-based chemotherapy and are usually metastatic at diagnosis. Although validated biomarkers of response are not yet available, advances in the understanding of the molecular basis of NETs may lead to new diagnostic and therapeutic strategies, and holds the promise of an individualized therapy.

Challenging the Treatment Paradigm for Advanced Renal Cell Carcinoma: A Review of Systemic and Localized Therapies

Axel Bex, MD, PhD, James Larkin, FRCP, PhD, and Martin Voss, MD

OVERVIEW

The current standard of care for the management of advanced renal cell carcinoma (RCC) revolves around systemic therapy with molecularly targeted agents. Over the last decade, a total of seven targeted drugs have been approved but, altogether, only exploit two molecular targets in this disease: the vascular endothelial growth factor (VEGF) axis and the mammalian target of rapamycin (mTOR). Introduction of these agents has markedly improved outcomes compared with those in the cytokine era, yet comparatively little progress has been made since registration of the first targeted therapeutics occurred 10 years ago. In this article, we review efforts to improve on this current treatment paradigm. We discuss novel targets in this disease and corresponding new agents under investigation. The article dedicates particular attention to targeted immunotherapeutics, which are rapidly emerging as a new category of interest in this disease. Last, we review current data supporting the use of surgical interventions to improve outcomes in patients with metastatic disease.

Targeted therapy for kidney cancer has revolutionized the management of metastatic disease in the last 5 years, but major challenges remain. First, these drugs typically control disease for approximately 9 months in fit patients in the first-line setting and for approximately 5 months in subsequent lines of therapy. As such, there is a clear scope for identifying new pathways and targets as well as better selection of patients for therapy. Second, a new generation of immunotherapy agents is in development; should these drugs be approved for use, their integration into current treatment paradigms requires investigation. Third, local therapy for metastatic disease plays a significant role in the management of metastatic kidney cancer and is associated with prolonged survival, despite the lack of a high-quality evidence base. We review here these three areas of clinical and scientific literature in kidney cancer in 2015.

NEW PATHWAYS AND TARGETS IN CLEAR CELL KIDNEY CANCER

Since the approvals of the multitargeted kinase inhibitors sorafenib and sunitinib and the mTOR inhibitor temsirolimus almost 10 years ago for the treatment of advanced kidney cancer, it could be argued that relatively little progress has been made with targeted therapy for this disease. A number of new, but similar, agents, such as pazopanib, axitinib and everolimus, have subsequently been approved. However, gains in efficacy, if any, have been modest compared with the efficacy of the earlier generation of agents, and sunitinib remains a standard of care for the first-line treatment of advanced disease in 2015. Furthermore, all of the approved targeted agents, with the exception of the anti–VEGF monoclonal antibody bevacizumab, are either mTOR inhibitors or multitargeted kinase inhibitors. Moreover, the multitargeted kinase inhibitors all inhibit at least one isoform of the VEGF receptor in addition to, sometimes, dozens of other targets. Notably, there is currently no strong evidence that any of the other targets inhibited by these agents is of therapeutic relevance in clear cell renal carcinoma.

Augmenting Anti-VEGF and mTOR Strategies

Two recent approaches to developing new agents for the treatment of kidney cancer have focused, first, on broader targeting of the phosphoinositide 3-kinase (PI3K)/mTOR signaling pathway and, second, on the evaluation of multitargeted kinase inhibitors and drug combinations that in addition to targeting the VEGF axis also target other putative drivers in advanced renal cell carcinoma (RCC) and potential mediators of resistance to VEGF inhibition (e.g., fibroblast growth factor receptor [FGFR] and c-MET).

Initial attempts to better target the mTOR signaling pathway have not met with success to date. For example, a small, randomized, phase II study of the dual pan-PI3K and TORC1/2 inhibitor apitolisib (GDC0980) versus everolimus in patients refractory to anti-VEGF therapy reported inferior

progression-free survival (PFS) for patients treated with apitolisib.[1] The results of further trials, such as those investigating the dual TORC inhibitor AZD2014 in comparison with everolimus, are awaited with interest.

Preclinical data have suggested that a number of targets may be relevant for resistance, both intrinsic and acquired, to anti-VEGF therapy in advanced kidney cancer. In this context, the phase III GOLD trial investigated the VEGF receptor (VEGFR) and FGFR inhibitor dovitinib compared with sorafenib in patients who had experienced failure of both VEGF- and mTOR-targeted therapy (i.e., in the third-line setting).[2] This trial showed activity for dovitinib, but the activity was not superior to that of sorafenib; as such, the trial was negative for its primary endpoint of PFS. A null hypothesis in interpreting the efficacy data from this trial is that the activity of dovitinib was a sole consequence of activity against the VEGF pathway and that the activity against FGFR was not relevant to efficacy, but this contention remains unproven.

A further target of recent interest in RCC is the tyrosine kinase c-MET. Analogous to the GOLD trial, the phase III METEOR trial is investigating the VEGFR and c-MET inhibitor cabozantinib in patients who have experienced failure of prior anti-VEGF therapy. However, even if cabozantinib has superior efficacy to everolimus in this setting, c-MET is not necessarily validated as a bona fide target in clear cell kidney cancer, given that cabozantinib also targets VEGF. It is noteworthy in this regard that two recent trials have shown superior efficacy for anti-VEGF therapy compared with mTOR-targeted therapy. Specifically, a phase III trial of sorafenib versus temsirolimus in patients in whom first-line therapy with sunitinib had failed[3] reported similar PFS in both arms, but overall survival (OS) was superior in the sorafenib arm. The reason for this is unclear. Furthermore, a randomized,

phase II trial of sunitinib versus everolimus in the first-line setting[4] of almost 500 patients reported a median PFS of 10.7 months for sunitinib versus 7.9 months for everolimus (hazard ratio [HR] 1.4; 95% CI, 1.2 to 1.8).

Combinations of Targeted Therapy in 2015

A further approach to try to improve outcomes of drug therapy in advanced RCC that has been investigated for a number of years is the combination of targeted therapies. Attempts of combining currently approved agents have not been successful and have resulted typically in excessive toxicity, the need to reduce drug doses, and no evidence of clinical benefit.[5-8] This approach remains of interest, nevertheless, and the results of a randomized, phase II trial (NCT01136733) comparing the combination of the multitargeted kinase inhibitor lenvatinib and everolimus with either agent alone are expected soon. Recognizing that von Hippel-Lindau (VHL) loss is essentially universal and, hence, that dependence on tumor neovascularization is omnipresent in clear cell RCC, several studies are exploring combinations of approved VEGF-targeted therapies with novel inhibitors of non-VEGF–mediated angiogenesis. Examples include the ongoing DART trial, a randomized, phase II study of axitinib plus the activin receptor-like kinase-1 (ALK1) – directed trap molecule dalantercept versus placebo (NCT01727336); this combination demonstrated favorable tolerability and encouraging activity in a recent phase I trial in RCC.[9] Similarly, the addition of the antiendoglin antibody TRC105 to standard therapy with axitinib is being evaluated in another randomized, placebo-controlled, phase II trial that is currently accruing (NCT01806064).

Challenges for Targeted Therapy in Advanced RCC

Perhaps the fundamental problem with improving outcomes with targeted therapy in advanced RCC is the lack of molecular predictive factors for selecting therapy and the consequent one-size-fits-all approach. This is in contrast to the use of targeted therapies to treat most other advanced malignancies, in which factors such as mutations in driver oncogenes (e.g., *BRAF* in melanoma) are used to select patients for appropriate therapy. A pertinent observation in this respect, though, is that clear cell renal carcinoma is characterized molecularly by aberrations in tumor suppressor genes rather than activating mutations in oncogenes, as in the melanoma example. The consequence of the loss of tumor suppressor genes in clear cell RCC is a pathologic dependence on signaling via the VEGF axis; to date, there is no way to measure this dependence in a way that is clinically useful in selecting systemic therapy. A related issue is whether or not a particular molecular target is relevant as a driver of the disease in an individual tumor. In many ways, it might be surprising if one target, such as c-MET or FGFR, was responsible for resistance to anti-VEGF therapy in the majority of patients. Thus, even if such targets are potentially relevant in some cases, it will remain difficult to make significant progress with targeted therapy in this disease if patients entering clinical trials are molecularly unselected.

KEY POINTS

- Since the advent of molecularly targeted therapy for the treatment of advanced renal cell carcinoma (RCC), further improvement in outcomes with subsequent approval of additional agents has been modest, at best.
- Two key strategies of developing novel agents have been (1) broader targeting of the phosphoinositide 3-kinase/mammalian target of rapamycin signaling pathway and (2) combined inhibition of other targets with vascular endothelial growth factor–directed therapies.
- Targeted immunotherapy with checkpoint inhibitors is rapidly emerging as a new class of agents in this disease. Ongoing studies test its utility alone and in combinations with approved agents.
- A growing body of data supports the use of metastasectomy to improve outcome in patients with metastatic RCC.
- Clinical and radiographic parameters could help optimize the selection of patients with metastatic disease for surgical intervention and should be validated prospectively.

Finally the issue of intratumor heterogeneity is potentially relevant for the further development of targeted therapy in kidney cancer.[10] A critical consideration is whether or not a particular molecular aberration is a driver of tumor progression at all tumor sites—that is, a truncal driver. To make a further analogy with melanoma, activating mutations in *BRAF* are truncal drivers in *BRAF*-mutant melanoma. That is, disease progression at primary and metastatic sites is driven by this aberration, and *BRAF*-targeted therapy results in disease regression, at least temporarily, in the vast majority of cases. Some data in clear cell renal carcinoma suggest that mutations in VHL may be the only bona fide truncal driver in this disease.[11] Other mutations, for example those in *SETD2* or *PBRM1*, may not be present at all tumor sites. This may be therapeutically relevant, because aberrations in the mTOR signaling pathway are relatively common in clear cell RCC, but the overall activity of mTOR inhibitors is less than that of anti-VEGF therapy. One possible explanation for this is that mTOR signaling aberrations are rarely truncal drivers. This contention, however, requires further study, particularly in characterizing the genomic architecture of the disease at metastatic sites.

Agents like cabozantinib may be approved in due course for the treatment of advanced RCC, and combination therapy remains of interest as an approach to treating this disease. Nevertheless, without molecular characterization of patients who have advanced RCC and clinical trials directed at resultant specific populations, it is difficult to see how the next decade will see the same progress in molecularly targeted therapy that we have witnessed in the last 10 years.

INTEGRATING IMMUNOTHERAPY INTO THE CURRENT TREATMENT PARADIGM IN ADVANCED RENAL CELL CARCINOMA

Immunotherapy has a longstanding history in the management of advanced renal cancer. Although monotherapy with interferon alfa largely has been abandoned since the introduction of targeted agents, high-dose interleukin-2 remains an approved standard in the first-line setting, albeit only utilized for a select subgroup of patients (as reviewed by McDermott et al[12]). Recently, a novel class of immunotherapeutics is rapidly gaining recognition for RCC and other diseases. These so-called checkpoint inhibitors interfere with inhibitory cell-cell interactions that suppress the tumor-directed T-cell response via molecules like cytotoxic T-lymphocyte-associated protein 4 (CTLA4) and programmed death-1 (PD-1).

With a number of phase II and III trials underway, checkpoint inhibitors presently are being tested on their own and in combination with approved targeted agents. This growing body of clinical data, particularly around agents targeting PD-1 or its binding partner PD-ligand 1 (PD-L1), raises the question of how to integrate this class of agents into the present treatment paradigm for this disease.

Checkpoint Inhibitors in Advanced RCC: Monotherapy

Since the early 2000s, RCC drug development has chiefly revolved around inhibition of VEGF and mTOR, which relies on the sequential use of different agents targeting the same pathway in any given patient who has metastatic disease (e.g., following VEGF inhibition with another VEGF inhibitor). The advent of targeted immunotherapy may provide an opportunity to add a novel class of agents to this sequence of therapies.

Furthest in clinical development for metastatic RCC is the fully human IgG4 monoclonal antibody nivolumab (Bristol-Meyer Squibb, New York, NY), which targets PD-1. A dose-randomized, phase II study in patients pretreated with one to three prior antiangiogenic therapies was recently reported.[13] Objective response rates (ORRs) of approximately 20% and a median PFS of approximately 4 months were comparable to efficacy data for approved targeted agents in the pretreated space.[14,15] OS exceeded historic controls (median OS, approximately 25 months in the higher dose-levels versus approximately 15 months for approved targeted agents in pretreated patients). Such cross-trial comparisons are of limited value, but this marked difference in the reported OS may reflect longer-lasting immunomodulatory effects that may enhance the effectiveness of subsequent agents, particularly in the light of the modest PFS findings. This would argue in favor of using nivolumab maximally early, ideally first line, in a patient's course of disease. The sponsor has chosen to develop nivolumab for monotherapy in pretreated patients (with parallel development of combination strategies in first-line settings); a phase III trial that randomly assigned patients to nivolumab versus everolimus after one or two prior antiangiogenic therapies (NCT01668784) has completed accrual. The primary endpoint is OS, prompted by the phase II signal; this endpoint represents a paradigm shift for this disease, in which registration studies have typically pursued PFS as the primary endpoint.

It has been suggested that the antitumor effects of nivolumab and other compounds can extend beyond the end of treatment; anecdotally, a number of patients have not required further therapies for extended periods of time. For those patients who experience disease progression during treatment, however, it is unclear if and how immune modulation with checkpoint inhibitors affects effectiveness and tolerability of subsequent, nonimmunotherapy treatments. As the field's clinical experience with these compounds increases, it will be important to investigate these questions prospectively to optimize the clinical use of targeted immunotherapy.

There are no established biomarkers for the use of approved VEGF- and mTOR-directed agents, and patients are not selected for therapy on the basis of molecular features. With the introduction of a novel class of agents, the question of whether this paradigm should change has arisen. The significance of the expression of PD-L1 on tumor cells or tumor-infiltrating lymphocytes is best studied for PD-1 inhibition. With monotherapy, stronger expression levels appear to correlate with higher response rates, but patients who have

limited expression levels can still benefit from treatment.[13,16] The limitations of using immunohistochemistry as a biomarker chiefly lie in the dynamic nature of PD-L1 expression and in differences in tissue processing, among other differences. Recent data in melanoma revealed that neoantigen signatures, which are the results of acquired somatic mutations, can correlate with treatment effectiveness of CTLA-4 inhibition.[17] These data suggest that genomic profiling of the tumor tissue may prove useful as a predictive biomarker for checkpoint inhibitors.

Checkpoint Inhibitor Combinations

Concurrent blockade of PD-1 and CTLA4 is hypothesized to be complementary in regulating adaptive immunity. For RCC, this notion is supported by data from a phase I study combining nivolumab with the CTLA4-directed fully humanized monoclonal antibody ipilimumab in a heterogeneous group of 44 patients (80% pretreated).[18] A 45% ORR, with 80% of the responses ongoing at the time of report, prompted the sponsor to move straight into a phase III study (NCT02231749), which is presently ongoing. This trial is recruiting untreated patients with metastatic disease, who are randomly assigned 1:1 to receive the combination of nivolumab plus ipilimumab versus sunitinib on the comparator arm. With PFS and OS as the coprimary endpoints, the trial is designed to challenge the current treatment paradigm of a VEGF kinase inhibitor as the widely accepted standard of care in first-line settings. Note that the combination's unique toxicity profile frequently requires the use of systemic corticosteroids and other immunosuppressants for the treatment of immune-mediated adverse events. This challenge raises the question of whether the combination, if proven successful in this pivotal trial, could enter practice as a new standard in lieu of a VEGF kinase inhibitor.

Other checkpoint inhibitor combinations, including CTLA4-directed tremelimumab plus the PD-1 inhibitor Medi4736 (NCT02261220) or the anti-KIR–directed antibody lirilumab plus nivolumab (NCT01714739), are much earlier in their development for RCC. Potential synergism with cytokine therapy is being explored in an RCC expansion cohort of a phase I study combining nivolumab with recombinant IL-21 (NCT01629758).

Combining Checkpoint Inhibitors with Approved Targeted Agents

Beyond its principal role as a regulator of angiogenesis, VEGF has various immunomodulatory effects. Accordingly, VEGF tyrosine kinase inhibitors (TKIs) as well as the VEGF-A directed monoclonal antibody bevacizumab have demonstrated immune stimulatory effects across various tumor models (reviewed by Vanneman et al[19]), lending support to combining checkpoint inhibitors with approved targeted therapies. High response rates for combinations of VEGF TKI therapy with CTLA4 inhibition[20] as well as with PD-1 blockade[21] suggest that such synergism in fact exists. At the same time, these trials reported a notable increase in treatment-induced organ dysfunction. The combination of

nivolumab and standard-dose sunitinib, for instance, demonstrated encouraging antitumor activity, with an ORR of 52% across 33 patients, but grade 3 to 4 treatment-related adverse events were recorded in greater than 70% of patients.[21] Such findings make this combination hardly appear suitable for further development on a larger scale. With the suggestion of synergism, however, and in consideration of the notion that immunotherapy may extend the duration of disease control, the field should not prematurely abandon combinations of TKI and checkpoint inhibition. For further development, however, we may need to explore alternate treatment schedules, such as lower dosing levels, sequenced introduction of agents, or alternating dosing schedules. Safety data from other TKI/PD-1 combination trials is awaited, including the two combination trials pairing the PD-1–directed monoclonal antibody pembrolizumab plus pazopanib (NCT02014636) or axitinib (NCT02133742).

Similar to prior experiences combining VEGF-targeted therapy with other agents, bevacizumab seems to pair with checkpoint inhibition without notable increases in toxicity. Data from a phase I study combining bevacizumab and the monoclonal PD-L1–directed antibody MPDL3280 suggested a favorable safety profile, with less than 5% grade 3 to 4 adverse events and four of 10 patients achieving a partial response; nine of 10 patients remained on study at the time of the report.[22] This result prompted a large, randomized, phase II study (NCT01984242) that is presently enrolling untreated patients with 1:1:1 random assignment among standard-dose sunitinib, MPDL3280 monotherapy, and the combination of MPDL3280 plus bevacizumab. Thus, its favorable tolerance when used as a partner with other agents may bring attention to bevacizumab, an agent previously approved in the first-line setting but currently underutilized in that setting.

Vaccine Studies

A number of vaccination strategies, including autologous, multipeptide, and antigen-directed vaccines, are being tested in metastatic RCC.[23] Although it is unlikely that these could replace the current standard of targeted therapy in treatment-naive patients, immunomodulatory effects argue in favor of pairing vaccines with approved targeted therapies. In the phase III ADAPT trial (NCT1582672) patients undergoing cytoreductive nephrectomy were randomly assigned to standard targeted therapy plus autologous vaccination with AGS-003 or to standard therapy alone. This trial is based on encouraging data from a previous open-label, phase II study of sunitinib plus AGS-003 that reported a median PFS of 11.2 months and a median OS of 30.2 months.[23] Another phase III study (NCT01265901) is comparing standard sunitinib to vaccination with sunitinib plus IMA901, a multipeptide vaccine of nine tumor-associated peptides administered after a single dose of cyclophosphamide. Both studies have OS as a primary endpoint, because successful vaccination should have a longer-lasting immunomodulatory anticancer effect. The substantial efforts to bring checkpoint inhibitors into routine practice now raise questions for the further develop-

ment of vaccination strategies: Will these immunotherapies compete with one another in the space of metastatic RCC, or should the two approaches be investigated for synergy?

METASTASECTOMY IN ADVANCED RCC

On the basis of epidemiological estimates, up to 30,000 patients a year are diagnosed with synchronous or metachronous metastatic RCC in the European Union alone.[24] Figures for the United States are comparable.[25] There is a preference for pulmonary (45.2%), followed by skeletal (29.5%), lymph node (21.8%), liver (20.3%), and brain (8.1) % metastases.[26] Other locations of metastasis have been described at lower frequencies. Because of the extent of disease, most patients with metastatic RCC are candidates for systemic therapy rather than metastasectomy. With current targeted treatments, a cure remains elusive, and the median OS may reach 40 months in select patients with sequential therapy.[27] However, in those patients who have solitary or oligometastasis, surgical resection of all lesions when technically feasible provides the only potentially curative treatment, aside from the occasional durable responses achieved with high-dose IL-2. Surgical resection is the preferred approach for metastasectomy, but stereotactic radiosurgery (SRS) or body radiotherapy (SBRT) may be noninvasive alternatives.[28] Unlike surgical metastasectomy, SRS, SBRT, or ablative techniques have been preferred for brain, bone, and liver metastases.[29] These focal therapies are being expanded to multiple anatomic regions, but thermal ablation has been applied only in small series.

Case Selection for Metastasectomy

No reliable data exist that identify a percentage of patients with metastatic RCC who are candidates and eligible for complete surgical metastasectomy or local therapy. According to a population-based analysis, up to 65% of patients with metastatic RCC have a single anatomic site of metastasis, but most of these metastases are either multiples at that site or not resectable.[26] Potentially, only 25% of patients with metachronous metastases are suitable for metastasectomy.[30,31] For patients with synchronous metastasis, the proportion may be lower than 10%.[32] Patient selection for metastasectomy is challenging because of the heterogeneous biology of metastatic RCC and an absence of randomized, controlled trials in this setting. In addition, most retrospective studies reported results before the introduction of targeted therapy. The clinical course of metastatic RCC is unpredictable. Metastasis may present at diagnosis or within a year after nephrectomy with rapid disease progression, whereas disease-free intervals of more than 20 years followed by slow metastatic growth have been reported. In a few cases, spontaneous regression of metastases has been documented.[33,34]

The Renal Cancer Guideline Panel of the European Association of Urology performed a systematic review to address the questions of whether local therapy for RCC metastases is beneficial, and, if so, what the best therapeutic approaches are.[35] In accordance with Cochrane Review methodology and PRISMA guidelines, including all types of comparative studies on local treatment of RCC metastases in any organ, 2,235 studies were identified. However, only 16 small, retrospective, comparative studies reporting on a total of 2,350 patients were eligible for inclusion. The systematic review revealed a benefit for complete metastasectomy compared with either incomplete or no metastasectomy for metastases to various organs in terms of survival and symptom control, such as pain relief in bone metastases. There may be an additional role in delaying the start of targeted therapy and its associated adverse events. However, there were extensive risks of bias across all studies, which resulted in a significant risk of confounding. Because of the relatively poor quality of the studies, the evidence retrieved was associated with large uncertainty, and no general recommendations were made. Retrospective series are biased by comparing patients who had solitary and oligometastatic disease and a prolonged metachronous interval with those who did not undergo resection because of extensive metastatic burden, rapid disease progression, and reduced performance status. The most important determinant of outcome, therefore, may be the biologic behavior of the tumor.[36] In one series, a high nuclear tumor grade was the only adverse factor for survival.[37] In a metastasectomy-specific prognostic model, primary tumor T stage greater than or equal to 3 , primary tumor grade greater than or equal to 3, presence of nonpulmonary metastases, a disease-free interval of 12 months or fewer, and multiorgan metastases were independent pretreatment prognostic factors for survival after metastasectomy in a multivariable analysis.[38] In contrast to the commonly used Memorial Sloan Kettering Cancer Center (MSKCC) and International Metastatic Renal Cancer Database Consortium (IMDC) prognostic models, which estimate survival in metastatic RCC on the basis of five to six clinical factors, the results have not been externally validated.

Identification of patients who may benefit from metastasectomy is important, because surgical resection, including other forms of local therapy alone or in combination with targeted agents, may result in superior outcome compared with systemic therapy alone. The decision to resect metastases depends on a number of clinical factors, such as the tumor-node-metastasis staging system classification, performance status, prognostic risk factors, the length of the disease-free interval, synchronous or metachronous metastasis, the burden of metastatic disease, and the number and location of sites involved.[39] Since then, multiple retrospective series have been published that support the use of these favorable factors (Sidebar).[40-42] In particular, complete metastasectomy is a favorable prognostic variable according to data from Europe, the United States, and Japan.[43,44] Metastasectomy is associated with survival and clinical benefit across the various MSKCC risk groups.[31,45] In a retrospective analysis of 129 patients who developed metachronous metastases from RCC, metastasectomy improved 5-year survival from 36% to 71% in favorable-risk patients. For intermediate-risk patients, the 5-year survival was 38% after metastasectomy ver-

sus 0% in the same risk group without metastasectomy or with poor prognosis. Even after adjusting for risk groups in a multivariate analysis, patients without metastasectomy had a 2.7-fold increased risk of death. Previously, the same institution reported on 118 patients who had a median survival of 21 months from the time of recurrence.[31] OS was strongly associated with risk-group category (p < 0.0001). The median OS times for low-, intermediate-, and high-risk groups were 76, 25, and 6 months, respectively, and the 2-year survival rates were 88% (95% CI, 77% to 99%), 51% (95% CI, 37% to 65%), and 11% (95% CI, 0% to 24%), respectively, which suggest that only favorable- or intermediate-risk patients are candidates for metastasectomy. After the introduction of targeted therapy, the MSKCC risk model has been largely superseded by the IMDC risk model but remains a valid tool among other similar risk scores to identify potential candidates for metastasectomy.[46,47] Though the factors related to prognosis seem to be generally applicable to metastasectomy at any site, some sites may demand specific management strategies, especially when solitary metastasis or oligometastasis is present.

Metastasectomy by Anatomic Site

The lungs are the most frequently affected site, with a prevalence rate of 74% in autopsy studies.[48] Pulmonary metastasectomy is associated with longer survival than that of other sites, even when multiple lung lesions are resected. The best outcome is reported for patients who have completely resected solitary metastases after a long disease-free interval. Complete resection of up to but not exceeding seven lung metastases is associated with a 5-year survival rate of 37% to 54%.[30,49-52] Because of the high frequency of lung metastases, there is a wealth of retrospective, nonrandomized studies on pulmonary metastasectomy that suggest that unilateral lung involvement, absence of lymph node metastases, and smaller size are additional site-specific favorable factors. Complete resection, size greater than 3 cm, positive node status of the primary tumor, synchronous metastases, pleural invasion, and mediastinal lymph node metastases were independent prognostic factors on multivariate anal-

ysis identified in a lung-specific prognostic score developed from 200 patients with pulmonary metastases.[53] Three risk groups were discriminated with median OS times of 90, 31, and 14 months for low-, intermediate-, and high-risk groups, respectively. This score is not yet externally validated.

Resection of bone metastasis is mainly performed for palliation but may result in 5-year survival rates of 75%, particularly in metachronous and appendicular solitary bone lesions.[54] For symptomatic bone metastases, surgery is superior to radiotherapy. A randomized, prospective trial in patients with bone metastasis from various malignancies, which included a minority of RCC, revealed that direct decompressive surgery plus postoperative radiotherapy was superior to treatment with radiotherapy alone for patients with spinal cord compression caused by metastatic cancer.[55] The best approach for asymptomatic solitary bone lesions is unclear. If surgery is chosen, wide excision with fixation or reconstruction is preferable. For brain metastases, SRS has largely replaced surgery as local treatment. However, surgery may be preferable in lesions greater than 2 to 3 cm, with rapid onset of symptoms, and in lesions with a midline shift. Selection factors in patients for local therapy of brain metastases regardless of the primary tumor site include performance status, extracranial tumor load, and the course of disease, as summarized in the Radiation Therapy Oncology Group (RTOG) recursive partition analysis (RPA).[56] SRS yields a median OS of 24 months in patients with RTOG-RPA prognostic class I. Whole-brain radiotherapy is only adequate for patients who have a poor performance status.[57-59]

For most other metastatic sites, detailed selection criteria are not available, and indication for resection should follow the factors associated with a favorable outcome (Sidebar). Hepatic metastasis is associated with poor prognosis. Nevertheless, after complete resection for solitary lesions, 5-year survival rates of 62% have been reported.[60] Liver metastasectomy may cause significant morbidity and mortality, and it is unclear if surgery is superior to ablative percutaneous techniques. Synchronous solitary adrenal metastases are usually resected at the time of nephrectomy.[61] Management of isolated metachronous ipsi- and contralateral adrenal lesions is often reported in series of local recurrences. Survival of up to 70 months has been reported after metastasectomy after a long disease-free interval.[62] Though not regarded as a distant metastatic site in the tumor-node-metastasis staging system classification, lymph node metastases are frequent and associated with a poor outcome, similar to systemic disease.[63,64] Synchronous regional lymph node metastases often are resected at nephrectomy. Isolated lymph node metastasis without further systemic disease is rare,[65,66] but resection may be curative. Resection of metachronous isolated lymphonodular metastases often is reported in series on local recurrences.[67] Complete metastasectomy of solitary lesions in the pancreas, thyroid, and other less frequently involved sites results in 5-year survival rates comparable to those observed

after pulmonary metastasectomy.[68] Remarkably, repeat complete metastasectomy and complete resection of multiple metastatic sites are associated with long-term survival and a 50% decrease in the risk of death.[36] Multiple case reports and series on the integration of targeted therapy with surgery report neoadjuvant targeted therapy to downsize lesions or select candidates for complete resection.[69] However, the approach is experimental and not supported by prospective studies. Ultimately, to derive a higher quality of evidence regarding metastasectomy and other local treatment options in RCC, larger and prospective, randomized studies need to be performed.

The Role of Surveillance versus Adjuvant Treatment in Stage I Germ Cell Tumors: Outcomes and Challenges

Alan Horwich, MBBS, MRCP, FRCR, PhD

OVERVIEW

Germ cell cancers of the testis arise in young adults, and, if identified in stage I, have an excellent prognosis. Thus, we should minimize management-related toxicities. Surveillance (observation) following orchiectomy can avoid further treatment; however, patients who experience relapse receive more treatment than what would have been used during initial adjuvant therapy. For the individual patient, it is important to be aware of their particular risk of relapse, the treatment they would receive for the treatment of relapse and the alternative adjuvant approaches. For seminoma, the risk of relapse during surveillance is 15% to 20%; the size of the primary tumor and the presence of rete testis invasion are prognostic factors. Most relapses occur within 3 years; however, approximately 10% occur more than 5 years after orchiectomy. The alternative adjuvant strategies are either one cycle of carboplatin or radiotherapy (RT), which reduce recurrence risk to less than 5%. The cure rate is around 99%, regardless of which management option is implemented. For stage I nonseminoma, the risk of relapse during surveillance in unselected series is 26% to 30%. Lymphovascular invasion and the amount of embryonal carcinoma are risk factors. Most relapses occur within the first year after orchiectomy, and relapse after 3 years is rare. Ninety percent of relapse patterns are classified as ''good prognosis,'' and cure rates are 99%. The alternatives to surveillance include adjuvant strategies such as one cycle of adjuvant bleomycin/etoposide/cisplatin (BEP) chemotherapy; however, evidence is emerging that a single cycle is effective. There is controversy whether to offer surveillance for all patients or to offer adjuvant chemotherapy to select patients.

Germ cell cancers of the testis are defined as stage I when radiologic investigations show no evidence of metastasis. These generally comprise of CT scans of the thorax and abdomen, although the pelvis should also be included in patients with previous inguinal or scrotal surgery. Serum tumor markers elevated prior to orchiectomy should fall with an appropriate half-life (less than 5 days for alpha-fetoprotein and less than 2 days for human chorionic gonadotropin) after resection of the primary tumor. Men with normal radiology but persisting elevated blood tumor markers are regarded as having metastases and will not be considered further in this manuscript. Despite an increase in the sensitivity of radiologic staging tests, there appears to be an increase over recent decades in the proportion of patients with germ cell cancer in stage I,[1] with approximately 80% of seminomas and 60% of nonseminomas presenting in this stage.

A number of management policies have been followed postorchiectomy, and all are associated now with very high cure rates (around 99%). The shared aim of these policies is to address patients in stage I who actually have subclinical metastasis. These policies include surveillance, adjuvant chemotherapy, retroperitoneal lymph node dissection (RPLND), and RT.

SURVEILLANCE

This management policy involves regular monitoring of patients postorchiectomy to detect any development of clinically overt metastases at a stage in which the disease would still be highly curable. Initially, there was anxiety about allowing subclinical disease to progress, and consequently, surveillance was rather intensive. There are few prospective studies, but a Medical Research Council trial that randomly assigned 414 patients who were undergoing surveillance for stage I nonseminomas to receive five scans at months 3, 6, 9, 12, and 24, or two scans at months 3 and 12 reported similar outcomes.[2] The Royal Marsden schedule for the surveillance of patients with nonseminoma involves monthly tumor markers and chest radiographs for the first year, chest radiographs every 3 months for the second year, and chest radiographs every 4 months in the third year, as well as CT scans of the abdomen at 3, 12, and 24 months. However, a number of guidelines recommend fewer assessments without clear detriment. Similarly, there are few prospective seminoma studies; an ongoing U.K. trial is comparing CT scan schedules and MRI versus CT imaging. The Royal Marsden schedule has clinic assessments every 3 months in the first and

---

second years, assessments every 4 months in the third year, and assessments every 6 months until the end of year 5, and thereafter annually up to 10 years. CT scans of the abdomen are conducted every 6 months for 2 years, then annually for an additional 3 years.[3]

In a systematic review of larger case series of nonseminoma published between 1986 and 2004, relapse rates during surveillance was 26% to 30%, and the most commonly agreed adverse prognostic factor was lymphovascular invasion (LVI) in the primary tumor.[4] A recent retrospective report[5] on surveillance outcomes based on more than 1,000 patients found that only 19% relapsed; this reduction may be a result of more sensitive staging or the practice of offering adjuvant chemotherapy to patients at higher risk. Only 16% of patients had LVI-positive disease.[5] The median time to relapse was 6 months, and the relapse risk was 44% in patients with LVI compared with 14% in patients without LVI. Out of 214 patients whose disease relapsed, 192 were prognostically classified as good risk, 16 were intermediate risk, and six were poor risk. At the time of reporting, there had been only five disease- or treatment-related deaths and an additional two patients were alive with disease.

Surveillance poses different challenges in patients with stage I seminoma because tumor markers are not necessarily helpful and the disease has a slower natural history requiring a longer period of observation. In addition, seminoma has a more predictable pattern of metastasis, which initially occurs in the retroperitoneal nodes. Approximately 15% to 20% of patients with seminoma will experience relapse during surveillance.[4] There has been some controversy over the prognostic risk model, first proposed by Warde et al[6] based on a retrospective review of 638 patients from Canada and Europe. This prognostic model suggested that the combination

of primary tumor diameter greater than 4 cm and invasion of the rete testis conferred a relapse risk of 31%, whereas only one of these factors conferred a risk of 16%, and an absence of both factors conferred a risk of 12%. Although the model has not been validated, the same risk factors were reported in the Swedish and Norwegian Testicular Cancer Group (SWENOTECA) community-based studies[7] and in the Spanish Germ Cell Group trials.[8] A retrospective study of surveillance in 1,344 patients with stage I seminoma reported that 173 patients experienced relapse and all but two patients were classified as good risk upon relapse, with most patients (87%) diagnosed by abdominal CT imaging.[5] Only one patient died as a result of the disease or treatment.

ADJUVANT CHEMOTHERAPY

The rationale for considering adjuvant chemotherapy following orchiectomy is based on the avoidance of the risk of toxicities that may occur during a full treatment of relapsed disease, as well as the disappointment and natural anxiety experienced when relapse occurs. For nonseminoma, initial studies suggested a benefit of two cycles of BEP[9]; however, more recently there have been persuasive reports suggesting a benefit with a single cycle. A German Testicular Group trial randomly assigned patients to undergo RPLND and one cycle of BEP.[10] Of 191 patients treated with BEP, the relapse risk was only 0.5%. Similarly, a community protocol by the SWENOTECA group that included 517 patients who received one cycle of adjuvant BEP reported relapse rates of 1.6% for patients with LVI-negative and 3.2% for patients with LVI-positive tumors.[7] An ongoing U.K. prospective trial (The 111 Trial) that will evaluate the outcomes of one cycle of BEP completed recruitment of 246 high risk patients in July 2014 and results are expected to be reported soon.

In patients with seminoma, the decision to offer adjuvant chemotherapy has been based on a low toxicity approach using single agent carboplatin. A large, prospective, randomized, controlled trial compared traditional adjuvant RT to one cycle of carboplatin at a dose intended to achieve an area under the curve (AUC) of 7 mg × mins/mL.[11] Of 573 men randomly assigned to receive carboplatin, the relapse rate was 4%, which was similar to RT. This result for carboplatin was similar to the SWENOTECA community study conducted in 188 patients with seminoma, in whom the relapse rate was 4% after a median follow-up of 3.4 years.[12] In the Spanish Testicular Germ Cell Group trials, the relapse rate after two cycles of carboplatin was 3.2%.[8]

RETROPERITONEAL LYMPH NODE DISSECTION

The rationale of this approach was to provide more accurate staging of retroperitoneal nodes and to reduce relapse risk in those with subclinical metastases confined to those nodes. However, the surgery is not trivial and is only proficiently performed in specialized centers. The German Testicular

---

KEY POINTS

- Men with stage I testicular germ cell cancer have an excellent prognosis with reported cure rates of 99%, regardless of the management option chosen postorchiectomy.
- In unselected patients with nonseminoma, there is a relapse risk of 25% to 30% during surveillance, and the most widely recognized risk factor is lymphovascular invasion.
- In unselected patients with seminoma, there is a relapse risk of 15% to 20% during surveillance, and the most widely recognized risk factors are tumor diameter and rete testis invasion.
- Radiotherapy has the relative disadvantage that it is carcinogenic.
- The primary management options following orchiectomy are surveillance or adjuvant chemotherapy, and patient preferences should be respected. Risk-adapted selection for adjuvant chemotherapy markedly reduces the risk of recurrence during the remainder of the time spent in surveillance.

Group multicenter trial discussed previously had 15 recurrences in 191 patients who were randomly assigned to undergo RPLND (92% of patients achieved 2 years of relapse-free survival), of which seven patients had disease involvement in the retroperitoneal nodes.[10] Single, specialized center experience suggests that careful staging and selection for adjuvant chemotherapy can increase the proportion of patients with stage II found to have low volume node disease and achieve a very low recurrence.[13]

RADIOTHERAPY

This has been a standard adjuvant approach in patients with stage I seminoma, traditionally to a field including both para-aortic and ipsilateral pelvic lymph nodes. Many series reported recurrence risk of less than 5%. More recently, prospective, randomized trials have shown that reducing the field to just the para-aortic region[14] and reducing the dose to only 20 Gy[15] did not reduce efficacy. The disadvantage of RT is that it is carcinogenic. For example, a multicenter U.K. and Norwegian study of 2,692 patients with stage I seminoma demonstrated a cancer Standardized Incidence Ratio of 1.53 when second testicular cancers were excluded,[16] with increased risk mainly affecting cancers of abdominal organs. This risk has led to the option of adjuvant RT for patients with stage I seminoma being abandoned or reduced considerably in some communities.[17-19]

DISCUSSION

In most oncology centers, the primary management options in 2015 for patients who have undergone an orchiectomy for stage I testicular cancer are surveillance or adjuvant chemotherapy. There are advocates in favor of surveillance for almost all patients with stage I testicular cancer on the grounds that it is safe in terms of ultimate cure rate and that it confines the potential toxicities of treatment to the minority of patients whose disease has already formed subclinical metastases.[20] The arguments for adjuvant chemotherapy suggest that the limited total drug doses in one treatment cycle are safer for patients than the drug doses in a full treatment for metastatic relapse. In addition, adjuvant chemotherapy has a particular indication in patients with high risk features, in patients who are unlikely to adhere to surveillance, and in patients with comorbidities that might compromise a full course of treatment for metastases. This leads to a so-called risk-adapted strategy, with surveillance for patients at low risk and adjuvant chemotherapy for patients at a high risk of developing metastasis, as promoted particularly in the Spanish Germ Cell Cancer Group trials.[21] There is a strong argument to involve the individual patient in the discussion of both approaches.[22]

Germ Cell Tumors: Looking to the Future

George J. Bosl, MD

OVERVIEW

Our knowledge about the management of men with germ cell tumors (GCTs) and its tumor biology continues to evolve. Vascular disease, metabolic syndrome, second malignant neoplasms, and hypogonadism occur after treatment for GCTs and the latency pattern resembles that seen in patients treated for Hodgkin lymphoma. Patients receiving treatment for GCTs should be informed not only of the near-term toxicity (experienced during or shortly after administration), but also the delayed and late effects of chemotherapy and the need for lifelong surveillance for all late outcomes, including late relapse. Recent data suggest that the treatment outcome of patients with intermediate-risk, poor-risk, and relapsed GCTs can be improved through multicenter trials that include the general oncology community. Finally, GCTs are a malignancy of primordial germ cells. Programmed differentiation is clinically evident in vivo and probably related to chemotherapy resistance. This biology has much clinical relevance, some of which is already in use.

In 2015, more than 90% of men with newly diagnosed GCTs will be cured. The chemotherapy backbone of etoposide/cisplatin (EP) with or without bleomycin (BEP) cures patients with even far advanced newly diagnosed metastatic disease. A sizable proportion of patients who relapse or progress after initial chemotherapy are cured with standard and high-dose regimens.[1] Since chemotherapy cures nearly all patients with low-volume disease, surveillance has become a standard of care for patients with clinical stage (CS) I seminoma and CS I-A nonseminomatous GCT (NSGCT), few of whom relapse after orchiectomy. Adjuvant chemotherapy with one or two chemotherapy cycles has been adopted by some for CS I-B disease and is often recommended for patients who have pathologic stage IIB disease at primary retroperitoneal lymph node dissection.[1,2]

However, physicians and patients should not be misled. Attention to detail may be more important in the management of patients with GCTs than in any other curable malignancy since a large proportion of patients is observed without treatment after orchiectomy and easily lost to follow-up. The number of survivors is increasing, with close to 250,000 survivors of GCTs comprising approximately 4% of all male cancer survivors, more than lung cancer.[3] Despite the low death rate, the number of lost life years is greater for patients with GCTs than for any other cancer in adults.[4] Complacency, fostered by the high cure rate, obscures the effect of rare fatal events resulting from improper diagnosis, loss to follow-up, late chemotherapy side effects, the need for improved therapy for intermediate-, poor-risk, or relapsed disease, and the poor understanding of GCT bi-

ology. What should oncologists be looking for in the next 10 years?

MANAGEMENT OF SURVIVORS

"An individual is considered a cancer survivor from the time of diagnosis to the balance of his or her life" (Office of Cancer Survivorship) and survivorship deals "…with the full spectrum of survivorship issues related to living with, through, and beyond the cancer diagnosis" (National Coalition of Cancer Survivors).[5,6] Hence, men with GCT should be followed long after being rendered free of disease. Indeed, the oncologist may be the only physician that these young patients have. Although persistent peripheral neuropathy, ototoxicity, and hypogonadism are observed, cardiovascular disease and second malignant neoplasms are the most important late effects since they can be life threatening.

Cardiovascular Disease

Both acute and late toxicities exist for men with GCTs. Venous and arterial vascular events may occur during cisplatin-based chemotherapy (and rarely carboplatin), including myocardial infarction, stroke, peripheral arterial thrombosis, and pulmonary emboli.[7,8,9] Delayed vascular toxicity presenting as Raynaud's phenomenon occurs in 6% to 7% of patients receiving bleomycin as part of chemotherapy for GCT.[10,11,12] Cardiac and rare cerebrovascular morbidity and mortality may occur 10 to 20 years (or more) after the completion of chemotherapy.[13,14,15] Although the mechanism is not understood, insulin resistance, increased abdominal visceral fat, and hyperlipidemia may appear shortly after che-

motherapy, and metabolic syndrome with or without hypogonadism, which is associated with increased cardiovascular morbidity and mortality, is more frequent in men who receive GCT chemotherapy.[16,17,18]

To mitigate these risks, patients should be monitored after chemotherapy for the onset of hypertension, obesity, hyperlipidemia, and hypogonadism, with intervention at the earliest opportunity.[19] Smoking cessation and weight reduction are key to cardiovascular protection. If the oncologist will not be following the patient long-term, then a primary care physician should oversee general health maintenance.

Second Malignant Neoplasms

Patients with GCTs have an increased risk for second non-GCT neoplasms after both radiation therapy (RT) and chemotherapy,[20,21] but not after surgery alone.[21] RT increases the incidence of several intra-abdominal neoplasms, including colon, pancreas, and stomach cancer.[20,22] Although surveillance has largely replaced RT for CS I seminoma, RT exposure is prevalent among survivors of GCT since most received RT for seminoma before 2005, the year of the Travis report.[20] Early screening colonoscopy should be considered, as is recommended for survivors of childhood malignancy.[23] The lower bound of chemotherapy dose associated with the risk for second non-GCT malignant neoplasms is unknown. Therefore, the use of chemotherapy in the adjuvant setting, particularly CS I-B NSGCT, has unknown long-term risks. However, even the lowest doses of etoposide are associated with an increased risk for leukemia,[24] suggesting that the long-term effects of adjuvant administration, merits consideration. Last, men with GCT are disproportionately likely to have multiple atypical nevi and melanoma.[20,25] Although melanoma is not caused by treatment, dermatologic referral of patients with GCT and pigmented nevi should also be considered.

KEY POINTS

- Late effects of cisplatin-based chemotherapy for GCT are known and should be discussed with all patients who require it.
- In good-risk disease, new guidelines list four cycles of etoposide/cisplatin and three cycles of bleomycin/etoposide/cisplatin as options for clinical stage IIA and IIB seminoma.
- Treatment outcome in patients with intermediate-, poor-risk, and relapsed disease may improve because of recent and ongoing trials.
- Most data indicate that few GCTs display driver mutations and a better knowledge of tumor biology is needed to identify potential therapeutic targets.
- Progress will require a national and international trial effort including participation by community oncologists to accrue adequate patients and tumor sample for studies.

SYSTEMIC THERAPY FOR METASTATIC DISEASE
Good Risk

Since 90% to 95% of patients with good-risk disease are cured, improvements on three cycles of BEP (BEPx3) and four cycles of EP (EPx4) are unlikely. The lower bound of efficacy is known and carboplatin is inferior to cisplatin in both relapse rate and cure rate.[1] The management of CS IIA and IIB metastatic seminoma with chemotherapy rather than RT is evolving. Recent studies report no relapses among 20 patients with CS IIA disease and 22 patients with CS IIB disease.[26,27] Since RT leads to an increased incidence of intra-abdominal malignancy, and RT followed by chemotherapy leads to an even greater likelihood of both late cardiovascular and second cancer events than either modality alone,[28] primary chemotherapy has been added to the National Comprehensive Cancer Network guidelines for these two groups.[29]

Intermediate and Poor Risk

Four trials suggest that better outcomes can be achieved in patients with intermediate-risk and poor-risk disease, who have cure rates of approximately 75% and 50%, respectively.

In the first trial, paclitaxel added to BEP in intermediate-risk disease led to a significant 12% improvement (p = 0.03) in 3-year progression-free survival when ineligible patients were excluded, but a nonsignificant improvement in the intent-to-treat analysis.[30]

A second randomized trial comparing standard-dose BEP with a dose intense regimen with stem cell support resulted in a 16% improvement in failure-free survival, which was not significant (p = 0.057).[31] Both trials were closed early because of slow accrual, partly because of separation of intermediate-risk and poor-risk groups into different studies, leading to nonsignificant results despite trends suggesting improved survival.

A third randomized trial of standard BEPx4 compared with a complex BEP-based regimen with paclitaxel, oxaliplatin, and ifosfamide in patients with poor-risk disease and an unfavorable tumor marker decline showed an improvement in 3-year progression-free survival from 48% to 59% (p = 0.05), but with more grade 3 to 4 toxicity.[32]

Finally, a phase II trial of four cycles of paclitaxel/ifosfamide/cisplatin (TIPx4) demonstrated a 95% 3-year overall survival and 79% 3-year progression-free survival.[33]

Together, these results suggest that the outcome of intermediate- and poor-risk disease can be improved. Since three of these trials incorporated paclitaxel, a direct comparison of TIPx4 to BEPx4 is now open at several institutions (NCT01873326). A worse outcome when the half-life of either alpha-fetoprotein (AFP) or human chorionic gonadotropin (HCG) is prolonged was also demonstrated in an intergroup study in which an improvement in 1-year survival was observed in patients with slow marker decline from 34% for BEPx4 to 61% for BEPx2 followed by two cycles of high-dose chemotherapy.[34] Thus, a randomized trial testing a new regimen in patients selected for unfavorable marker decline is reasonable. In both cases, the trials should be multicenter/multinational and include and stratify for intermediate- and poor-risk disease.

Salvage Therapy

Patients who have relapsed after complete remission or responded but failed to achieve a complete remission (incomplete response) have potentially curable disease.[35-38] Some groups favor standard-dose therapy for relapse after a complete response and high-dose therapy restricted to incomplete responders, whereas others favor the administration of high-dose chemotherapy to all patients.[36,37] Disagreement exists as to the proper management of patients with mediastinal and nontesticular NSGCT (e.g., ovarian, pineal).[36,37] Other investigators question the benefit of high-dose therapy.[38] A randomized trial in Europe and the United States stratified for prognostic subgroups will test the hypothesis that high-dose chemotherapy is better than standard-dose chemotherapy as initial salvage treatment for patients with relapsed or progressive GCT.[39,40]

GCT BIOLOGY AND ITS CLINICAL IMPLICATIONS

GCT biology is clinically relevant. One of the provocative questions raised by the National Cancer Institute is the study of "what molecular properties make some cancers curable with conventional chemotherapy."[41] The differential chemotherapy sensitivity of seminoma and NSGCT is reflected in the International Germ Cell Cancer Consensus Group (IGCCCG) classification.[42] In metastatic seminoma, only nonpulmonary visceral metastases qualify as intermediate risk; poor-risk seminoma does not exist. In contrast, blood marker levels, sites of nonpulmonary metastases, and mediastinal primary site establish the good-, intermediate-, and poor-risk strata in NSGCT, on which the choice of treatment depends. Adherence to the IGCCCG classification is central to assuring neither overtreatment nor undertreatment. Although both seminoma and NSGCT are highly curable, the biology responsible for the differential chemotherapy sensitivity of seminoma/NSGCT histology, marker production, and mediastinal primary site is unknown.

Derivation from Primordial Germ Cells

GCTs are derived from primordial germ cells (PGCs). The fetal migration of PGCs from the genital ridge to the testis is regulated by the interaction of CD117 (the c-kit receptor) expressed by PGC and its ligand, stem cell factor (kit ligand), and is essential to spermatogenesis in the postpubertal male.[43] The expression of CD117 disappears during early meiosis. Seminoma are closest to the unipotent germ cells and expresses CD117 and embryonal carcinoma acquires pluripotency and does not express CD117. *NANOG, POU5F1,* and *SOX2* are genes that encode three key master regulator transcription factors (Nanog, Oct4, and Sox2) required for the maintenance of pluripotency in murine and human embryonic stem cells (ESC).[44,45] Both seminoma and NSGCT express Nanog and Oct4; only embryonal carcinoma expresses all three. Downregulation of these genes' expression during differentiation in both embryonal carcinoma and ESC is associated with a large and complex transcription

factor network, whose dysregulated expression is probably responsible for the diverse but disorganized differentiated histologies displayed by NSGCT.[46]

These observations are useful clinically. Immunostaining for Oct4 has replaced placental alkaline phosphatase (PLAP) as the immunohistochemical marker for seminoma and embryonal carcinoma. Immunostaining for CD117 characterizes seminoma and is absent in embryonal carcinoma. CD30, generally regarded as a marker of anaplastic large cell lymphoma and Reed-Sternberg cells, is also expressed by embryonal carcinoma but not seminoma.[47] Subsequent work indicated that CD30 is a survival factor for transformed human pluripotent human ESC. Finally, embryonal carcinoma expresses keratins and seminoma does not, indicating its more differentiated state. A combination of Oct4, CD117, CD30, and keratins is now part of the standard diagnostic immunohistochemical panel when a diagnosis of GCT is under consideration.[48,49]

Differentiation and Resistance

Treatment resistance in GCTs is likely related to genetic events leading to differentiation.[50] Clinical observations support this hypothesis. Seminoma is more sensitive than NSGCT.[42] Teratoma, usually displaying benign-appearing mature and immature cell types, is insensitive to chemotherapy and must be surgically excised. Yolk sac and trophoblastic differentiation, reflected by secretion of AFP and HCG, respectively, is associated with worsening prognosis as serum levels become higher.[42] Late relapse of NSGCT often displays yolk sac differentiation and is associated with a relatively poor prognosis and reduced chemotherapy sensitivity. Finally, somatic malignant differentiation within teratoma has the prognosis of the de novo tumor arising at its natural primary site and is not sensitive to cisplatin-based GCT chemotherapy.

The secretion of AFP and HCG by embryonal carcinoma implies that the genetic machinery to manufacture these proteins may exist even if yolk sac or trophoblastic morphology is absent. Therefore, NSGCT may also express many of the intracellular proteins that represent differentiation into ectodermal, mesodermal, and endodermal lineages during normal development, sometimes with and sometimes without the characteristic morphology of teratoma.[51] A molecular signature prediction model, independent from the IGCCCG risk strata, was developed that showed that the dysregulated expression of these developmental proteins, including neuroectoderm, kidney, and other markers, was associated with a worse outcome in NSGCT.[51] This finding is consistent with clinical observations that show somatic malignant transformation of teratoma has a poor prognosis, including primitive neuroectodermal tumors (PNET), one of the more frequent forms of malignant transformation.[52,53] Replication and validation of that study on paraffin-embedded tissue are needed. Studies of gene expression within primary tumors may point to which teratoma needs resection, which will remain quiescent after chemotherapy, and why mediastinal NSGCT has such a poor prognosis. Hence, the link between pluripotency,

TABLE 1. Late Effects Spectrum of Germ Cell Tumors and Hodgkin's Lymphoma to Include in Your Treatment Discussion[28,62,63]

Disease	Modality	Event	15 Years (Approximate)	25 Years (Approximate)
Hodgkin's Lymphoma	Not stated	CVD	3%	8%
		SMN	5%	15%
GCT	RPLND	CVD + SMN	2%	8%
	RT	CVD + SMN	4% to 5%	13%
	Chemotherapy	CVD + SMN	4% to 5%	13%
	RT + chemotherapy	CVD + SMN	12%	32%

Abbreviations: CVD, cardiovascular disease; GCT, germ cell tumor; RT, radiation therapy; RPLND, retroperitoneal lymph node dissection; SMN, second malignant neoplasm.

differentiation, and drug resistance in GCT requires further study.

Genomic Change and Targeted Therapy

Although GCT displays hyperdiploidy and excess 12p copy number, most frequently as an isochromosome of 12p [i(12p)], GCT is infrequently associated with oncogene driver mutations. *BRAF* mutations were reported to be associated with a poor outcome, but a larger study showed that zero of 46 resistant tumors harbored a *BRAF* mutation.[54,55] *FGFR3* mutations were rarely detected in both sensitive and resistant tumors, whereas, *RAS, AKT1,* and *PI3KCA* mutations were observed rarely only in resistant tumors.[55] Together, these data imply that newer targeted therapies are not likely to be effective.[55] Gene amplification and *TP53* mutations have been reported in a few resistant tumors, but further study is needed to determine their relevance to prognosis and therapy.[56,57]

The expression of CD117 by seminoma and CD30 by embryonal carcinoma raises the possibility of therapy directed at these known targets. Unfortunately, imatinib was not effective in a small group of resistant tumors expressing CD117.[58] Brentuximab vedotin in embryonal carcinoma might be more promising since a complete response has been reported.[59] However, its value is likely to be minimal since most NSGCT are mixed tumors and CD30 is expressed only by embryonal carcinoma. Sunitinib and ARQ197 (a MET inhibitor) demonstrated no activity.[60,61]

Summary

Knowledge about GCTs continues to expand. Postchemotherapy vascular disease, metabolic syndrome, second malignant neoplasms, and hypogonadism occur with a latency resembling that seen in patients treated for Hodgkin lymphoma (Table 1).[62,63] Acute leukemia has been reported with the use of etoposide 500 mg/m^2 to 1,000 mg/m^2 (one to two cycles) and even a single dose of cisplatin has a measurable effect on renal function.[24,64] Although chemotherapy will cure most metastatic disease, its use should be carefully considered in adjuvant settings and patients should be informed not only of the near term effects of chemotherapy (experienced during or shortly after its administration), but also its delayed and late effects that require lifelong surveillance for late outcomes, including late relapse.[65] Clinical trials designed to improve treatment outcome in patients with intermediate-risk, poor-risk, and relapsed GCTs are feasible, but require collaboration for adequate accrual. Finally, GCT is a disease of PGCs, and differentiation is clinically evident in vivo and probably related to chemotherapy resistance. This biology has much relevance, some of which is already in clinical use. More study is needed.

Salvage Therapy in Patients with Germ Cell Tumors

Lawrence H. Einhorn, MD

OVERVIEW

Testicular cancer is the most curable metastatic solid tumor. Initial chemotherapy is evidence based with risk stratification into three prognostic categories: good, intermediate, and advanced disease. Guidelines for disease management following progression after initial cisplatin combination chemotherapy are less clear. Options include salvage surgery for patients with anatomically confined relapse, standard-dose cisplatin combination chemotherapy, or high-dose chemotherapy with carboplatin plus etoposide with peripheral blood stem cell transplantation. Proper interpretation of a presumed relapse can be complicated. Growing masses on imaging studies might reflect a growing teratoma. Persistent elevations of serum human chorionic gonadotropin (hCG) or alpha fetoprotein (AFP) are only an indication for salvage therapy if there is a definitive rise in the tumor marker. Elevated and rising serum hCG as the only evidence of recurrence can be because of cross reactivity with luteinizing hormone or usage of marijuana rather than progressive cancer. Elevated liver function tests can cause rising serum AFP.

The initiation of cisplatin combination chemotherapy 40 years ago transformed metastatic testicular cancer into a highly curable malignancy.[1] It is widely recognized to be the most curable solid tumor. Subsequent salvage strategies have allowed for cure in a substantial percentage of progressive disease following first-line cisplatin combination chemotherapy. This article will detail strategies for salvage chemotherapy, the judicious use of salvage surgery, and data from published studies.

The first curative salvage chemotherapy utilized the two-drug synergistic combination of cisplatin plus etoposide in patients in which cisplatin plus vinblastine plus bleomycin failed.[2] Our strategy at the inception of this phase II study, initiated in 1978, is still appropriate today, namely the continued use of cisplatin unless a patient's disease progressed within 4 weeks from his prior regimen (platinum refractory) and the incorporation of other active agent(s) not previously utilized. In this early study, we achieved a 25% cure rate, demonstrating the synergism of this two-drug combination. Neither single-agent cisplatin nor etoposide would be expected to have any realistic prospect for cure as second-line chemotherapy. Subsequently, etoposide replaced vinblastine as first-line chemotherapy. Subsequent standard-dose salvage regimens for patients who did not have platinum refractory disease consisted of either vinblastine plus ifosfamide plus cisplatin or paclitaxel plus ifosfamide plus cisplatin (TIP).[3-5] Today either of these standard-dose salvage chemotherapy programs are appropriate as second-line chemotherapy.

The era of successful high-dose chemotherapy with bone marrow or peripheral blood stem cell transplant began in 1986 with the introduction of carboplatin. The philosophy of autologous stem cell transplant is to utilize high doses of cytolytic agents that are active for that particular malignancy and for which major dose-limiting toxicity can be rescued by the stem cell transplant, namely myelosuppression. This has largely been a failed strategy in other solid tumors such as melanoma and breast cancer. We began studies with high-dose carboplatin and etoposide in 1986 with bone marrow transplants,[6] and subsequently with peripheral blood stem cell transplants in 1996.[7] The latter study enrolled 184 consecutive patients, of whom 116 of 184 (63%) are continuously disease free, including 22 of 49 (45%) who received treatment as third-line therapy, and 18 of 40 (45%) who were deemed to have platinum refractory disease.[7] This study demonstrated the ability of high-dose platinum plus etoposide to overcome drug resistance from standard doses of cisplatin and etoposide.

Memorial Sloan Kettering Cancer Center has pioneered an innovative approach with three courses of high-dose carboplatin plus etoposide (compared with the tandem transplant at Indiana University) albeit at somewhat lower doses.[8] This regimen is preceded by paclitaxel and ifosfamide (TI-CE). There are no randomized studies suggesting any specific strategy of high-dose chemotherapy is preferred. There does not appear to be optimal benefit when only one course of high-dose chemotherapy is used.[9] Likewise, there is indirect evidence that adding a third drug to carboplatin plus etoposide is not beneficial.

There also have been no randomized phase III studies suggesting or proving superiority of one form of standard-dose salvage chemotherapy. Likewise, there is no evidence-based medicine demonstrating that initial salvage chemotherapy should be high-dose versus standard-dose chemotherapy. A retrospective international analysis was performed by Lorch et al that categorized salvage chemotherapy patients into five prognostic subtypes.[10] In a retrospective analysis, the same group of

investigators compared standard-dose with high-dose chemotherapy as initial salvage chemotherapy in 1,594 patients. Seven hundred and seventy-three patients received a standard dose and 821 received high-dose chemotherapy with 2-year progression-free survival being 27.8% versus 49.6% and 5-year survival being 40.8% versus 53.2%.[11] High-dose chemotherapy is the preferred option for patients with platinum refractory disease or for patients with disease progressing after standard-dose salvage chemotherapy. However, there are no prospective randomized studies proving superiority of high-dose chemotherapy. An argument can also be made that there are no phase III trials proving the merit of standard-dose cisplatin plus ifosfamide combination chemotherapy. A randomized trial comparing TIP versus TI-CE is on the drawing board for initial salvage chemotherapy. If this trial can be completed, it would answer the question comparing these two regimens.

Testis cancer is clearly a remarkably chemosensitive and chemocurative tumor. However, it is also the most curable cancer with surgery alone as initial therapy for node-positive disease. Salvage surgery is the preferred option for initial salvage therapy if progression is anatomically confined and surgically resectable.[12]

ADDITIONAL SALVAGE THERAPIES

It is very difficult, if not impossible, to cure disease with further standard-dose platinum-based chemotherapy after high-dose chemotherapy fails. Approximately 10% of such patients will experience a 5-year disease-free survival with weekly paclitaxel plus gemcitabine, assuming they have not received prior paclitaxel therapy such as TIP.[13] Modest success has also been achieved with gemcitabine plus oxaliplatin or adding paclitaxel plus gemcitabine plus oxaliplatin.[14,15] There remains a cohort of patients in which their disease is not cured. Feldman et al evaluated 97 such patients treated with various single agents. There was only one patient partial remission and 15 patients with stable disease.[16] Daily oral etoposide is as reasonable as any approach in the management of this disease in this patient population.[17]

SPECIAL CONSIDERATIONS

A rising tumor marker (e.g., serum hCG or AFP) usually implies progressive cancer. However, marijuana, recent mononucleosis, or cross-reactivity with luteinizing hormone can cause double-digit hCG elevation. Benign liver disease can cause high AFP levels. A rising LDH should never be an indication for salvage chemotherapy. Also, a rising hCG or AFP in the absence of radiographic progression might indicate a sanctuary site relapse in the brain or a second primary in the contralateral testis. Patients with persistent elevated tumor markers after initial chemotherapy should not be considered for salvage chemotherapy unless there is a clear increase in hCG or AFP. This is especially true for patients with advanced disease presenting with serum hCG higher than 50,000 mIU/mL. Such patients will have a rapid descent in hCG after the first two courses and then have a plateau in further decline. It might take several months postchemotherapy to normalize an hCG in this patient population.[18]

Radiographic progression with normal markers might indicate a growing teratoma rather than progressive germ cell cancer.

Late relapse ($>$ 2 years postchemotherapy) occurs in 2% to 3% of patients. Disease in these patients is rarely curable with any form of salvage chemotherapy in the absence of surgery. Resection, if feasible, is the preferred option.[19]

Progressive primary mediastinal nonseminomatous germ cell tumors are particularly difficult to cure with salvage therapy.[20] Standard-dose salvage therapy will virtually always fail to produce a durable remission. Options are high-dose chemotherapy or surgical resection of a localized relapse.[8,21]

CONCLUSION

Patients with relapsing disease after being managed with cisplatin combination chemotherapy are still curable, but it is very complicated. It is recommended that such patients be seen, or at least consulted, at tertiary centers with surgical and medical oncology expertise in germ cell tumors.

KEY POINTS

- Optimal strategy for management of relapse after initial cisplatin combination chemotherapy can be complicated.
- Occasionally localized relapsed disease can be cured with salvage surgery rather than salvage chemotherapy.
- Standard-dose cisplatin-combination salvage chemotherapy incorporates active drugs not previously utilized.
- Paclitaxel plus ifosfamide plus cisplatin or vinblastine plus ifosfamide plus cisplatin are examples of standard-dose salvage chemotherapy.
- High-dose chemotherapy with carboplatin plus etoposide with peripheral blood stem cell transplant has a high cure rate with acceptable toxicity.

Why Chemotherapy Should be Given Early for Men with Metastatic Prostate Cancer

Leonel F. Hernandez-Aya, MD, and Maha Hussain, MD, FACP, FASCO

OVERVIEW

Metastatic hormone-sensitive prostate cancer (mHSPC) is an incurable disease, and despite a high response rate to androgen-deprivation therapy (ADT), outcomes have not significantly changed for many decades. Earlier attempts at multitargeted strategies with the addition of cytotoxic chemotherapy to ADT did not affect survival. As more effective therapies are emerging, including cytotoxic therapy for patients with metastatic castrate-resistant prostate cancer (mCRPC), there is increasing interest for testing these drugs earlier in the disease course. The premise is that agents with clinical benefit in advanced mCRPC may have a better effect if used preemptively before the development of significant resistance and to attack earlier de novo androgen resistant/independent clones. The recent results of the phase III clinical trial E3805 investigating ADT with or without docetaxel in mHSPC provide compelling support for this strategy. Docetaxel combined with ADT significantly improved overall survival from 44 to 57.6 months (p = 0.0003), particularly in patients with high-volume disease (from 32.2 to 49.2 months; p = 0.0006). Longer follow-up is needed to assess the effect on patients with low disease burden. Further studies are needed to further maximize the antitumor effect in patients with mHSPC and to investigate the effects of advancing therapy to this disease setting on the efficacy of respective agents in the castration-resistant setting.

Despite stage migration, a significant number of patients with prostate cancer develop metastasis despite curative intent primary therapy or are diagnosed with de novo metastatic disease. Until recently, the initial management of patients with newly diagnosed mHSPC has not radically changed. Since 1941 when Huggins and Hodges demonstrated the androgen dependency of prostate cancer, the mainstay of therapy has been surgical or medical castration. Clinical research has mostly focused on investigating and optimizing different strategies to deliver, potentially enhance the ADT effect, and reduce its side effects such as combining androgen receptor (AR) blockade with primary gonadal suppression, peripheral blockade only, or using intermittent versus continuous ADT. ADT with a luteinizing-hormone-releasing hormone (LHRH) agonist with or without an antiandrogen, and more recently LHRH antagonist, has almost completely replaced surgical castration as first-line treatment. Irrespective of ADT modality or schedule, patients with mHSPC treated with ADT have a median overall survival (OS) around 49 months.[1] Despite the very high initial response rates to ADT, the duration of response is limited and most patients will eventually progress to castration resistance, the deadly phenotype of the disease.

The last decade has witnessed substantial scientific progress and developments that have impacted management of metastatic castration-resistant prostate cancer (mCRPC).

This began with the key discoveries indicating that emergence of resistance to ADT is in part an adaptive process via AR-dependent and AR-independent mechanisms.[2-4]

Microtubule targeting chemotherapy, docetaxel and cabazitaxel, have demonstrated activity in advanced prostate cancer, supporting the concept that castration-resistant cells are inhibited by chemotherapy.[5-7] The effect of targeting the AR signaling in patients with advanced prostate cancer is now well established with the survival benefits demonstrated by abiraterone and enzalutamide in men with castration resistance disease irrespective of prior chemotherapy.[8-11] Drugs targeting other pathways such as sipuleucel-T (dendritic cell-based vaccine) and radium-223 (alpha-emitter and calcium mimetic) have also shown improved survival benefits in patients with mCRPC.[12-13] Despite the recent success of novel therapies, the overall effects on survival are still modest. Furthermore, the quality/quantity of responses observed in patients being treated with AR-signaling agents decrease in the context of prior treatment with another AR-signaling agent in mCRPC.[14]

Although docetaxel was the first agent approved for mCRPC, the rapid proliferation of newer non chemotherapeutics particularly oral AR targeted therapy has shifted the dynamics to delay chemotherapy. Population based studies have shown that only about a third of patients with mCRPC

are receiving docetaxel.[15] Although speculative, one explanation may be the poor performance status of patients in the context of disease progression after receiving several lines of therapy. Anecdotal experience and recent report by Azad et al[14] on a retrospective study investigating the efficacy of enzalutamide following abiraterone in docetaxel-naïve and docetaxel-exposed patients indicated that the antitumor activity of enzalutamide following abiraterone is limited. The median duration of enzalutamide treatment was 4.1 months. Importantly, the efficacy of enzalutamide was comparable in docetaxel-naïve and docetaxel-exposed patients in terms of PSA response rates (26% vs 22%; p = 0.8), median time to radiologic/clinical progression (6.6 vs. 4.6 months; p = 0.6), and median OS (8.6 vs. 10.6 months; p = 0.2). These findings are important given the increasing evidence suggesting benefits with earlier use of docetaxel in advanced prostate cancer.

CHEMOTHERAPY IN METASTATIC HORMONE-SENSITIVE PROSTATE CANCER: SCIENTIFIC RATIONALE

Elucidating the mechanisms of prostate cancer progression to castration resistance has captivated the interest of re-searchers over several decades. Molecular adaptation of cancer cells to an androgen-deprived environment, including AR-driven pathways, activation of survival pathways bypassing AR, and clonal selection of androgen-insensitive clones, appear to be some of the major mechanisms of resistance. Molecular adaptation involves the activation of the AR through different mechanisms including AR-gene amplification, AR-overexpression or mutation, extragonadal production of androgens, ligand-independent activation by growth factors, or alteration in survival pathways bypassing AR.[2-4] In clonal selection, androgen ablation creates a host environment in which the androgen-insensitive tumor cells have a selective growth advantage over the androgen-dependent cells. The continuous proliferative growth of these androgen-independent tumor cells leads to the relapse phenomenon.[16] Isaacs and Coffey conducted the initial studies to show that progression from an androgen-sensitive to androgen-insensitive state is dependent on the initial heterogeneity of the tumor with preexisting clones of both androgen-dependent and androgen-independent cells.[16] Following castration, adult male rats bearing the androgen-sensitive Dunning R-3327-H tumor showed an initial response with decreased growth rate. However, after 60 days, androgen ablation causes selection and growth advantage of androgen-independent cells. In this model, the continuous exponential growth of the androgen-insensitive tumor cells eventually kills the host animals.[16]

The heterogeneity with regard to androgen sensitivity and the selection of resistant cells supports the need for a multi-targeted treatment approach early in the course of the disease to maximize the antitumor effect and prevent development of resistance. The use of early chemotherapy may address the phenotypically heterogeneous subpopulation of tumor cells and eliminate androgen-independent clones, allowing for a potentially improved therapeutic effect.

Traditionally, chemotherapy including docetaxel is offered to patients with mCRPC, often when symptomatic and with large disease burden. In fact, several of the recently designed trials had "delay time to chemotherapy" as a metric for "clinical success." However, delaying chemotherapy to this point may very well limit the efficacy of chemotherapy possibly because of a larger proportion of resistant cells, including chemotherapy-resistant cells within the bigger population of castration-resistant cells. The early use of cytotoxic chemotherapy may improve outcomes by attacking clones resistant to ADT before they expand or acquire more resistance or simply killing more cancer cells when they are more vulnerable.

Preclinical data by Tang et al[17] evaluated different sequences of docetaxel and androgen ablation in severe combined immunodeficient mice inoculated with the LNCaP prostate cell line. Tumor volume was at least 50% smaller in all docetaxel groups compared with castration alone. The smallest tumors at week 4 and the greatest growth delay were found in mice treated with docetaxel for 2 weeks, followed by castration. Apoptosis assays also indicated a greater degree of apoptosis in the docetaxel followed by castration group. As in other studies, the bax-to-bcl-2 ratio decreased following cas-

<div style="border: 1px solid; padding: 10px;">

KEY POINTS

- The established therapeutic limitation of ADT coupled with the biologic heterogeneity of prostate cancer with the presence of androgen-sensitive and androgen-insensitive clones provide the rationale for a preemptive multitargeted strategy with the addition of chemotherapy to ADT.
- Before docetaxel, trials investigating the addition of different chemotherapy regimens to ADT in mHSPC did not show significant benefits.
- The proven efficacy of docetaxel in the castration-resistant setting provided rationale to investigate this drug earlier in the course of the disease.
- Results of E3805 (CHAARTED trial), a phase III clinical trial conducted in patients with mHSPC comparing ADT alone to ADT plus docetaxel chemotherapy, demonstrated a significant 13.6-month improvement in median overall survival for the chemo-hormonal approach. Importantly, in patients with high-volume disease, there is a 17-month survival improvement for ADT plus docetaxel. In patients with low-volume disease, longer follow-up is needed to assess effect.
- Six cycles of docetaxel in addition to ADT is an appropriate therapeutic approach for men with newly diagnosed mHSPC initiating ADT, particularly those with high volume disease, and who are otherwise medically candidates for docetaxel therapy.
- Emerging data suggest that sequential use of current AR targeted agents in metastatic castration resistant prostate cancer (mCRPC) is not associated with optimal efficacy. The latter coupled with disease related impact on performance status and medical condition provides the rational for integrating docetaxel chemotherapy earlier in the treatment course of patients with mCRPC.

</div>

tration. However, the bax-to-bcl-2 ratio remained increased following docetaxel, indicating increased apoptosis.[17]

Numerous AR-independent intracellular oncogenic pathways including MAPK, RB1, and PI3K/AKT/mTOR are dysregulated through a variety of mechanisms in advanced prostate cancer. Downstream effects of genetic alterations in these pathways promote survival, proliferation, cell-cycle progression, and conversely regulate AR signaling through feedback mechanisms.[18-23] Chemotherapy may attack cells with AR-independent signaling pathways driving mechanisms of castration resistance. Considering the biologic observations and the experience in prostate cancer and other cancers, it is logical to hypothesize that earlier use of effective systemic therapies could result in a more significant impact in hormone-sensitive disease.

CLINICAL TRIALS OF CHEMOTHERAPY IN MHSPC

The initial trials investigating the combination of chemotherapy with ADT in mHSPC did not show overall survival advantage. Since the 1970s, more than 10 randomized studies were conducted investigating different chemotherapy drugs in combination with ADT. Regimens included a variety of cytotoxic drugs such as cyclophosphamide, estramustine, doxorubicin, fluorouracil, mitomycin, and vinblastine, but failed to demonstrate a significant survival benefit when combined with ADT in metastatic prostate cancer[24-33] (Table 1). However, there were some hints with regard to potential benefits of chemotherapy in specific subgroups of patients. Murphy et al conducted a randomized trial comparing diethylstilbestrol (DES) or orchiectomy, DES plus cyclophosph-

Adapted from Millikan et al.[33]

amide, or estramustine plus cyclophosphamide in patients with newly diagnosed metastatic prostate cancer. There was no overall survival difference between the three groups (92, 91, and 94 weeks, respectively); however, subgroup analysis within groups having pain versus those not having pain showed a survival benefit for the cyclophosphamide and estramustine arm in patients presenting with pain at study entry.[24] Osborne et al compared endocrine therapy alone (DES or orchiectomy) to a chemo-endocrine approach (DES plus cyclophosphamide/doxorubicin hydrochloride) in a randomized trial lead by SWOG.[26] Although there was a higher response rate in the chemo-endocrine group (63%) compared with endocrine alone (48%), this effect did not translate to a significant difference in overall survival. Epirubicin has also been studied in this setting. A prospective randomized trial conducted by Pummer et al investigated the addition of weekly epirubicin to androgen blockade (orchiectomy and flutamide) for 18 weeks.[27] At a median follow-up of 81 months, the chemo-hormonal arm showed a significant benefit in progression-free survival (PFS;18 months) compared with the hormonal arm (12 months, p < 0.02). However, there were no OS differences between the groups. In patients with more than five sites of bone metastasis, PFS was 9 and 14 months (p = 0.005) and OS, 17 and 27 months (p = 0.06), respectively. Estramustine has also been tested in addition to hormone therapy in patients with newly diagnosed metastatic prostate cancer without evidence of survival advantage. In subgroup analysis, estramustine prolonged time to progression when added to orchiectomy in patients with bone metastasis.[28]

More recently, Millikan et al conducted a phase III clinical trial investigating the addition of ketoconazole, doxorubicin, vinblastine, and estramustine (KAVE regimen) to androgen ablation therapy.[33] The primary endpoint of time to castrate-resistant progression was 24 months for the androgen ablation arm, and 35 months for the chemo-hormone therapy (p = 0.39). Median overall survival was not different between the groups (5.4 and 6.1 years, respectively). Similar to other trials, time to progression was significantly delayed in the high-volume group but not in those with less advanced disease. In patients with high-volume disease (three or more bone lesions or visceral involvement) the median time to progression was 11.2 months in the control group and 20.5 months in the KAVE arm (p = 0.08). Nearly all patients (in either arm) did receive cytotoxic therapy for castrate-resistant disease, usually including a taxane.[33]

Most of these trials had substantial limitations in design, sample size, and most importantly, used chemotherapy drugs without significant clinical activity in advanced prostate cancer. Specifically, none of the trials included cytotoxic chemotherapy that prolonged survival in the castration-resistant setting.

DOCETAXEL: FIRST AGENT TO IMPROVE SURVIVAL IN METASTATIC CASTRATION-RESISTANT PROSTATE CANCER

Docetaxel, a taxane chemotherapeutic drug, induces polymerization of microtubules and phosphorylation of the bcl-2

protein.[34] Docetaxel was approved in castration-resistant prostate cancer after two randomized landmark studies, TAX 327 and SWOG-9916, independently demonstrated improvements in overall survival in men with mCRPC.[5,6] Docetaxel triumphed over the longstanding paradigm that prostate cancer cells were resistant to cytotoxic agents. The TAX 327 study reported an improved overall survival of the group treated with docetaxel every 3 weeks (18.9 months) compared to the group treated with mitoxantrone (16.5 months). The hazard ratio for death of docetaxel compared with mitoxantrone was 0.83 (95% CI, 0.70 to 0.99; p = 0.04). Quality of life was also significantly improved in the group treated with docetaxel.[5] Petrylak et al reported a similar improvement in survival for docetaxel plus estramustine in comparison with mitoxantrone plus prednisone in the SWOG-9916 study.[6] The median overall survival was 17.5 months in those treated with docetaxel-based therapy versus 15.6 months in patients in the mitoxantrone group (p < 0.001). Docetaxel became the standard of care for men with CRPC in 2004.

The role of chemotherapy in prostate cancer management was further supported by the approval of a third chemotherapy agent, cabazitaxel, which is also an inhibitor of microtubule depolymerization based on improving survival in a phase III trial in patients with CRPC previously treated with docetaxel as compared to mitoxantrone (15.1 vs. 12.7 months; 95% CI, 0.61 to 0.84).[7] The risk of death was significantly lower in those patients treated with cabazitaxel versus patients treated with mitoxantrone (HR 0.70; p < 0.0001). Cabazitaxel received U.S. Food and Drug Administration (FDA)-approval in 2010 for men with CRPC that had progressed on docetaxel.

RANDOMIZED CLINICAL TRIALS OF EARLY DOCETAXEL PLUS ADT

The use of docetaxel in the mHSPC setting was driven by its established activity in two phase III randomized clinical trials demonstrating a survival advantage as compared with an active control of mitoxantrone. The underlying premise is that an agent with clinical benefit in mCRPC might prolong the lives of men with mHSPC if used before the disease becomes resistant to ADT and to attack the de novo androgen resistant/independent clones much earlier. There are also emerging data that docetaxel may act as a hormonal agent, interfering with androgen receptor (AR) nuclear translocation on microtubules.[35]

Two phase III clinical trials were designed to evaluate the role of docetaxel in mHSPC (Table 2). GETUG-AFU 15 was a randomized, open-label, phase III trial that enrolled 385 patients with newly diagnosed mHSPC.[36] In this study, patients were randomly assigned to receive ADT alone (orchiectomy or LHRH agonists) or in combination with docetaxel (75 mg/m² on day 1 of a 3-week cycle; nine planned cycles). The median number of docetaxel cycles was eight. With median follow-up of 50 months, there was a trend in favor of do-

TABLE 2. Randomized Clinical Trials of ADT with or without Docetaxel in Hormone-Naive Metastatic Prostate Cancer

Trial, Accrual Period	No. of Patients	Median Follow-up (Months)	Treatment Arms	Median PFS (Months)	Median OS (Months)
GETUG-AFU 15[36], 2004–2008	385	82.9	A: ADT	A: 12.9	A: 46.5
			B: ADT+ docetaxel for 6 cycles	B: 22.9	B: 60.9
				(HR = 0.72, p = 0.0021)	(HR = 0.9, p = 0.44)
E3805: CHAARTED[38], 2006–2012	790	29	A: ADT	A: 19.8	A: 44
			B: ADT + docetaxel for 6 cycles	B: 32.7	B: 57.6
				(HR = 0.49; p = <0.0001)	(HR = 0.61; p = 0.0003)

Abbreviations: PFS, progression-free survival; OS, overall survival; ADT, androgen-deprivation therapy; HR, hazard ratio.

cetaxel; however, the primary endpoint of overall survival was not significantly different between the groups at 58.9 months for patients that received docetaxel plus ADT versus 54.2 months for those who were treated with ADT alone (HR 1.01; 95% CI, 0.75 to 1.36; p = 0.955). On the contrary, the addition of docetaxel to ADT did significantly improve the biochemical PFS (secondary endpoint), which was 22.9 months for the combined treatment group and 12.9 months for those treated with ADT alone (HR 0.72; 95% CI, 0.57 to 0.91; p = 0.005). Seventy-two serious adverse events were reported in the group given ADT plus docetaxel: more frequently neutropenia (21%), febrile neutropenia (3%), abnormal liver function tests (2%), and neutropenia with infection (1%). Four treatment-related deaths occurred in the ADT plus docetaxel group. An updated report with longer follow-up of the GETUG-AFU 15 trial was presented at the 2015 Genitourinary Cancers Symposium.[36] With a median follow-up of 82.9 months, the median OS was 60.9 months and 46.5 months in the ADT plus docetaxel and ADT alone arms, respectively (HR 0.9; 95% CI, 0.7 to 1.2; p = 0.44). In patients with high-volume disease, median OS rates were 39 months in ADT plus docetaxel arm and 35.1 months in the ADT alone arm (HR 0.8; 95% CI, 0.6 to 1.2; p = 0.35).[36]

The GETUG-AFU 15 trial did not show statistically significant survival benefit to adding docetaxel to ADT for mHSPC. However, the overall survival trend and the HR in the high-volume patients favors the docetaxel arm. The trial had a relatively small sample size,[1] included a substantial percentage of patients with good prognostic factors at baseline: 49% of the patients in the ADT plus docetaxel group and 50% of the patients treated with ADT alone. Another concern about this trial is the unusually high toxicity reported, with more than 10% incidence of grade 3 neutropenia and four deaths in the group given ADT plus docetaxel; 21% of men who received docetaxel plus ADT discontinued treatment because of toxicity. Results may have also been affected by cross-over treatments since 62% of patients given ADT alone received docetaxel at progression, compared with 28% of patients given ADT plus docetaxel who were re-treated with docetaxel. Interestingly, the Kaplan-Meier curves for overall survival seem to separate after 36 months of follow-up. How-

ever, only 199 patients are at risk at 36 months, and 124 at 48 months.

Data Presented at the 2014 ASCO Annual Meeting Plenary Session

The results of the E3805 (Chemo-Hormonal Therapy Versus Androgen Ablation Randomized Trial for Extensive Disease in Prostate Cancer [CHAARTED]) trial recently reported by Sweeney et al[37] provide practice-changing evidence. CHAARTED is a U.S. intergroup phase III trial in which 790 men with hormone-naive mHSPC received either ADT alone or ADT with 75 mg/m^2 of docetaxel every 3 weeks for a maximum of six cycles. At enrollment, patients were stratified by extent of metastatic disease as high-volume or low-volume; high volume was defined as visceral metastasis and/or four or more bone metastases with at least one beyond axial skeleton (pelvis and vertebral column). The primary endpoint was OS, and secondary endpoints included time to biochemical, radiographic, or symptomatic progressive disease (PD) and time to radiographic or symptomatic PD. The trial was first designed to include high-volume patients as they have poor prognosis. Eligibility was subsequently expanded to allow all patients with mHSPC.

The addition of docetaxel to ADT significantly improved overall survival; a median of 57.6 months in the ADT plus docetaxel arm and 44.0 months in the ADT arm (HR 0.61; 95% CI, 0.47 to 0.80; p = 0.0003). The survival improvement was seen specifically in men with high-volume disease; median OS was 49.2 months with docetaxel plus ADT compared with 32.2 months with ADT, a difference of 17 months (HR 0.60; 95% CI, 0.45 to 0.81; p = 0.0006). In men with low-volume disease, median OS had not been reached at the time of the presentation. The secondary endpoints demonstrated higher PSA responses (< 0.2 ng/mL) at 6 and 12 months in the docetaxel plus ADT group (27.5% and 22.7%, respectively) compared to the ADT alone group (14% and 11.7%, respectively), longer median time to castration resistance (20.7 months vs. 14.7 months) and longer median time to clinical progression in favor or the combination arm; 32.7 months, compared to 19.8 months (p < 0.0001).

With regard to toxicity, 6% of men receiving docetaxel plus ADT experienced febrile neutropenia, 1% experienced sig-

nificant effects on sensory nerves, and 1% on motor nerves, and 1 of the 397 patients who received early docetaxel died as a result of treatment. The cause of death was prostate cancer in 84 patients in the ADT plus docetaxel arm (83.2%) and 112 patients in the ADT-alone arm (83.6%).[37]

In summary, this study shows that starting docetaxel along with hormone therapy in men with newly diagnosed hormone-sensitive prostate cancer improved OS by more than 13.6 months in comparison with standard hormone therapy alone. The bulk of the benefit appears to be in patients with high-volume disease. This striking survival benefit supports the use of upfront docetaxel in hormone-sensitive prostate cancer, especially in patients with high-volume disease.

Before CHAARTED, docetaxel was reserved for patients relapsing after initial ADT. In that setting, docetaxel produced only 2 to 3 months prolongation of survival. More recently, abiraterone, enzalutamide, and radium-223 also produce 3- to 5-month prolongations of median survival when they are given as successive single agents. The magnitude of survival improvement with docetaxel plus ADT upfront is unprecedented. The most likely explanation is biologic; therapy works best when it is multitargeted, administered in a lesser disease volume as a preemptive strike before adaptive resistance. Other potential factors include better drug tolerance and less toxicity in less sick patients.

CONCLUSION

The heterogeneity of prostate cancer and the diverse mechanisms of resistance support a multitargeted approach to maximize the antitumor impact. The totality of the current data would favor not delaying the use of docetaxel chemotherapy; pending the final peer-review publication of the CHAARTED trial, results strongly suggest that survival benefits of docetaxel are significantly higher when given in combination with ADT early in the course of mHSPC and that the combination has a more profound return on investment as compared with sequential therapy. The unprecedented survival benefits of this chemo-hormonal approach appear to be related to the better antitumor effect as reflected by higher rates of undetectable PSA levels and longer median time to castration resistance and clinical progression. Overall, patients tolerated therapy very well. Therefore, patients with newly diagnosed mHSPC who are deemed chemotherapy eligible, especially those with high-volume disease, should be counseled regarding this data and offered combination therapy.

Radium 223: How Can We Optimize This New Tool for Metastatic Castration-Resistant Prostate Cancer?

Tanya Barauskas Dorff, MD, and Mitchell E. Gross, MD, PhD

OVERVIEW

Radium 223 is an alpha-emitting intravenous radiotherapy approved for the treatment of men with metastatic castration-resistant prostate cancer (mCRPC). The approved indication covers men with pain from bony metastatic disease and no visceral involvement; however, questions remain as to optimal patient selection and timing of this treatment relative to other life-extending therapies for mCRPC. Limited data exist to guide clinicians on how to position radium 223 in the therapeutic sequence, however, some theoretical considerations and data derived from the ALSYMPCA trial populations pre- and postdocetaxel will be outlined. Subgroup analyses may provide some insight into patient selection.

Radium 223 is a calcium-mimetic alpha-emitting radio-pharmaceutical that was approved by the U.S. Food and Drug Administration for the management of mCRPC in 2013. Unlike previous radiopharmaceuticals, such as samarium-153-lexidronam and strontium chloride Sr 89 that provide pain palliation without having a known effect on survival,[1,2] radium 223 has been found to prolong survival in patients with mCRPC.[3] The approved dosing of radium 223 is 50 kBq/kg given intravenously over 1 minute every 28 days for 6 doses. Questions remain as to its optimal application, particularly in terms of patient selection and sequencing of this therapy relative to other approved life-extending therapies for mCRPC. There are a paucity of real-world data, and key limitations for the use of radiopharmaceuticals include special licensing requirements to administer therapy and lack of comparative data. Ongoing studies aim to address questions of sequence and combination, but we will discuss patient selection and timing for radium 223 therapy in the context of the limited available data.

WHICH PATIENTS?

The ALSYMPCA trial randomly assigned 928 men with pain of any intensity related to bone metastases from mCRPC and whose disease had either progressed on docetaxel or who were not docetaxel candidates, to receive 50 kBq/kg of radium 223 intravenously over 1 minute each month for 6 doses or placebo IV each month for 6 doses in conjunction with standard care (Table 1).[3] Men with known visceral metastases were excluded, but malignant lymphadenopathy smaller than 3 cm in short axis diameter was allowed. Adequate hematologic function is required. Before the first administration of radium 223, the abso-

lute neutrophil count was 1.5×10^9/L or higher, the platelet count was 100×10^9/L or higher, and hemoglobin was 10 g/dL or higher. Before subsequent administrations of radium 223, the absolute neutrophil count was 1×10^9/L or higher and the platelet count was 50×10^9/L or higher. The primary endpoint was overall survival and the main secondary endpoint was time to symptomatic skeletal-related event (sSRE). Most patients (58%) had received docetaxel, and 41% had received bisphosphonate therapy.

A significant increase in overall survival was observed across all patients treated with radium 223 (hazard ratio [HR] 0.7; 95% CI, 0.58 to 0.83; p < 0.001), however, analysis of subsets may help clarify the characteristics of optimal candidates for this treatment based on blood or imaging biomarkers. Serum alkaline phosphatase, one marker of overall osteoblastic activity, did seem to define patients who benefited the most from radium 223 treatment. Specifically, no increase in overall survival was seen in the subgroup treated with less than 220 U/L of serum alkaline phosphatase. In contrast, there was no clear separation of radium 223 benefit according to the extent of disease as defined by the number of lesions on the bone scintigraphy. Although subgroup analysis revealed a statistically significant (HR 0.95; 95% CI, 0.46 to 1.95 for < 6 bone metastases; no p value given) survival benefit with radium 223 for men with more than six bone metastases, the subgroups of men with two to six metastases or superscan had confidence intervals crossing 1, calling into question the benefit of therapy for these subgroups. Although small group sizes may limit the strength of these subset analyses, the results do validate continuing efforts to better define patient groups who are most likely to benefit from this treatment.

Table 1. Clinical Characteristics of Patients Eligible versus Optimal for Radium 223

Eligible Patients	Optimal Patients
Two or more bone metastases	More than 6 bone metastases
Pain from bone metastases	Serum alkaline phosphatase greater than or equal to 220 U/L
Adequate marrow reserve	Concurrent bisphosphonate use
No visceral metastases	Question not in the setting of "superscan"
Prior docetaxel (or ineligible/ declined docetaxel)	

TIMING OF RADIUM 223 VERSUS CHEMOTHERAPY OR OTHER TREATMENT OPTIONS

The treatment landscape for patients with symptomatic CRPC is complex and manifested by the availability of a wide array of therapeutic modalities ranging from oral androgen inhibitors, cytotoxic chemotherapy, and external beam radiotherapy as well as radium 223. Although radium 223 may have a place in treatment for many patients with symptomatic CRPC, timing its use in a treatment sequence for any specific patient presents a challenging decision for a treating physician. Given the potential for additive and long-term myelosuppression associated with bone-target radiopharmaceuticals and cytotoxic chemotherapy, most of the available analyses focus on the timing of radium 223 before or after docetaxel-based chemotherapy.

Tolerability of radium 223 was similar in men who had received chemotherapy first and in those who declined or were not felt to be eligible for chemotherapy. A retrospective analysis from ALSYMPCA identified modestly higher rates of hematologic toxicity in docetaxel-pretreated patients receiving radium 223 compared with those not previously treated with docetaxel (Table 2). There was also a higher rate of packed red blood cell transfusion, which persisted during the 13-week time period after completion of the sixth cycle of radium 223 therapy.[4] Nonhematologic toxicities were similar in the two groups, although there was more nausea (40% vs.

KEY POINTS

- Radium 223 delays time to symptomatic skeletal-related events and prolongs overall survival for men with mCRPC and more than two bone metastases with pain attributed to bone metastases.
- Greater benefit may occur in subgroups of men with more than six bone metastases and elevated serum alkaline phosphatase over 220 U/L.
- There is a modestly higher rate of hematologic toxicity in men receiving radium 223 after previous docetaxel therapy, but no data exist regarding the effect of radium 223 on bone marrow reserve for subsequent chemotherapy.
- Follow-up data are limited regarding the possibility of long-term myelosuppression and secondary myelodysplasia or leukemia.
- Prostate-specific antigen changes should not be used to determine response to treatment or duration of treatment.

Table 2. Rates and Grades of Hematologic Toxicity in Patients Receiving Radium 223 by Prior Docetaxel Therapy Status

	Prior Docetaxel (347 Patients)	No Prior Docetaxel (253 Patients)
Anemia		
All grades	120 (35%)	67 (27%)
Grade 3	42 (12%)	24 (10%)
Grade 4	8 (2%)	3 (1%)
Grade 5	0	0
Neutropenia		
All grades	24 (7%)	6 (2%)
Grade 3	8 (2%)	1 (<1%)
Grade 4	3 (1%)	1 (<1%)
Grade 5	0	0
Thrombocytopenia		
All grades	53 (15%)	16 (6%)
Grade 3	15 (4%)	5 (2%)
Grade 4	16 (5%)	2 (1%)
Grade 5	0	1 (<1%)

30%) and vomiting (24% vs. 11%) for docetaxel-pretreated compared with nonpretreated patients.

Efficacy of radium 223 was seen in both docetaxel-pretreated and docetaxel-naive patients in ALSYMPCA. However, subgroup analysis did identify that symptomatic skeletal events were not substantially delayed in the docetaxel-naive group.[5] Specifically, the median time to sSRE was 17 months for patients treated with radium 223 and 19.5 months for placebo in docetaxel-naive patients (p = 0.12), whereas the median time to sSRE was 13.5 months in the radium 223 group compared with 7.8 months for placebo in docetaxel-pretreated patients (p = 0.00087). Although this is a subgroup analysis, and this finding warrants caution in interpretation, it may be that patients pretreated with docetaxel with bone pain represent an enriched, more aggressive subgroup in which bone targeting therapy may yield a greater effect.

In terms of the tolerability of chemotherapy after radium 223, no published data exist regarding how many men treated with radium 223 went on to receive docetaxel (or other chemotherapy) and how they tolerated therapy in terms of myelosuppression. This may be because of the fact that enrollment in ALSYMPCA was restricted to men who had either received docetaxel or were not eligible for *or* declined docetaxel therapy such that there may be limited numbers of patients from this trial who subsequently received docetaxel. As noted above, the increased need for blood transfusions persisted in the 13 weeks following completion of radium 223 therapy, which suggests that tolerance of chemotherapy may be affected, at least in the short term. Thus the potential for higher rate of hematologic toxicity during radium 223 treatment when docetaxel has been administered first must be considered against the possibility that radium

223 may confer fewer benefits when administered first, before docetaxel as well as against the theoretical concern for compromised marrow reserve affecting future docetaxel therapy. Data are still awaited to answer these questions with greater certainty. However, given the relatively mild myelosuppression and previous experience with samarium in combination with docetaxel, combination therapy is undergoing study (NCT01106352). In the phase I experience of radium 223 and docetaxel, substantial hematologic toxicity limited administration of full doses and thus further combination studies will utilize a reduced dose of docetaxel 60 mg/m^2.[6]

Another significant concern when the potential for earlier administration is considered is the risk of secondary myelodysplasia. Very limited long-term data are currently available. The long-term report presented at 2014 American Society of Clinical Oncology Genitourinary Cancers Symposium consisted of median follow-up of 10.4 months.[7] At that time point, no myelodysplastic syndrome or acute myeloid leukemia had been reported, and secondary solid tumors were similar in the radium 223 and placebo arms. However, longer follow-up will be critical to address this concern.

Much less is known about the timing and interaction between radium 223 and the newer antiandrogen agents (abiraterone or enzalutamide). Both agents have demonstrated noteworthy clinical activity defined by increases in overall survival in patient subsets defined by the presence of cancer-related bone pain. Further, both agents have shown important benefits in quality-of-life measures including palliation in bone pain or delay to skeletal-related events in certain patient subpopulations.[8,9] ALSYMPCA allowed standard care, including ketoconazole and older androgen receptor antagonists, but this cannot be extrapolated to assume that newer agents such as abiraterone and enzalutamide can be safely combined with radium 223. No data exist to suggest that combination use is superior to single sequential therapy. The open-access protocol did allow abiraterone, and the safety and efficacy of these combinations will be formally evaluated in an ongoing clinical trial (NCT02034552).

DURATION

Just as questions emerge as to the optimal timing for initiation of radium 223 dichloride, many questions also arise as to when it should be discontinued. The approved treatment course is 6 monthly doses, although the relative efficacy and tolerability of fewer or more doses is not well established. At the time of the *New England Journal of Medicine* publication from the ALSYMPCA trial,[3] 42% of patients on the radium 223 arm had not received all 6 doses although the median number of doses was 6; updated data regarding clinical factors associated with completion of the treatment course may be helpful. The phase I study evaluated a single dose in patients with breast and prostate cancer with bone metastases and the phase II study in prostate cancer gave 4 doses at monthly intervals,[10,11] but there is no way to evaluate what number of doses is optimal from the available data. Given that no cumulative toxicities were seen with 6 monthly doses, and the rate of hematologic toxicities was tolerable, it is reasonable to explore the effect of additional dosing on disease control and the duration of pain palliation. The effect of extended therapy with up to 6 additional doses, or a total of 12 doses of radium 223, is being evaluated in a clinical trial (NCT01934790). Additionally, we do not have data about retreatment of patients who were previously treated. Thus at this time no conclusions can be made as to the efficacy nor safety of more than 6 monthly doses of radium 223.

Effectiveness may be difficult to gauge during the nominal 6-month treatment period. Prostate-specific antigen (PSA) is an unreliable marker of response to radium 223 as it often continues to increase (unabated) during the treatment independent to the effect on overall survival. In the ALSYMPCA trial the median time to PSA progression was 3.6 months for men in the radium 223 arm compared with 3.4 months in the control arm (HR 0.64; 95% CI, 0.54 to 0.77) and 16% achieved a PSA decline at 12 weeks compared with 6% of control patients. These PSA changes must be viewed in the context that the patients could receive additional standard therapy (in ALSYMPCA, standard care could include antiandrogens, ketoconazole, estrogens, and external beam radiotherapy). Nevertheless, discontinuation of radium 223 in patients with rising PSA but no clinical disease progression is not indicated, and rather application of additional standard therapy may be considered. Thus, even in patients without early pain relief from radium 223 or with rising PSA, it may be preferable to add external beam radiotherapy or additional systemic therapy, and proceed through the course of 6 doses rather than stopping therapy early.

Immunotherapeutic Approaches in Prostate Cancer: Combinations and Clinical Integration

Susan F. Slovin, MD, PhD

OVERVIEW

Despite multiple immunologic approaches with peptide, protein, and DNA vaccines, no single therapy has induced complete remission or maintained durability of response in patients with castration-resistant prostate cancer (CRPC). Historically, immunotherapy has had limited effect on solid tumors with the exception of melanoma and renal cell carcinomas, which have been deemed as immunologic cancers given their potential for remissions either spontaneously or after removal of the primary lesion. There is considerable excitement about using an immunotherapy in combination with biologic agents such as checkpoint inhibitors, cytokines, other vaccines, or chemotherapy. Sipuleucel-T represents one of several novel immunologic therapeutic approaches to treat prostate cancer in addition to other solid tumors. It is the first in its class of autologous cellular therapies to demonstrate safety and an overall survival benefit in patients with asymptomatic or minimally symptomatic CRPC and represents a unique treatment method that may be further enhanced with other agents. Although sipuleucel-T can be used as a foundation on which to build and enhance future immunologic clinical trials, other exciting strategies are in development that may be easily integrated into the algorithm of current care.

The introduction of immunotherapy for the treatment of CRPC has been transformative in that it has revitalized an area of research that had waned for many years. Although there are five new therapies that have changed the standard treatment algorithms used for treating CRPC, a personalized medicine approach is now being embraced as a means of developing and directing therapies based on unique patient molecular profiling and the ability to target actionable mutations with specific drugs. Despite the enthusiasm held for immunotherapy, there are still concerns about how to best integrate a specific type of immunotherapy into the current treatment algorithm and whether combinatorial approaches will improve antitumor responses. Jerome Groopman, MD,[1] a well-known physician who on occasion presents his views on controversial medical issues in *The New Yorker* magazine, has noted that there are many new oncology drugs now available to patients with different cancers, but the question remains whether it is possible to "control cancer without killing it." Immunotherapy may in fact provide sufficient control in prostate cancer that may minimize the need for immediate cytotoxic agents.

Immunotherapy for solid tumors is not new; preclinical studies have suggested that animals can be cured with a wide variety of approaches from conjugate and DNA vaccines, to combinatorial schemes with chemotherapy or biologic modifiers. However, stunningly successful preclinical vaccine strategies have not successfully translated into similar results in humans. Each of the five new drugs approved for prostate cancer—sipuleucel-T,[2] enzalutamide,[3,4] abiraterone,[5] cabazitaxel,[6] and radium 223 dichloride[7]—has shown a survival benefit, benefits in pain control, and quality of life, but sipuleucel-T has revitalized the role of immunotherapy in treating a solid tumor. Sipuleucel-T stands out as the first immunotherapy approved by the U.S. Food and Drug Administration (FDA) for prostate cancer with the added benefit of improvement in overall survival (OS).[2] Its approval was determined by the results of a placebo-controlled, randomized trial (the IMPACT trial),[2] conducted in 512 asymptomatic or minimally symptomatic men with metastatic CRPC. Although no difference in time to progression or prostate-specific antigen (PSA) response rate was reported, a significant 4.1-month improvement in median survival was achieved in the active arm compared with the placebo arm (25.8 vs. 21.7 months; p = 0.03). The survival benefit was comparable to that seen with other standard agents.[3-7] In fact, given how many of the androgen receptor (AR)-directed therapies have been introduced earlier in the treatment paradigm, the same may prove beneficial with immune-based therapies. Although sipuleucel-T's indication is for patients with asymptomatic or minimally symptomatic CRPC, it has broad applicability to all clinical states of the disease, that is, from neoadjuvant, to biochemical relapse post-primary therapy, to castrate nonmetastatic disease, and castrate metastatic disease.[7]

CHANGING THE TREATMENT PARADIGM

Sipuleucel-T is an autologous cellular product vaccine that mandates that patients undergo leukapheresis to obtain peripheral blood mononuclear cells that are processed, expanded, and incubated with a prostatic acid phosphatase (PAP)/granulocyte macrophage-colony stimulating factor (GM-CSF) fusion protein within a 48-hour window. The cells are divided into three reinfusions, one given every 2 weeks. In clinical trials, patients were then monitored per clinical practice with imaging and PSAs. Overall, the treatment was well tolerated with expected transfusion-associated side effects such as fever and chills. Since the FDA approval of sipuleucel-T, additional studies have sought to expand its use and to identify in which patients the greatest clinical benefits may be derived. A retrospective analysis of the IMPACT trial found that patients in the lowest quartile of PSA values derived a greater benefit from sipuleucel-T with a 13-month improvement in OS (41.3 months with sipuleucel-T compared with 28.3 months with placebo; [HR 0.51; 95% CI, 0.35 to 0.85]). However, for those patients in the highest baseline PSA quartile, the median OS was 18.4 months compared with 15.6 months for placebo (HR 0.84; 95% CI, 0.55 to 1.29), with an improvement of only 2.8 months.[8] Most of the studies of sipuleucel-T have been retrospective and its mechanism of action is still controversial. A report by Drake et al[9] postulated that antigen cascade (Fig. 1) may be responsible for its mechanism of action. This also is thought to be a key factor for ProstVAC.[10] Though antibodies to PAP were generated, and a robust ki57 proliferative response was induced, this may be suggestive of an adaptive immune response. Additional evaluation of retrospective studies by Drake et al[9] suggested that OS was improved in patients who received sipuleucel-T and had immunoglobin G antibody responses to greater than two secondary antigens compared with those patients who did generate antibodies. It should be noted that

the term response should be used within the context of an association of antibody induction with a change in biology of the cancer, that is, clinical outcome, and not the generation of the antibody in response to an immunogen per se. Similarly, a caveat in determining whether there is an effect of the immune therapy on either the humoral or cellular compartments is that any induction of a component of either compartment, that is, antibody or T cell population, should correlate with a biologic change in the cancer.

Sipuleucel-T has been met with enthusiasm as the first immunotherapy approved for a solid tumor malignancy; the observation that OS was improved in the absence of significant clinical benefit has encouraged further evaluation of the mechanism for survival benefit and whether, over time, a significant antitumor response could be induced. Many physicians in the field felt that knowing the mechanism of action was important for future clinical trial development; whereas, others felt that knowing the mechanism of action made little difference in their use of the drug as long as the drug provided some clinical benefit. As such, investigators have sought to identify a biomarker that may indicate that a target has been hit or that the immune system has been stimulated. Because of mixed cellular nature of the autologous mononuclear cell product, it was unclear as to the nature of the effector population that may have been relevant in inducing a potential antitumor effect, and ultimately survival. Other than T-cell–proliferation assays, no other cellular marker was indicative of this product inducing immunogenicity. The working premise has always been that the cellular product was enriched with antigen presenting cells (APC). This was confirmed by the observation by flow cytometry that CD54+ cells were responsible for antigen uptake and that CD54+ cells harbored the PAP-specific antigen presentation activity as assayed using a PAP-specific HLA-DRβ1–restricted T cell hydridoma.[11,12] The marker CD54 or intracellular adhesion molecule-1 (ICAM-1) serves as a ligand for the CD11a/CD18 (LFA-1) leukocyte integrin complex, and its interaction with other cells types is thought to be relevant in its role as a potential costimulatory receptor.[11,13,14] In the setting of sipuleucel-T, the fusion protein, PA2024, comprised of PAP fused to GM-CSF was used as the immunogen, with the PAP portion of the molecule providing the necessary immunogenicity and the GM-CSF serving to activate the APC. Studies confirmed that the isolated CD54+ cells took up the antigen as well as presented and processed the antigen in an MHC-restricted manner.[11] Similar results were obtained with an HLA-DRβ1 restricted T cell hybridoma specific for a different PAP-derived peptide. These findings provided some insight to how the product might work in vivo but still required validation. This was later confirmed. The opportunity to further validate the earlier role of CD54+ cells was provided by the availability of cellular products from three phase III double-blind, placebo-controlled trials in patients with metastatic CRPC including the IMPACT trial, which led to the product's FDA approval. Patients were randomly selected 2:1 in favor of sipuleucel-T or to control. This included a minimum of at least one treatment with the cellular product as

KEY POINTS

- Sipuleucel-T remains a standard for patients with asymptomatic or minimally symptomatic castration-resistant prostate cancer.
- The checkpoint inhibitor ipilimumab has shown activity in phase I, II, and III trials in patients with prostate cancer with durable responses; however, the phase III trial did not show a survival benefit.
- A subset analysis of patients with castration-resistant prostate cancer who had visceral metastases did not show a survival benefit with ipilimumab and radiation, suggesting that there may be some advantage to patients without visceral metastases.
- Future work with combination approaches with immunotherapy, including chimeric antigen receptor-directed T lymphocytes, represents novel approaches.
- Establishment of appropriate immunologic biomarkers that are associated with disease response/outcome is needed.

well as additional information provided from the product prepared at the primary manufacturing facility in Seattle. APC number, APC activation, and total nucleated cells (TNC) were assessed in both the control and investigational product. Also assessed were T cell proliferation and interferon-gamma secretion by ELISPOT at treatment weeks 0, 2, and 4 in the IMPACT trial.[2,15,16] In the three trials, ex vivo APC activation was greater with sipuleucel-T relative to the control at weeks 0, 2, and 4 with the median APC activation increased approximately 6.2 fold. The median cumulative APC activation with sipuleucel-T alone across the three dose preparations was 26.7 (21.5 to 33.6). Elevated levels of T-cell activation-associated cytokines were noted during manufacture but not induced before and after exposure to GM-CSF alone. The treatment generated PA2024- and/or PAP-specific humoral responses in 68% (102/151) of patients compared with 3% (2/27) of control patients. The anti-PA2024 and anti-PAP antibody titers were greater in the

sipuleucel-T arm compared with controls at all time points post-therapy, and a persistent response detectable 26 weeks after initial post-treatment baseline. It should be noted that overall product activation was confirmed by TH_1 cytokines (IFN-gamma, TNF-alpha); TH2 cytokines (interleukin [IL]-5, IL-13) were also present implying that both TH_1 and TH_2 cells were activated in an antigen-specific manner. IL-10 was less detectable relative to those cytokines that facilitate T cell expansion such as IL-2, IFN-gamma, TNF-alpha.[12] There also appeared to be a correlation between OS and T-cell secretion of IFN-gamma by ELISPOT and PA2024-specific antibody.[12]

Can reducing or limiting the regulatory T-cell population improve the vaccine response? Apart from chemotherapy, improving vaccine response by inactivating T-regulatory (Treg) cells has been attempted through the specific targeting of the T-cell cytotoxic T-lymphocyte associated (CTLA)-4 receptor with a monoclonal antibody such as

ipilimumab.[17-19] Preliminary clinical trials suggest that administering a therapeutic vaccine followed by ipilimumab enhances immune responses and tumor reduction in prostate and ovarian cancers as well as melanoma.[20-23] In a noncomparative phase I trial (30 patients) of ipilimumab plus the PSA-TRICOM[24] vaccine in prostate cancer, OS was 31.8 months compared with an expected survival of 18.5 months based on baseline factors (Halabi nomogram–predicted survival [HPS][25]).

Fong et al[26] used microarrays spotted with more than 8,000 human proteins to assess the diversity of antibody responses modulated by treatment with CTLA-4 blockade and GM-CSF. Patients with advanced prostate cancer who had clinical responses developed robust antibody responses to a higher number of antigens than nonresponders. The antibody responses appeared to target antigens on which preexisting antibodies were likely to be present in patients who responded compared with nonresponders. Although the majority of antibody responses were patient-specific, there appeared to be a commonality of immune responses to shared antigens within the responder population. They identified one shared antigen, PAK6, which is also expressed in prostate cancer and to which CD4+ T cell responses were induced.

THE CHECKPOINT INHIBITORS: DOES ONE SIZE FIT ALL?

Although sipuleucel-T still remains an active choice for patients with asymptomatic or minimally symptomatic CRPC, the stunning and durable responses seen by the checkpoint inhibitors, ipilimumab[26-28] and nivolumab,[29,30] in prostate,[27,28] melanoma,[26,29,30] non–small cell lung,[29,30] renal,[29,30] and bladder[29,30] cancers, have provided rationale for their investigation in CRPC. The phase I/II report of a dose-escalating study of ipilimumab with and without radiation therapy to a single site in bone showed stable disease and several dramatic and durable responses. This provided the impetus for the recently reported phase III trial[28] for patients who progressed after docetaxel treatment and were randomly assigned 1:1 to receive bone-directed radiotherapy (8 Gy in one fraction) followed by either ipilimumab 10 mg/kg or placebo every 3 weeks for up to four doses. Nonprogressing patients could continue to receive ipilimumab at 10 mg/kg or placebo as maintenance therapy every 3 months until disease progression, unacceptable toxic effect, or death. This came close to, but did not meet, its endpoint of OS. An exploratory and post-hoc subgroup analysis, noted an OS benefit for ipilimumab in a subset of patients without visceral metastases, with normal or mildly elevated alkaline phosphatase, and without anemia. This suggested that ipilimumab may still be effective but in patients with more favorable prognostic features. Unlike melanoma, a highly mutated disease,[31] for which ipilimumab has been shown to have favorable effects, this has not been the case for prostate cancer. Similarly, nivolumab (anti-programmed death [PD]-1),[29,30] and its ligand (anti-PD-L1) have shown robust activity in melanoma, renal cell, non-small lung cancers, and now blad-

der cancer but minimal activity in prostate cancer. Despite this, there is still consideration to trying to maximize their effectiveness in prostate cancer via other combinatorial approaches.

DNA VACCINES

For the first time in CRPC, a phase III clinical trial of a viral-based vaccine, rilimogene galvacirepvec/rilimogene glafolivec (PROSTVAC).[32-34] Many viral-based cancer vaccines are produced via the insertion of a plasmid encoding tumor proteins (i.e., PSA, prostate-specific membrane antigen [PSMA]) into a viral vector, often a poxvirus (e.g., vaccinia, fowlpox).[35-37] After administration, host epithelial cells are infected and can, on lysis, continue to release a variety of encoded antigens that are taken up and processed by APCs for presentation to the T cell. This is accompanied by activation of CD4+ and CD8+ T cells. Alternatively, as in PROSTVAC, not only are plasmids used that encode tumor associated antigens (i.e., PSA) but there is inclusion of costimulatory molecules. In the case of PROSTVAC, three T-cell costimulatory molecules, that is, B7.1, intercellular adhesion molecule-1 (ICAM) and leukocyte function-associated antigen-3 (LFA-3) are included. As in all vaccine strategies, there are limitations especially when preclinical studies showed marked tumor regressions but the responses in man are disappointing. One shortcoming of the viral-based vaccine preparation lies in that the antibody response to vector antigens may be more exaggerated compared with the response to the plasmid encoded tumor antigens. This can induce neutralization of the vaccine with recurrent administrations.[38] PROSTVAC circumvents this by using an immunologic prime boost that by sequencing two different viruses, a vaccinia virus prime followed by a fowlpox virus boost, results in potent immune responses. Although there has been an effect on cancer cellular proliferation, the cancer cell rate of growth was also affected.[39] The authors suggest that this may provide an alternative explanation to why vaccines that yield an improved OS are not accompanied by a delayed time to progression.

A recent paper by Madan et al[40] showed that ipilimumab could be safely combined with the PSA-targeted vaccine PSA-Tricom without significantly exacerbating the agent's immune-related adverse event profile. Those patients who were chemotherapy-naive experienced a PSA decrease from baseline levels. In support of this approach, another phase I study also confirmed that ipilimumab could safely be combined with GVAX prostate.[41] Preclinical models continue to be performed to assess the translatability of these combinatorial approaches. A combination of GVAX and anti-CTLA-4 in an autochthonous prostate cancer model expressing hyaluronic acid in a prostate-restricted manner reported on the importance of timing and dosage in this kind of regimen, which may have importance in future trials with ipilimumab combinations.[42] GVAX plus anti-CTLA-4 combination therapy reduced peripheral tolerance and promoted

TABLE 1. Rationale for Combinatorial Strategies

Pros	Concerns
Although cancer cells are not highly immunogenic, therapeutic vaccines containing tumor-associated antigens plus costimulatory molecules have been found to elicit substantial immune responses.	Repeated rounds of chemotherapy at maximum-tolerated doses can reduce tumor burden and suppress, rather than enhance, immunologic efficacy.
Metastatic tumors develop highly sophisticated strategies for derailing immune defenses. Therapeutic vaccines, therefore, need support that sets the tumors back and/or resets the immune system.	Patients status post standard chemotherapy have resistant tumor cells, a shorter survival, and more suppressed immune systems. This population may not be optimal for evaluation of a novel vaccine.
Chemotherapy, if not myeloablative, has immunomodulatory effects that help restore antitumor immunity while affecting the tumor microenvironment.	Timing of chemotherapy relative to therapeutic immunization may be a critical factor in the success of a combination regimen. Is chemotherapy being used to debulk tumor burden or to improve synergism with the therapy?
Moving forward, optimization of the effectiveness of vaccine/chemotherapy regimens requires the development of clear endpoints that include biomarkers that reflect the effect of the therapy on the biology of the disease.	Basic questions remain unanswered, including the dose and timing of chemo-therapy when used in conjunction with therapeutic vaccines. It is unclear how to design trials with viable endpoints for patients with biochemical relapse or nonmetastatic castration-resistant disease.

the activation and proliferation of tumor antigen-specific CD8 T cells.

BUILDING ON IMMUNOTHERAPY—ROLE OF BIOLOGICS AND/OR CYTOTOXIC AGENTS

There have been numerous reports touting the role of chemotherapy given before an immunotherapeutic agent particularly as it pertains to reducing the Treg cell population and making the immune milieu more sensitive to immune modulation. There are three basic unknowns with respect to chemotherapy administered with an immunotherapy: identifying the optimum chemotherapy, the maximum tolerated dose, and in which sequence the agents be given (Table 1). Chemotherapeutics of interest, with an ongoing body of preclinical and early human data, notably include taxanes, anthracyclines, and cyclophosphamide, which seem to offer some positive immune modulation that might enhance the response to a therapeutic vaccine. Chemotherapy could be administered at standard or maximum-tolerated doses if the purpose is to kill the most malignant cells, or trigger lymphopenia and reset immune homeostasis. As discussed, lower-than-therapeutic doses may be favored, as those may selectively alter cell populations and inhibit angiogenesis.[43] Higher doses set the tumor back further, allowing greater immune activity and more antigenicity because of tumor debulking and cell death.[44] Lower doses and/or abbreviated courses would be less toxic overall, and also less immunosuppressive. They would also allow frequent, even daily, dosing (metronomic administration) for a steady effect over time. Induction of tumor resistance to chemotherapy, including multidrug resistance, is a possibility when giving suboptimal drug doses.[45-47] The vaccine, possibly enhanced by the chemotherapy, might provide a barrier against tumor escape. Metronomic taxanes and other agents have supplemental antiangiogenic effects as well.[45,48]

Sequencing of chemotherapy, like dosing, depends on the agent's mechanism of action. Initiation of chemotherapy before vaccination would be an option if the goal was to reset the immune system by reducing the level of suppressive cells.

On the contrary, initiation of chemotherapy during or after vaccination would be an option if the strategy was to impede the tumor and potentiate or broaden the vaccine-induced responses.

The question of which patient, clinical state, and treatment history is most appropriate for therapeutic vaccine schemes also arises. Patients with late-stage disease may have had their immune systems compromised by extensive chemotherapy and the evolving tumor escape strategies.[49-52] One implication is that the patients with shorter life expectancies will not benefit from vaccine therapy, as demonstrated in the GVAX/docetaxel combination results. The original phase III trial of GVAX compared with docetaxel enrolled patients with less-advanced disease.[53] A trend toward superior survival in the GVAX recipients after 22 months follow-up was already emerging. In another vaccine example, in a phase II study of PSA-TRICOM (32 patients), patients with HPS of 18 months or longer lived significantly longer than expected (p = 0.035).[53] Median survival was 14.6 months for patients with HPS less than 18 months and was 37.3 months or longer for those patients with an HPS of 18 months or longer.[53] Considering the safety of vaccines relative to standard chemotherapy, clinical trials could justify enrolling patients in earlier stages of disease in lieu of conventional chemotherapy alone.

T-CELL STRATEGIES: CHIMERIC ANTIGEN RECEPTOR-MODIFIED T CELLS

The genetic engineering of T cells is a novel strategy designed to accelerate the generation of tumor-specific T cells and remedy the biologic limitations that constrain the antitumoral functions of normal T cells.[54-57] Unlike the physiologic T-cell antigen receptor (TCR), chimeric antigen receptors (CARs) encompass immunoglobulin variable regions or receptor ligands as antigen-recognition elements, thus, permitting T cells to recognize cell surface tumor antigens in the absence of HLA expression (Fig. 1). T-cell activation is mediated by the cytoplasmic domain of the CAR, which is typically derived from the CD3-zeta chain or the FcRI-gamma

TABLE 2. Target Molecules and Their Respective Constructs Used in Preclinical/Clinical Trials

Antigen	Malignancy	Receptor Type
CD19, 20	B-cell malignancies	scFv-CD3zeta
PSMA	Tumor neovasculature	scFv-CD3zeta
PSCA	Pan-carcinoma	Under study
ERBB2	Breast and others	scFv-CD28-CD3zeta
GD$_2$	Neuroblastoma	scFv-CD3zeta, scFv-CD28
MDM2	Pan-carcinomas	alpha beta TCR
CEA	Colorectal cancer	scFv-CD28-CD3zeta
VEGF-R2	Tumor neovasculature	scFv-CD3zeta
KDR	Tumor neovasculature	scFv-Fc xi Rl gamma
EGP2	Colorectal cancer	scFv-CD3zeta, scFv-Fc xi Rl gamma

chain (Table 2, Figs. 2 and 3). Our group has shown that the zeta chain–based CARs could induce strong activation capable of sustaining T-cell proliferation and permitting secondary antigenic restimulation in vitro provided that antigen was presented in the context of CD28-mediated costimulation.[54,58,59] In an effort to determine if T cells—particularly human T cells—expanded in this manner could mediate tumor eradication in vivo and if further in vivo costimulation would be needed to sustain their function, three tumors models using severe combined immunodeficiency-beige/beige mice were developed that showed that PSMA-targeted T cells could effectively eliminate prostate cancer. T cells were transduced with Pz1, a CAR-targeting human PSMA.[60,61] The Pz1 receptor encompasses the zeta chain of the CD3 complex as its activation domain and specifically redirects in vitro cytolysis again PSMA-positive tumor cells lines. The tumor models included orthotopic, subcutaneous, and pulmonary

diseases; tumor eradication was directly proportional to the in vivo effector-to-tumor cell ratio. Serial imaging studies revealed that the T cells had to survive for at least 1 week to induce durable remissions. The administration of Pz1-transduced T cells induced objective responses in all mice and cured a substantial fraction of them. Based on the favorable responses, several clinical trials have been actively pursuing this approach using unique combinations with constructs that encompass unique vectors or are given in combination with cytokines. Although these approaches have been well-tolerated—stable disease has been seen but in a majority of cases—a cytokine release syndrome is observed following administration of the cells suggesting T cell activation.[62,63] Achievement of maximal responses in solid tumor may depend on the nature of the vector, the ability of cells to migrate to and persist at the tumor site, incorporation of a multiantigen construct with molecules such as PSA, PAP, PSMA, or prostate stem cell antigen or delivering a sufficient number of cells to reach the tumor site without causing worsening toxicities.

HEREIN LIES THE FUTURE

Although prostate cancer is a suitable target for immunotherapy given the variety of prostate cell surface antigens that can serve as immune targets, the availability of a serum biomarker, that is, PSA, and the fact that immunotherapy is a reasonable treatment for all clinical states of the disease, how to build on current therapies remains a challenge. Alternative strategies include OX40 and its ligand OX40L, which are members of the tumor necrosis factor (TNF) superfamily and can augment T-cell expansion, cytokine production, and survival. OX40 signaling also controls regulatory T cell differentiation and suppressive function. OX40 agonists have

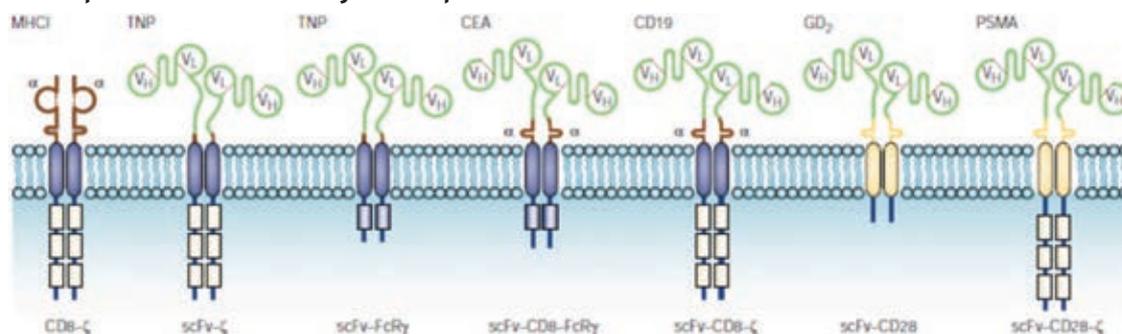
FIGURE 3. Examples of Chimeric Antigen Receptors[54]


Many chimeric antigen receptors (CARs) interact with antigen through ScFvs–the antigen binding regions of immunoglobin that consist of rearranged Heavy (VH) and light VL chains linked by a short peptide linker. The CD8/zeta fusion receptor engages HLA class I molecules. Other CARS specifically bind trinitrophenol (TNP), carcinoembryonic antigen (CEA), CD 19, G_{D2} ganglioside, and prostate specific membrane antigen (PSMA). They incorporate various portions of the B-cell antigen receptor (light green), T-cell receptor-CD3 complex (ivory), CD8alpha (brown), FcRgamma (blue ITAM domains), and CD28 (yellow) cytoplasmic activation domains (blue ovals). The P28 zeta receptor, which recognizes PSMA, includes signaling domains from both CD28 and CD3 zeta. Reproduced with permission of publisher.[54]

been shown to enhance antitumor immunity in preclinical models using immunogenic tumors.[64] A recent phase I trial in patients with metastatic castration- and chemotherapy-resistant prostate cancer evaluated the toxicity and the effect of cyclophosphamide combined with radiotherapy and an anti-OX40 agonist on peripheral blood lymphocytes (PBLs).[65] There was no effect of the combination on the degree of proliferation of PBLs. There was no change in the proliferation of CD4+ FoxP3+ T cells (Treg), but there was a trend toward a higher percentage of cycling CD8+ T cells expressing activation markers CD38 and HLA-DR. OX40 and its ligand remain interesting targets for future development.

Clinical trials in the castration-resistant nonmetastatic state evaluating combinations of the antiandrogen flutamide with or without the addition of PROSTVAC/PSA-TRICOM in delaying disease progression are ongoing [NCT00450463]. Another randomized phase II trial is examining the combination of PROSTVAC/TRICOM and the AR-directed agent enzalutamide to determine if the combination will increase time to progression (as defined by Prostate Cancer Clinical Trials Working Group 2 criteria [NCT01867333]). The results of the phase III multinational randomized trial of PROSTVAC in patients with asymptomatic of minimally symptomatic CRPC are eagerly awaited. This 800-patient trial has reached its target accrual and is comparing the OS and proportion of patients who remain event-free (radiological or pain progression, initiation of chemotherapy, or death) at 6 months.

CONCLUSION

The mix and match approach—that is, combining immunologic agents with different mechanisms of action or even within the same class[66]—supports the rationale for continuing research in immunotherapy for prostate cancer. While understanding mechanistically how antitumor effects may occur,[67] it is important to keep in mind that the manner in which a therapy induces an antitumor response may be unclear, and as such should not deter investigators from using the drug.

Evolving Immunotherapy Strategies in Urothelial Cancer

Sam J. Brancato, MD, Keidren Lewi, MD, and Piyush K. Agarwal, MD

OVERVIEW

The treatment of nonmuscle-invasive urothelial carcinoma with bacillus Calmette-Guérin (BCG) represents the importance of immunotherapy in the treatment of cancer. Despite its clinical efficacy, up to 30% of patients will ultimately experience progression to muscle-invasive disease. This, along with an improved understanding of the biologic pathways involved, has led to efforts to improve, enhance, or alter the immune response in the treatment of urothelial carcinoma. A number of novel therapeutic approaches currently are being pursued, including recombinant BCG to induce T helper type 1 (Th1) immune responses, nonlive *Mycobacterium* agents, targeted agents toward cancer-associated antigens, immune-modulating vaccines, and adoptive T-cell therapies. Here, we review the current and future immunotherapy treatment options for patients with urothelial cancer.

In 2013, cancer immunotherapy was declared the breakthrough of the year by *Science* magazine.[1] Since then, there has been a frenetic dash toward the development and implementation of immune-based therapies in all cancers, including urothelial cancer. However, immunotherapy has a long and successful history in the treatment of bladder cancer, with BCG intravesical immunotherapy as the leading therapy for nonmuscle-invasive bladder cancer (NMIBC). We will review the current and future immunotherapy treatment options for patients with urothelial cancer.

BCG

BCG is a live attenuated strain of *Mycobacterium bovis* developed initially in 1921 as a vaccine for tuberculosis. In 1976, Morales et al[2] reported the first successful use of intravesical BCG therapy in the treatment of recurrent superficial bladder cancer. It has been demonstrated to reduce recurrence rates and progression to muscle-invasive disease in patients with carcinoma in situ (CIS) and with superficial bladder tumors.[3-5] BCG has gone on to become the standard of care in the treatment of high-grade NMIBC after transurethral resection.

Although BCG has been a mainstay treatment of NMIBC for more than 3 decades, the exact mechanism by which BCG achieves its therapeutic effect remains an area of investigation. Zbar and Rapp[6] in 1974 discovered several conditions required to obtain an antitumor effect with BCG, including the ability to develop an immune response, a sufficient number of live BCG, close contact between BCG and cancer cells, and a low tumor burden.

As early as 1959, it was recognized that the antitumor effect of BCG was mediated through the activation of an immune response and induction of the inflammatory response.[7] Additional studies have confirmed that an intact immune system, particularly the cellular system, is required for achievement of a therapeutic response. Abundant evidence indicates that intravesical BCG results in an extensive influx of inflammatory cells and cytokine production, which results in an immune response against tumor cells.

The immune response is preceded by the attachment of BCG to urothelial cells. The normal urothelium is lined with glycosaminoglycans (GAGs), which have been suggested as a primary defense mechanism against noxious elements in urine.[8] The antibacterial properties of GAGs are secondary to its hydrophilic, highly negative charge, imposing a barrier between the urothelium and urine. After instillation into the bladder, BCG adheres to urothelial cells via fibronectin, a glycoprotein that is part of the extracellular matrix. BCG attaches to fibronectin through its fibronectin attachment protein. The importance of this interaction has been demonstrated in a mouse model, in which blocking fibronectin attachment reduced the delayed-type hypersensitivity response and antitumor activity.[9] Internalization of BCG by urothelial, tumor, and inflammatory cells triggers an inflammatory cascade of cytokine release and immune cell recruitment. This results in an influx of granulocytes, macrophages, natural killer cells, dendritic cells, and lymphocytes. Many studies have examined the cytokines present in the urine of patients treated with BCG and found elevated amounts of interleukin (IL)-1, IL-2, IL-6, IL-8, tumor necrosis factor (TNF)–alpha, interferon (IFN)-gamma, and granulocyte-macrophage colony-stimulating factor (GM-CSF).[10,11] In addition, an anti-BCG–specific immune response via antigen

presentation to T cells amplifies the response. Ratliff et al[12] showed that the absence of either CD4 or CD8 T-cell subsets eliminated the BCG-mediated antitumor activity.

Although BCG is a very effective intravesical treatment for high-grade NMIBC, ultimately 20% to 50% of patients will experience recurrence after a successful induction cycle.[13] Of these patients, 25% to 45% can benefit from salvage therapy with a second induction course.[14] Side effects of intravesical BCG are common. A randomized EORTC trial assessed the dose and duration of maintenance BCG in patients with intermediate- and high-risk NMIBC.[15] Of the 1,316 patients enrolled, 62.8% reported local side effects and 30.6% reported systemic side effects. The most frequent local and systemic side effects reported were chemical cystitis in 35% of patients and general malaise in 15.5% of patients.

Prolonged BCG treatment is limited in some patients by the development of severe local side effects and/or recurrent and/or progressive disease. Rarely, BCG systemic toxicity also can preclude further BCG use. Although radical cystectomy is an effective procedure for these patients, it can be accompanied by considerable morbidity and an altered quality of life.

RECOMBINANT BCG

Recombinant BCG (rBCG) options have been engineered to address the stated limitations of BCG. rBCG consists either of Th1 cytokine-secreting rBCG strains or of non-live rBCG strains that contain BCG subcomponents (see Table 1).

TH1 CYTOKINE-SECRETING RBCG

The most common Th1 cytokines incorporated into rBCG strains include IL-2, IL-12, IL-18, IFN-alfa, and IFN-gamma.[16] In vitro, IL-2 enhances the production of cytotoxic lymphocytes and the cytotoxic activity of natural killer cells and monocytes.[17] In patients treated with BCG, increased IL-2 levels are noted in the urine shortly after BCG adminis-

KEY POINTS

- Bacillus Calmette-Guérin (BCG) represents one of the most successful applications of immunotherapy and currently is the most effective treatment for high-grade nonmuscle-invasive bladder cancer.
- Recombinant BCG may enhance the cytotoxic T-cell response required for BCG-mediated antitumor effects while reducing local side effects.
- Checkpoint blockade inhibitors are a novel class of immunotherapeutics agents that target and interfere with immune stop signals.
- Vaccines present the opportunity for long-term success and are the ultimate goal.
- Adoptive T-cell immunotherapy can induce rapid immunity but carries the risk of off-target toxicities.

TABLE 1. Targeted Therapies

Agent	Target(s)
rBCG	
Th1, cytokine secreting	IL-2, IL-12, IL-18, IL-α, IL-γ
BCG, subcomponent based	Mycobacterial cell wall, BCG cell wall
Monoclonal Antibodies	
Checkpoint blockade inhibitors	CTLA-4, PD-L1
Tumor-associated antigens (CDX-1307)	β-HCG
Vaccine	
AdHER2 dendritic cell vaccine	HER2/neu
CTAs	NY-ESO-1, recMAGE-A3
PANVAC	MUC-1, CEA
Adoptive T-cell Therapy	
TIL	CTAs (eg, NY-ESO-1)
CART	TAA

Abbreviations: rBCG, recombinant bacillus Camille-Guerin; Th1, T helper cell 1; IL, interleukin; CTLA-4, cytotoxic T-lymphocyte-associated protein 4; PD-L1, programmed death ligand 1; HCG, human chorionic gonadotropin; CTA, cancer testis antigen; TIL, tumor-infiltrating lymphocyte; CART, chimeric antigen receptor T cell; TAA, tumor-associated antigen.

tration.[18] Therefore, IL-2 rBCG strains have been engineered and studied in animal models: IL-2 rBCG strains induce a more favorable ratio of IFN-gamma to IL-4,[19] accelerate greater antigen-specific proliferation,[20] and release more Th1 cytokines than BCG.[20] IL-12 has a very complementary function to IL-2 and has been shown to induce tumor regression and improve survival in animal models as a single agent.[21] Our colleagues at the National Cancer Institute (NCI) showed that intravesical IL-12 can be more successful than intravesical BCG in treating orthotopic murine tumors when it is combined with chitosan.[22] Furthermore, its role in immunotherapy is vital, because IL-12 knockout (and IFN-gamma knockout) mice do not respond to BCG therapy.[23] Unfortunately, a phase I trial of intravesical recombinant IL-12 demonstrated no activity in patients[24] (although the IL-12 in this trial was not combined with chitosan); to date, no trial results with IL-12– based rBCG are available. IL-18 is secreted from activated macrophages and, similar to IL-2 and IL-12, can synergize BCG activity by inducing Th1 cytokines.[25] In vitro, IL-18 – based rBCG enhances macrophage cytotoxicity and cellular proliferation of IFN-gamma–secreting cells.[26]

Unlike the previous cytokines, IFN-alfa has been widely used in patients, often in conjunction with BCG. Preclinical work demonstrates that IFN-alfa can induce apoptosis by increased TNF–related apoptosis-inducing ligand (TRAIL) expression[27] and reduced angiogenesis in bladder tumors.[28] Although a large, phase II trial showed the efficacy and tolerability of BCG given with IFN-alfa, it is unknown whether the combination offers any benefit compared with BCG monotherapy.[29] The IFN-alfa–secreting rBCG strain is superior to BCG in the production of IFN-gamma from peripheral blood mononuclear cells (PBMCs) and in the enhancement of PMBC cytotoxicity toward bladder cancer cells.[30,31] IFN-

gamma is an essential cytokine for BCG efficacy, and it has been shown to reduce proliferation in bladder cancer cell lines.[23,32] In a murine model, IFN-gamma–based rBCG up-regulated major histocompatibility complex (MHC) class I molecules on murine bladder cancer cells and, compared with the control rBCG strain, increased CD4[+] T cells, IL-2, and IL-4 in the bladder and prolonged survival after intravesical administration.[33]

BCG SUBCOMPONENT-BASED RBCG

Most of the evaluated subcomponents are portions of the BCG cell wall. Mycobacterial cell wall extract demonstrated excellent activity: 41.1% of patients had negative cystoscopies and biopsies at 60 weeks after therapy.[34] However, it contained thimerosal, a known organomercurial preservative with the potential for neurotoxicity. A newer formulation without thimerosal, called mycobacterial cell wall complex (MCC), was subsequently evaluated in a multicenter study in 2009. Fifty-five patients (82% of whom had previously experienced treatment failure with BCG) received MCC induction and maintenance at two different doses. At 26 weeks of follow-up time, the complete response rates were 27.3% in the 4-mg group and 46.4% in the 8-mg group.[35] Unfortunately, a phase III trial (NCT01200992) comparing MCC with mitomycin C in patients with BCG–recurrent/refractory bladder cancer closed early because of poor accrual. Finally, the BCG cell wall skeleton has been studied further after being incorporated into other particles, because it has unfavorable characteristics for penetration of the urothelium by itself. Both a liposomal and a lipid nanoparticle formulation have demonstrated antineoplastic effects in animal models.[36,37]

MONOCLONAL ANTIBODIES

Most excitement in immunotherapy is focused on monoclonal antibodies directed against tumor-associated antigens (e.g., beta-HCG, cytotoxic T-lymphocyte–associated antigen 4 [CTLA-4], programmed death ligand 1 [PD-L1]). Beta-HCG is expressed in 35% to 75% of bladder cancers, and expression correlates with a worse prognosis.[38] CDX-1307 is an interesting monoclonal antibody that functions like a vaccine in the body. It consists of the beta-HCG subunit genetically fused to the human monoclonal antibody B11 that is specific for the mannose receptor on antigen-presenting cells (APCs). On administration, CDX-1307 is internalized by APCs and, in processing, presents beta-HCG as an antigen to CD4[+] and CD8[+] T cells.[39] Thus, it has been proposed as a therapy in beta-HCG– expressing bladder cancers.

Checkpoint blockade inhibitors are extremely popular now, because they target inhibitors of the immune response. T cells engage APCs via their T-cell receptor as the primary signal; however, a secondary costimulatory signal is provided by CD28 (on the T cell) and B7 (on the APC). To prevent excessive T-cell proliferation, an inhibitory signal, CTLA-4, can be expressed by activated T cells and competes with CD28 in binding to B7 on APCs. This can mitigate a T-cell response in a normal circumstance. However, in cancer, T-regulatory cells (Tregs) are expressed in the tumor microenvironment and can constitutively express CTLA-4, which can suppress an anticancer immune response.[40] Therefore, CTLA-4–blocking antibodies have been developed as a therapeutic strategy. These antibodies have prolonged overall survival in metastatic melanoma but cause grade 3 or 4 toxicities in the 10% to 15% range.[41] A pilot presurgical trial in patients with urothelial cancer demonstrated that peripheral and tumor CD4 T cells had increased expression of inducible costimulator (ICOS) in response to an anti–CTLA-4 antibody. These CD4[+] ICOS (hi) T cells produced IFN-gamma, recognized NY-ESO-1 as a tumor antigen, and increased the ratio of effector T cells to Tregs.[42] A subsequent phase I trial of 12 patients with urothelial cancer demonstrated only grades 1 to 2 toxicities, and all patients expressed CD4[+] ICOS (hi) T cells in tumor tissues and systemic circulation. These preliminary findings with the use of CTLA-4–blocking antibodies have stimulated efforts to evaluate the efficacy of these antibodies in urothelial cancer.

As an immune response progresses, CD4 and CD8 T lymphocytes will upregulate the expression of other checkpoint inhibitors, such as the programmed death 1 (PD-1) receptor. Inflammatory conditions will prompt IFN release, which will upregulate PD-L1 and PD-L2 in peripheral tissues to maintain immune tolerance and prevent autoimmunity. Binding of PD-L1 and/or PD-L2 to PD-1 results in dephosphorylation of proximal signaling molecules downstream of the T-cell receptor complex via *src* homology region 2 domain–containing phosphatase (SHP)-1 and SHP-2 as well as augmentation of phosphatase and tensin homolog (PTEN), leading to decreased T-cell proliferation, survival, and protein synthesis.[43] However, many cancers take advantage of this checkpoint blockade by upregulating PD-L1 expression on their surface, and urothelial cancers have higher levels of PD-L1 relative to other tumors.[44] Among urothelial tumors, PD-L1 expression is higher among BCG treatment failures[45] and among more aggressive and metastatic tumors.[46]

The PD-L1 expression data would suggest activity in metastatic tumors with a PD-L1 blockade. A recently completed phase I clinical trial evaluated the anti–PD-L1 monoclonal antibody, MPDL3280A, in patients with metastatic urothelial bladder cancer.[47] This antibody has an Fc domain modification that prevents antibody-dependent cellular cytotoxicity so that local T cells were not killed and thereby depleted. As a result, the antibody inhibits the interaction of PD-L1 with PD-1. In this trial, 72% of the patients experienced failure of two or more prior systemic regimens. The overall objective response rate (ORR) for all 65 patients was 26%. However, the ORR varied on the basis of the degree of immunohistochemistry (IHC) staining of tumor-infiltrating cells or tumor cells. Strong (2+ to 3+) PD-L1 expression by IHC (5% or greater PD-L1 positive) resulted in a 43% ORR, whereas weak (0 to 1+) PD-L1 expression by IHC (less than 5% PD-L1 positive) resulted in an 11% ORR.

The median time to first response was 42 days, and the median overall survival times were 4.2 months for the strong IHC expression group and 2.7 months for the weak IHC expression group. Importantly, the main toxicity of the therapy was fatigue, and grade 3 adverse events only occurred in 4% of patients (no grade 4 or 5 toxicity noted). On the basis of the encouraging results of this trial, the U.S. Food and Drug Administration (FDA) granted MPDL3280A a breakthrough designation in June 2014.

VACCINES

HER2 status has prognostic and therapeutic value in breast cancer. Recently reported results from The Cancer Genome Atlas[48] found that HER2 alterations were almost as frequent in urothelial carcinoma compared to the TCGA breast cancer study. A meta-analysis of nine retrospective studies (2,242 patients) indicated that HER2 expression significantly correlated with poorer disease-specific survival (hazard ratio [HR] 2; 95% CI, 1.22 to 3.29; p = 0.006) and disease-free survival (HR 1.68; 95% CI, 1.33 to 2.14; p < 0.0001) of patients with bladder cancer.[49] DN24–02 is an investigational active cellular immunotherapy targeted at the HER2 receptor. It consists of autologous PBMCs, including APCs, which are activated ex vivo with a recombinant fusion protein. A randomized phase II study comparing adjuvant DN24–02 to the standard of care in patients with high-risk urothelial cell carcinoma met accrual and results are pending at this time. Colleagues at the National Institutes of Health Clinical Center are investigating the use of another HER2/*neu* vaccine in a phase I trial (NCT01730118). This trial investigates a novel therapeutic autologous AdHER2 dendritic cell vaccine in patients with HER2-expressing metastatic solid tumors as well as in patients with adjuvant bladder cancer who have HER2-positive tumors. In preclinical animal models, the vaccine was documented to eradicate large established tumors through the induction of polyclonal, anti-HER2 antibodies.

M phase phosphoprotein 1 and disheveled, EGL-10, and pleckstrin (DEP) domain have roles in the growth of bladder cancer cells. In addition, human leukocyte antigen (HLA)-A24–restricted peptide epitopes corresponding to parts of these two proteins have been identified that can induce peptide-specific cytotoxic T cells. Of the six patients with metastatic bladder cancer enrolled in a phase I trial, four developed vaccine-specific cytotoxic T cells.[50]

Cancer testis antigens (CTAs) are a group of tumor-associated antigens with restricted expression in normal tissues but with expression in a variety of tumors. Sharma et al[51] examined the expression patterns of nine CTA by IHC and reverse transcriptase (RT) polymerase chain reaction (PCR) in a panel of 95 high-grade bladder tumors. They found that at least one CTA was expressed in 77% of the tumors and that 61% of the tumors expressed more than one. A recombinant NY-ESO-1 protein vaccine coadministered with GM-CSF and BCG as immunologic adjuvant was tested in six patients with organ-confined disease.[52] NY-ESO-1–specific antibody responses were induced in five patients, CD8 T-cell responses occurred in one patient, and CD4 T-cell responses were seen in all six patients. A phase II trial (NCT01435356) evaluating the efficacy of the recMAGE-A3 vaccine after cystectomy is currently recruiting; a phase I trial (NCT01498172) evaluating MAGE-A3 plus BCG has just completed, and results are pending.

PANVAC is a poxviral cancer vaccine that has demonstrated therapeutic efficacy against a variety of carcinomas. PANVAC consists of a primary vaccination with a replication-competent recombinant vaccinia vector followed by multiple boosts with a replication-incompetent recombinant fowlpox vector. These vectors contain transgenes for both human T-cell costimulatory molecules and tumor-associated antigens against Mucin-1 (MUC-1)[53,54] and carcinoembryonic antigen (CEA).[55] MUC-1 and CEA are expressed in approximately 93% and 76% of high-grade bladder tumors, respectively. A phase II study (NCT02015104) assessing PANVAC in combination with intravesical BCG in patients who have experience treatment failure with prior BCG therapy is recruiting patients at the NCI and the Rutgers Cancer Institute of New Jersey.

ADOPTIVE T-CELL THERAPY

Adoptive T-cell therapy involves the infusion of externally manipulated T cells to give rapid immunity instead of relying on the immune system to generate T cells after being presented with an antigen. Before infusion, however, patients require nonmyeloablative leukoreductive therapy using irradiation and chemotherapy.[56] This area of cancer immunotherapy began with tumor-infiltrating lymphocytes (TILs). These TILs are extracted from tumor tissue, expanded ex vivo, and then reinfused into patients. This approach was applied recently to patients with metastatic urothelial cancer in a feasibility study. Tumor lymphocytes were obtained from lymph nodes draining metastatic tumors; after in vitro culture, the lymphocytes were reinfused into the patients without any adverse effects.[57] However, it is unclear how effective this approach will be. A more novel approach applies extraction of TILs from tumors and whole-exomic sequencing of the tumors to identify mutations characteristic of the tumor. The TILs are probed to see if they recognize any of the mutations; then, adoptive transfer of the TILs containing mutation-specific polyfunctional T cells is performed.[58] This technology can be applied to any malignancy, and, given that urothelial cancer has the third highest rate of mutations, it is well positioned for this type of therapy. We are assisting our colleagues who are performing this work at the NCI in the application of this approach to urothelial tumors.

TIL therapy is limited in that TILs have to be retrieved through an invasive procedure and require the ability to grow ex vivo. As a result, genetic modification of the T-cell receptor (TCR) only requires isolation from peripheral blood, viral transduction to express a recombinant TCR specific for a tumor antigen, and reinfusion after expansion of these genetically engineered TCRs. CTAs, as mentioned earlier, are good candidates for TCR gene therapy, because they are not present in adult somatic tissues and are found with high

frequency in some tumors. For example, NY-ESO-1 is expressed in 80% of patients with synovial cell carcinoma patients. In a trial of patients who had metastatic synovial cell carcinoma, four of six patients achieved objective clinical responses after treatment with a TCR directed against NY-ESO-1.[59] This technology still requires the presence of the target antigen on the tumors and is restricted to patients who have certain HLA alleles. Also, if the tumor responds by MHC downregulation, then this therapy may be limited. However, this therapy seems attractive to apply toward urothelial tumors, given their high expression of CTAs.

A novel form of adoptive immunotherapy has evolved that can avoid the MHC restriction and the immune escape phenomenon that may be seen with genetically engineered TCRs. Chimeric antigen receptor T-cell therapy entails isolation of a patient's peripheral T cells and subsequent transduction by a chimeric receptor that consists of a single-chain variable region of an antibody domain (scFv) that is specific for a desired tumor-associated antigen (TAA) with a CD3/T cell. Because the antibody portion of the chimeric receptor is binding to the TAA, the binding is non-MHC restricted. The T-cell portion engages the native T-cell receptor–mediated activation on binding. Therefore, this approach combines the cytotoxicity of a

$CD8^+$ T cell with MHC-independent antigen recognition of a monoclonal antibody.[56]

CONCLUSION

Immunotherapy has become a popular approach to target tumors in the last decade. Urothelial cancer is a malignancy that has a long history of successful treatment with BCG. Despite this success, the high recurrence and progression rates of localized disease along with the dismal prognosis of metastatic disease warrant improvement in the current treatment. Recombinant BCG strategies are promising for BCG-refractory disease or for patients who cannot tolerate further BCG. Monoclonal antibodies, and specifically checkpoint blockade inhibitors, have been especially exciting and are the newest therapies for metastatic urothelial cancer. These therapies likely will be applied to localized, BCG-refractory disease also. Vaccines that target TAAs, such as HER2, CTA, and MUC-1/CEA are promising, given the high expression in urothelial cancer and the tolerability of these treatments. Finally, adoptive T-cell therapy is very promising; although this area of immunotherapy has not been explored fully in urothelial cancer, the high rate of mutations in urothelial cancer and the prevalence of urothelial-specific TAAs make this a promising area of future research.

Disclosures of Potential Conflicts of Interest

The author(s) indicated no potential conflicts of interest.

Emerging Role for Novel Immunotherapy Agents in Metastatic Renal Cell Carcinoma: From Bench to Bedside

Matthew Weinstock, MD, and David F. McDermott, MD

OVERVIEW

Therapies that augment the antitumor immune response have been an established treatment modality for metastatic renal cell carcinoma (mRCC) since the 1980s. An improved understanding of the factors that limit the immune response to cancer have led to the development of novel therapeutic agents. Most notably, monoclonal antibodies that block the programmed death (PD)-1 immune checkpoint pathway have demonstrated encouraging antitumor activity against mRCC in phase I and II clinical trials. However, as monotherapy these agents are unlikely to offer substantial clinical benefit for the majority of patients with mRCC. Combination approaches and improvements in patient selection will be essential to enhance their efficacy and ensure the rational application of immunotherapy. This review summarizes the clinical and preclinical data that support the use of novel immunotherapies for mRCC and looks forward to future directions for this promising therapeutic strategy.

Cytokine-based immunotherapies, such as interferon-alfa and interleukin (IL)-2, have been used for the treatment of mRCC since the 1980s.[1-9] Although some patients experience a dramatic benefit with this approach, a majority fail to achieve long-term disease-free intervals. Substantial improvements in the outcomes of patients with mRCC have occurred over the past decade with the development of therapies targeting the vascular endothelial growth factor (VEGF) and mammalian target of rapamycin (mTOR) pathways,[10-22] but mRCC continues to account for an estimated 13,860 deaths per year in the United States.[23] Identifying therapeutic strategies that promote durable remission of metastatic disease remains critically important.

Conventional immunotherapies often fail to provide long-term control of cancers because neoplasms are able to evade immune-mediated attack through several mechanisms. These include: (1) preferential proliferation of T regulatory cells (Tregs), which leads to decreased acute inflammation, (2) increased intratumoral levels of immunosuppressive cytokines, such as interleukin (IL)-6, TGF-beta, and IL-10, (3) increased expression of immune checkpoint modulators that serve to limit the inflammatory response, and (4) poor trafficking of immune effector cells to the tumor itself.[24-26] Gajewski et al have described two distinct tumor phenotypes as a model to conceptualize these different mechanisms of resistance to immune-mediated destruction: a "noninflamed phenotype" in which tumors have low levels of chemokine production and lymphocyte infiltration (and therefore might benefit from therapies designed to increase lymphocyte traf-

ficking to tumors, such as tumor vaccination); and an "inflamed phenotype" in which tumors have rich chemokine levels and variable T-cell infiltration, but also contain increased levels of immunosuppressive Tregs and immune checkpoint modulators (and therefore might benefit from therapies designed to inhibit Tregs or immune checkpoint molecules).[26]

Although there is evidence that immunotherapy can be an effective therapeutic modality for mRCC, further efforts are needed to take full advantage of this approach for both tumors that display the inflamed phenotype and tumors that have the noninflamed phenotype. Novel immunotherapy strategies, including immune checkpoint inhibitors, suppressors of Tregs, T-cell agonists, and tumor vaccines, and combinations of these various modalities with FDA-approved therapies, have produced interesting preliminary data in ongoing clinical trials.

NOVEL IMMUNOTHERAPY FOR MRCC: A BRIEF SUMMARY OF THE ROLE OF IMMUNE CHECKPOINT INHIBITION

Interactions between molecules on the surfaces of T cells and antigen-presenting cells at the immune checkpoint can lead to the induction of immune tolerance. The most clinically relevant of these interactions are those between cytotoxic T lymphocyte associated protein-4 (CTLA-4) on T cells and its ligands B7-1 and B7-2 on antigen-presenting cells, and those between PD-1 on T cells and its main ligand PD-L1 on

antigen-presenting cells or tumor cells. It has been noted that mRCC tumor cells themselves can also express PD-L1 and thereby activate the immunoregulatory function of the PD-1/PD-L1 interaction to create an immunosuppressive tumor microenvironment.[27] Monoclonal antibodies that inhibit the negative immune regulators present in inflamed tumors lead to upregulation of antitumor immune function and have demonstrated potent effects in both laboratory and clinical studies of various malignancies, including mRCC.[28-39]

Nivolumab, a fully human monoclonal IgG4 antibody specific for human PD-1, demonstrated an objective response rate of 29% in a phase I trial and 21% in a phase II clinical trial of patients with mRCC who had failed standard therapy.[40-42] Blockade of PD-L1, the primary ligand for PD-1, with MPDL3280A yielded an overall response rate of 15% in a phase I cohort of patients with mRCC.[43-44] Additionally, a substantial number of patients in these early clinical trials experienced stable disease for longer than 24 weeks. Whether this level of antitumor activity will translate into prolonged overall survival remains the crucial question for phase III trials. A randomized trial of nivolumab versus everolimus (known as CheckMate 025) completed enrollment in February 2014, with results forthcoming.[45]

The antitumor activity produced by these agents indicates that the majority of patients with metastatic RCC will not experience durable improvement with PD-1/PD-L1 blockade as monotherapy, particularly once the treatment is stopped. Ongoing investigation will focus on improving antitumor activity, particularly in noninflamed tumors, by combining PD-1/PD-L1 blockade with other immunomodulatory agents.

FUTURE DIRECTIONS OF IMMUNOTHERAPY IN MRCC
Combinations of PD-1/PD-L1 Blockade and Other Immune Checkpoint Inhibitors or Angiogenesis Inhibitors

Combinations of PD-1/PD-L1 blockade and either angiogenesis inhibitors or other immune checkpoint inhibitors

may lead to improved antitumor effects compared to inhibition of either pathway alone.[46-52] Preliminary results of phase I clinical trials of these combinations have demonstrated encouraging response rates (e.g., 43 to 48% with nivolumab/ipilimumab and 52% with nivolumab/sunitinib) at the expense of markedly increased rates of toxicity.[53-54] Several other phase I trials of different combinations are currently under investigation (Table 1).[55-64] Randomized phase III studies will be necessary to better define the optimal combination of these agents and their proper sequence in relation to standard approaches.[65]

T-Cell Agonists

Therapies that increase T-cell activity, including IL-2, CD137 agonist antibodies, and interleukin-21 (IL-21), may improve the effectiveness of immune checkpoint inhibitors.[66] CD137 (also known as 4–1BB), which serves as a costimulatory molecule for T cells and leads to increased cytokine production, effector cytolytic activity, and T-cell survival, has been demonstrated to eradicate mRCC in murine models.[67-73] A phase IB clinical trial of a CD137 agonist monoclonal antibody (PF-05082566) in combination with anti–PD-1 therapy in humans with advanced solid malignancies is currently ongoing.[74]

The cytokine IL-21 is produced by activated $CD4^+$ T helper cells and has been demonstrated to increase the density of $CD8^+$ T cells in murine models of both melanoma and mRCC and lead to antitumor responses against these malignancies when administered to mice.[75-76] A phase I clinical trial of intravenous recombinant IL-21 in metastatic RCC demonstrated partial responses in 4 of 19 patients, with a tolerable toxicity profile.[77] Although a subsequent phase I trial of recombinant IL-21 in combination with sunitinib demonstrated dose-limiting hematologic toxicities,[78] a phase I/II trial of IL-21 and sorafenib revealed an acceptable toxicity profile with a response rate of 21%.[79] A trial of IL-21 and PD-1 blockade might therefore be a rational combination to test in mRCC.

Elimination of Tregs

Tregs are a subpopulation of $CD4^+CD25^+FOXP3^+$ T cells that serve an immunosuppressive function.[80-82] Therapeutic agents that deplete or eliminate Tregs, such as monoclonal antibodies against chemokine receptor 4 (CCR4) or CD25, or the cytokine–toxin conjugate denileukin diftitox, could therefore augment the immune response to malignancies.

CCR4 is expressed selectively on Tregs among immune cells, and also on some tumor cells themselves. In preclinical studies, blockade of CCR4 with monoclonal antibodies decreased the level of Tregs and induced T-cell responses specific to human tumor antigens.[83-86] Metastatic human RCC cells have increased proportions of both $CD25^+$ Treg cells and $CCR4^+$ T cells relative to primary neoplastic cells in the kidney,[87] suggesting that selective depletion of CCR4 may lead to regression of metastatic lesions in mRCC. Denileukin diftitox[88] and the anti-CD25 monoclonal antibody daclizumab[89] have been shown to augment the effect of tumor an-

TABLE 1. Ongoing Trials of Combinations of PD-1/PD-L1 Inhibition and Angiogenesis or Other Immune Checkpoint Inhibitors in mRCC

PD-1/PD-L1 Inhibitor	Second Agent (Mechanism)	Phase	Estimated Enrollment	ClinicalTrials.gov Identifier
Nivolumab	BMS-986016 (anti-LAG-3)	I	168	NCT01968109
Pembrolizumab	Pazopanib (angiogenesis inhibitor)	I	228	NCT02014636
Pembrolizumab	Axitinib (angiogenesis inhibitior)	I	60	NCT02133742

MEDI4736	Tremelimumab (anti-CTLA4)	I	102**	NCT01975831
MEDI4736	MEDI0680 (anti-PD-L1)	I	150**	NCT02118337
MPDL3280A	Bevacizumab (angiogenesis inhibitor), sunitinib (angiogenesis inhibitor)	II	300	NCT01984242
Nivolumab	Ipilimumab (anti-CTLA4)	III	1,070	NCT02231749

Abbreviations: PD-1, programmed death; PD-L1, programmed death ligand-1; mRCC, metastatic renal cell carcinoma; CTLA4, cytotoxic T lymphocyte associated protein-4.
*This study will enroll patients with both mRCC and metastatic melanoma.
**This study will enroll patients with various advanced solid malignancies (not solely mRCC).

tigen vaccination in a variety of solid malignancies, including breast cancer and mRCC. Further efforts to eliminate or inhibit Tregs may enhance the efficacy of immunotherapeutic strategies for mRCC.

mRCC Tumor Vaccines

Interest in vaccine therapies for the treatment of various malignancies has increased following FDA approval of the dendritic cell vaccine sipuleucel-T for metastatic castration-resistant prostate cancer.[90] In the specific context of mRCC, tumor vaccines may be of particular use in the noninflamed phenotype, as vaccination might be able to initiate a tumor-targeted immune response that would increase the initial trafficking of T cells to tumors.[26]

Several vaccines have been developed for clinical investigation of mRCC, including some targeted against peptide antigens (IMA901, TG-4010, and MVA-5T4)[91-96] and some developed from autologous dendritic cells (AGS-003). Of these, IMA901 and AGS-003 are currently in late-stage clinical trials.

Phase I and II studies of the multipeptide mRCC vaccine IMA901 have demonstrated encouraging overall survival in the subset of patients who also received a single dose of cyclophosphamide in addition to the vaccine.[97-98] A randomized phase III study of IMA901, cyclophosphamide, and GM-CSF plus sunitinib versus sunitinib alone as first-line therapy for patients with metastatic RCC is currently ongoing.[99]

AGS-003 is a personalized, autologous dendritic cell vaccine that has been examined in phase II clinical trials in combination with sunitinib. Preliminary data indicate improved progression-free survival and overall survival when compared to historic controls of patients with unfavorable-risk mRCC.[100-102] A randomized phase III trial of AGS-003 plus standard therapy (sunitinib) for metastatic RCC is currently recruiting participants.[103]

Recently, multiregion whole-exome sequencing, chromosome aberration analysis, and ploidy profiling of primary and metastatic RCCs have demonstrated substantial levels of intratumoral genetic heterogeneity in this disease.[104] Future re-

search into mRCC vaccines will attempt to exploit this intratumoral heterogeneity by targeting the tumor neoantigens that arise from such genetic diversity. A study of such a personalized neoantigen cancer vaccine ("Neovax") is currently recruiting participants and should enter phase I clinical trials for RCC in 2015.[105-106]

Ongoing studies will also address the optimal combinations and sequence of mRCC vaccines, targeted immunotherapy, and small-molecular inhibitors in an effort to further improve immune responses.

IMPROVING PATIENT SELECTION: DEVELOPING BETTER PREDICTIVE MODELS

The determination of appropriate biomarkers to better predict which patients with mRCC will benefit most from immunotherapy is an active area of investigation. Multiple clinical trials have indicated that responses to immunotherapy with checkpoint inhibitors have been observed both in patients whose tumors express PD-L1 and in those without such expression.[107-108] There are several potential explanations for this discrepancy, including: (1) heterogeneous expression of PD-L1 across the primary tumor and metastatic sites in individual patients, (2) inconsistent definitions of the threshold PD-L1 immunohistochemical positivity (e.g., 1% vs. 5% staining), (3) immunosuppressive effects of PD-L1 expression by other cells in the tumor microenvironment (e.g., macrophages or myeloid-derived suppressor cells), and (4) the potential impact of PD-L2 expression on responsiveness to anti-PD-1/PD-L1 therapy.

Preclinical and clinical trials of agents targeting PD-1/PD-L1 have used cutoffs of PD-L1 immunohistochemical positivity ranging from 1 to 5% staining, resulting in differences in response rates depending on which definitions are employed.[54] Standardization of the appropriate cutoff for a positive test will be essential for future development of meaningful predictive models.

Furthermore, a recent small series has demonstrated discordant PD-L1 expression between primary RCC sites and

metastatic RCC sites in 15% (5 of 33) of patients, suggesting that differential PD-L1 expression profiles between primary and metastatic lesions may contribute to the heterogeneity of responsiveness to anti-PD-1/PD-L1 targeted therapies.[109] In the setting of such heterogeneous PD-L1 expression, it is likely that the most useful models for prediction of response to immunotherapy will integrate PD-L1 status with other clinical, pathologic, molecular, and cytogenetic variables. These may include PD-L2 status,[110] gene expression profiling,[111] and/or clinical characteristics such as the Memorial Sloan Kettering Cancer Center (MSKCC) risk score[96] or International Metastatic RCC Database Consortium (IDMC or Heng) criteria.[112] Development of comprehensive predictive models for immunotherapy in mRCC is currently an active area of investigation.

CONCLUSION

Novel immunotherapies have produced encouraging initial results in the treatment of metastatic RCC; however, these agents are unlikely to be effective as monotherapy in the majority of patients. At present, intensive clinical study is focused on devising combinations of therapies and developing more accurate predictive biomarker models in an effort to improve clinical outcomes.

New and Promising Strategies in the Management of Bladder Cancer

Andrea B. Apolo, MD, Nicholas J. Vogelzang, MD, and Dan Theodorescu, MD, PhD

OVERVIEW

Bladder cancer is a complex and aggressive disease for which treatment strategies have had limited success. Improvements in detection, treatment, and outcomes in bladder cancer will require the integration of multiple new approaches, including genomic profiling, immunotherapeutics, and large randomized clinical trials. New and promising strategies are being tested in all disease states, including nonmuscle-invasive bladder cancer (NMIBC), muscle-invasive bladder cancer (MIBC), and metastatic urothelial carcinoma (UC). Efforts are underway to develop better noninvasive urine biomarkers for use in primary or secondary detection of NMIBC, exploiting our genomic knowledge of mutations in genes such as *RAS, FGFR3, PIK3CA*, and *TP53* and methylation pathways alone or in combination. Recent data from a large, randomized phase III trial of adjuvant cisplatin-based chemotherapy add to our knowledge of the value of perioperative chemotherapy in patients with MIBC. Finally, bladder cancer is one of a growing list of tumor types that respond to immune checkpoint inhibition, opening the potential for new therapeutic strategies for treatment of this complex and aggressive disease.

Cancer is a genetic disease.[1] A cancer cell inherits or acquires mutations that enable it to grow efficiently, replicate indefinitely, support angiogenesis, avoid apoptosis, and in some cases, metastasize.[2] Molecular profiles obtained by host and tumor DNA sequencing, single nucleotide polymorphism, RNA, and protein microarrays, and methylation screens are helping to pinpoint which mutations drive the cancerous phenotype and which are merely passengers on the malignant journey. Notwithstanding the role of individual genes, aggregate molecular profiles provide patient- and tumor-specific information that details the biologic complexity of a particular cancer and can be exploited for its clinical implications, therapeutic insights, and diagnostic benefit.

DETECTION AND MONITORING OF BLADDER CANCER IN THE GENOMIC ERA

Although the treatment for UC has improved over the last several decades, diagnostic techniques have progressed more slowly. Cystoscopy is still considered the best method for diagnosing UC, but it is invasive, uncomfortable, and can only detect approximately 90% of lesions.[3] In addition, when a tumor is discovered and must be biopsied and/or removed, a second procedure is required, transurethral resection of the bladder tumor (TURBT), which requires general anesthesia. Last, the cost of cystoscopy, especially when used to monitor recurrence, is the major reason why per-patient expenses for

UC are among the highest for all cancers.[4] The major problem associated with NMIBC is that after initial TURBT, 50% to 70% of patients develop multiple recurrences; 10% to 20% of these will progress to MIBC.[5] This risk of recurrence and progression calls for life-long surveillance. The current standard procedure is to perform cystoscopy and evaluate urine cytology every 3 to 4 months in the first 2 years, twice per year in years 3 to 4, and yearly thereafter.[5]

The burden of this follow-up on the patient, as well as the direct and indirect costs for the patient and society in terms of lost wages, have led to extensive efforts to develop noninvasive urine biomarkers for UC. However, to date, none have demonstrated sufficient specificity and sensitivity to monitor the general population or replace cystoscopy and cytology in monitoring for recurrence.[6] Urine cytology is particularly insensitive for detecting low-grade tumors. However, advances in genomics have clearly demonstrated that DNA alterations offer great promise for detecting primary or secondary bladder cancer.

NMIBC and MIBC are genetically different.[7-10] NMIBC is characterized by a high frequency of mutations in the *FGFR3* oncogene, leading to constitutive activation of the RAS/ MAPK pathway. In MIBC, mutations in the *TP53* gene prevail. In general, mutations in *FGFR3* and *TP53* are mutually exclusive, suggesting that NMIBC and MIBC develop along different oncogenetic pathways. However, these mutations often occur simultaneously in stage pT1 tumors that invade the connective tissue layer underlying the urothelium. Re-

cently, somatic mutations in the *PIK3CA* oncogene, which encodes the catalytic subunit p110α of class-IA PI3 kinase, were described in 13% to 27% of bladder tumors.[11] These mutations often coincided with *FGFR3* mutations. Mutations in the *RAS* oncogenes (*HRAS*, *KRAS*, and *NRAS*) have also been found in 13% of bladder tumors and in all stages and grades; they are mutually exclusive with *FGFR3* mutations. Given these findings, analyzing urine sediment for genetic mutations may be a promising strategy for noninvasive detection of bladder cancer.

FGFR3

FGFR3 mutations occur in around 50% of both lower and upper urinary tract tumors, clustering in three distinct hotspots in exons 7, 10, and 15.[12] The most common mutations in exon 7 and 10 favor ligand-independent dimerization, transactivation, and signaling.[13-17] Mutations in exon 15 are rare and induce a conformational change in the kinase domain, resulting in ligand-independent receptor activation and signaling, as well as *FGFR3* cellular localization, with aberrant endoplasmic reticulum signaling.[18] *FGFR3* mutations are thought to occur early during urothelial transformation, as they are reported in over 80% of preneoplastic lesions,[13,14] pointing to an overall "benign" effect of *FGFR3* mutation in the bladder.[17,19] *FGFR3*-mutant tumors are more chromosomally stable than their wild-type counterparts. A mutually exclusive relationship between *FGFR3* mutation and overrepresentation of 8q was observed in NMIBC.[20] A recent study found that around 80% of NMIBC and 54% of MIBC have dysregulated *FGFR3* with discordant mutation and protein expression patterns, suggesting a key role for *FGFR3* in both NMIBC and MIBC, either through mutation, overexpression, or both.[21] These discrepancies may reflect differential downstream signaling of wild-type and mutant receptors or the different molecular pathways instigating the development of these tumors. The mechanisms driving *FGFR3* overexpression in UC are largely unknown, although a recent study demonstrated the regulation of *FGFR3* expression in urothelial cells by two microRNAs (miR-99a/100) that are often downregulated in UC, particularly in low-grade and low-stage tumors.[22]

FGFR3 mutations were among the first to be used as urine biomarkers of recurrent disease, especially low-grade disease, which is challenging to detect by urine cytology. van Rhijn et al[23] reported that combined microsatellite and *FGFR3* mutation analysis could detect UC in voided urine. *FGFR3* mutations were found in 44% of urothelial tumors (59 tumors), but were absent in 15 G3 tumors. The sensitivity of microsatellites to detect cancer in voided urine was lower for tumors harboring *FGFR3* mutations (15 out of 21 tumors; 71%) than for *FGFR3* wild-type UC (29 out of 32 tumors; 91%). By including the *FGFR3* mutation, the sensitivity of molecular cytology increased from 71% to 89% and was superior to the sensitivity of morphologic cytology (25%) for every clinical subdivision. These findings highlighted the potential of molecular biology as an adjunct to cystoscopy and cytology in informing follow-up care.

HRAS

The *HRAS* gene, which codes for p21 Ras (or Ras), a small GTPase, was the first identified human oncogene. It was found in the T24/EJ urothelial cell line.[24-26] In the normal urothelium, normal Ras protein diminishes with differentiation, with highest expression in the basal (progenitor) cells.[27] The role of Ras in UC is supported by its ability to transform Simian vacuolating virus 40 (SV40)-immortalized human urothelial cells into invasive transitional-cell carcinomas.[28,29] In addition, in elegant transgenic studies, Ras overexpression has been shown to lead to NMIBC.[30] Ras interacts with Raf, a serine/threonine kinase, which is activated in tumor cells containing enhanced growth signaling pathways in both NMIBC, MIBC, and metastatic disease with subsequent activation of MAPK.[31,32]

P53

The p53 tumor suppressor encoded by the *TP53* gene located on chromosome 17p13.1[33] inhibits phase-specific cell cycle progression (G1-S) through transcriptional activation of p21$^{WAF1/CIP1}$.[34] Most UCs exhibit loss of a single 17p allele. Additional mutations in the remaining allele can inactivate *TP53*, leading to increased nuclear accumulation of the mutant protein, which has a longer half-life than its wild-type counterpart.[35] *TP53* deletion was correlated with grade and stage of UC.[36-41] Invasive carcinoma can also progress from recurrent papillary carcinoma by acquiring additional alterations in *TP53*, *RB1*, *PTEN*, *EGFRs*, *CCND1*, *MDM2*, or *E2F*.[42] In addition, oncogenic HRas has been shown to promote the malignant potency of UC cells that have acquired

deficiencies of *TP53*, *RB1*, and *PTEN*.[42] Mutations in the *TP53* gene that result in a truncated protein (or no protein), homozygous deletion of both alleles of the gene, or gene silencing by methylation of the promoters of both alleles cannot be detected by nuclear accumulation of p53 protein,[43,44] thus limiting the sensitivity of immunohistochemistry (IHC) for p53 alterations. Notwithstanding this caveat, overexpression of nuclear p53 protein by IHC has been used as a surrogate marker for detection of mutant p53 in clinical specimens. The expression of p53 has been associated with increased risk of progression of NMIBC or mortality in patients with MIBC, independent of tumor grade, stage, and lymph node status.[33,34,45-56] Interestingly, in a recently reported randomized, prospective trial, this was not borne out in patients treated with cystectomy.[57] In this and other studies, discordance in the identification of p53 as an independent prognostic marker for UC progression, recurrence, mortality, and response to therapy may be a result of patients' genetic and epigenetic status, cohort selection, and technical and statistical variations.[41,58-60]

COMBINING GENOMIC ASSAYS

To develop more sensitive and specific assays, recent studies have simultaneously evaluated *RAS, FGFR3,* and *PIK3CA* in UC.[61] A study of 257 patients with primary bladder tumors found that 64% (164 out of 257) of tumors contained an *FGFR3* mutation, 11% (28) samples were mutant for one of the *RAS* genes, and 24% (61) harbored a *PIK3CA* mutation.[61] Of the 257 primary tumors, 26% overexpressed p53, which is indicative of missense mutations, as noted above. When *RAS, FGFR3,* and *PIK3CA* mutations were calculated with *TP53* mutations, only 27 tumors (11%) were wild-type for all examined genes. In 54 patients who developed one or more recurrences, tissue was available from 184 recurrent tumors, including multifocal recurrences. Using the SNaPshot-based mutation assay, investigators examined these tumors for *FGFR3, PIK3CA,* and *RAS* mutations. The frequency of p53 overexpression was low (6 out of 54) in the primary tumors of this group of patients, consisting mainly of NMIBC tumors. In patients with a wild-type primary tumor, recurrences were mostly wild-type (49 out of 54), whereas five harbored an *FGFR3* mutation. One recurrent tumor contained two different *PIK3CA* mutations. In recurrences, *PIK3CA* mutations in addition to an *FGFR3* mutation were associated with higher-grade tumors compared with recurrences harboring an *FGFR3* mutation alone. Importantly, there was 100% consistency in the type of mutation for *RAS* and *PIK3CA* among different tumors in the same patient.

Investigators also developed a methylation assay for specific detection of recurrent NMIBC in voided urine.[62] Microsatellite analysis was also used to detect loss of heterozygosity in voided urine samples.[23] Mutation analysis of *FGFR3, PIK3CA, HRAS, KRAS,* and *NRAS* was recently combined with methylation-specific assays to determine whether this combination outperformed either examination alone.[63] Results were compared with those of urine cytology in a large, retrospective, longitudinal co-

hort that was part of the European FP7 UROMOL project. A total of 716 voided urine samples from 136 patients with NMIBC (Ta/T1, G1/2) were collected at TURBT. Patients with a history of carcinoma in situ were excluded from the analysis. Urine was collected at regular follow-up visits immediately before cystoscopy. During follow-up, 552 histologically proven recurrences were detected, including mainly stage Ta (92%), G1/2 (82%), and solitary tumors (67%). Sensitivity for detecting a recurrent tumor varied between 66% and 68% for the molecular tests after patient stratification based on tumor DNA analysis. A combination of markers increased sensitivity, but decreased the number of patients eligible for a certain test combination. Combining urine cytology with *FGFR3* analysis without stratifying for *FGFR3* status of the incident tumor increased sensitivity from 56% to 76%.

This study highlights the challenge of molecular examination of urine using genomics, and the importance of including all available information (i.e., cytology). However, there is no doubt that next-generation exome sequencing of paired tumor and peripheral blood samples will uncover many more potential biomarkers that could be added to these panels to improve their performance. Such examination was first performed in 2011 in a small set of patients.[9] Initial findings from this cohort were examined in light of findings from an additional 88 patients with bladder cancer[10] and by the The Cancer Genome Atlas (TCGA) consortium.[64] From these contributions, several previously defined mutations were observed (in *TP53, RB1,* and *HRAS*), but novel mutations were also noted, the most common of which was in *UTX,* which was identified in 21% of tested individuals. Of note, most of the identified new mutations were related to chromatin remodeling, suggesting a potential new area for bladder cancer research. Mutations in chromatin remodeling genes are commonly found in several other cancer types, suggesting their fundamental contribution to carcinogenesis. Adding to this complexity is a recent study of 537 patients with locally advanced or metastatic UC of the bladder, 74 patients with nonbladder, and 55 patients with nonurothelial bladder cancers profiled using mutation analysis, in situ hybridization, and IHC assays.[65] Compared with nonbladder UC, bladder UC exhibited more frequent expression of abnormal protein (and increased amplification) in HER2, androgen receptor, serum protein acidic and rich in cysteine (SPARC), and topoisomerase 1. These findings suggest that bladder UC has higher levels of actionable biomarkers that may have clinical implications for treatment and diagnostic options.

NEOADJUVANT AND ADJUVANT CHEMOTHERAPY IN MUSCLE-INVASIVE BLADDER CANCER

Approximately 25% of patients with bladder cancer present with a tumor invading the muscle layer of the bladder wall (T2 to T4).[66] MIBC is associated with a high rate of recurrence and poor overall prognosis, despite aggressive local and systemic therapies. Radical cystectomy is the standard treatment for MIBC, but even with substantial improvements in surgical techniques, mortality remains high because of a high

rate of systemic failure. The 5-year mortality rate for patients with MIBC is about 50% to 70%.[67,68] MIBC behaves as a systemic disease, and therefore needs systemic therapy early in the disease process to eradicate micrometastases.[69]

Phase III clinical trials of neoadjuvant cisplatin-based chemotherapy have demonstrated a survival benefit in patients with MIBC,[67,70,71] mainly by pathologic down-staging of muscle-invasive tumors (stage T2 to T4a) to nonmuscle-invasive tumors (< T2).[67,72-74] In the randomized Southwest Oncology group 8710 trial, neoadjuvant methotrexate, vinblastine, doxorubicin, and cisplatin (MVAC) followed by cystectomy demonstrated a 77-month median survival compared with a 46-month median survival with cystectomy alone. In this study, the likelihood of long-term survival was over 85% at 5 years for patients who achieved pathologic down-staging to pT0 either by TURBT alone before cystectomy or by the addition of neoadjuvant MVAC chemotherapy. However, long-term survival was less than 40% at 5 years in patients with residual muscle-invasive tumors (> pT2) at the time of cystectomy in both treatment arms.[67] Patients who do not respond to neoadjuvant chemotherapy have a poor prognosis. However, no data demonstrate a survival benefit for additional chemotherapy in the adjuvant setting after three to four cycles of neoadjuvant cisplatin-based chemotherapy. Large clinical trials are currently in development in this setting.

Data for adjuvant chemotherapy[57,75-77] are less compelling than for neoadjuvant chemotherapy. However, some patients benefit from adjuvant chemotherapy, including those who received up-front radical cystectomy and have extensive tumor invasion of the bladder wall or lymph node involvement. European Organisation for Research and Treatment of Cancer (EORTC) 30994 was a phase III trial of adjuvant versus delayed chemotherapy after cystectomy for patients with pT3 to T4 or node-positive disease.[77] The study randomly assigned 298 patients to one of three adjuvant cisplatin-based chemotherapy regimens (MVAC, high-dose MVAC, or gemcitabine/cisplatin) or observation and chemotherapy at relapse. After a median follow-up of 7 years, 66 out of 141 patients (47%) in the adjuvant chemotherapy arm had died compared with 82 out of 143 (57%) in the observation arm. No significant improvement in overall survival was noted with adjuvant chemotherapy compared with observation (adjusted hazard ratio [HR] 0.78; 95% CI, 0.56 to 1.08; p = 0.13). However, adjuvant chemotherapy significantly prolonged progression-free survival compared with observation (HR 0.54; 95% CI, 0.4 to 0.73, p < 0.0001), with a 5-year progression-free survival rate of 47.6% (95% CI, 38.8 to 55.9) in the adjuvant chemotherapy arm and 31.8% (95% CI, 24.2 to 39.6) in the observation arm. Although this study did not meet its accrual goal of 644 patients and was terminated early, it is the largest randomized adjuvant trial to date. Although the study

was limited in power to show a significant improvement in overall survival with adjuvant chemotherapy, it is possible that some subgroups of patients might benefit from adjuvant chemotherapy. Cisplatin-based neoadjuvant chemotherapy remains the standard of care in MIBC. Table 1 summarizes neoadjuvant and adjuvant clinic trials in MIBC.

IMMUNE CHECKPOINT INHIBITION IN SOLID TUMORS

Immune checkpoint inhibition for cancer treatment is an area of growing research. Immune checkpoint pathways regulate T-cell activation to escape antitumor immunity. Immune checkpoint molecules involved in this mechanism include CTLA-4, programmed cell death 1 (PD-1) and its ligands PD-L1 and PD-L2, T-cell immunoglobulin mucin-3, and lymphocyte activation gene-3.[78] Ipilimumab, a monoclonal antibody targeting CTLA-4, a potent immune checkpoint molecule expressed on T cells, demonstrated a survival benefit in a phase III study of patients with metastatic melanoma.[79] PD-1 is an immune inhibitory receptor expressed on several immune-cell subsets, particularly cytotoxic T cells.[80] PD-1 interacts with PD-L1 (B7-H1, CD274), which is expressed on tumor cells and immune cells, including T cells.[81,82] Recent studies have demonstrated that upregulation of PD-L1 is an important mechanism of immune escape in NMIBC.[83-86] Overexpression of PD-L1 in UC correlates with high-grade disease and worse clinical outcome. Anti-PD-1 and anti-PD-L1 have an improved toxicity profile compared with historic data from anti-CTLA-4 clinical trials.[87,88] In September 2014, the U.S. Food and Drug Administration (FDA) granted accelerated approval of pembrolizumab for the treatment of unresectable or metastatic melanoma, and in December 2014 granted accelerated approval to nivolumab for unresectable or metastatic melanoma refractory to standard therapy.

TREATMENT OF METASTATIC BLADDER CANCER

The treatment options for metastatic UC are very limited; however, progress has been made in treating metastatic transitional carcinoma of the urothelial tract with combination chemotherapy. The median survival of 15 to 18 months with either MVAC or gemcitabine/cisplatin is substantially better than the 6 to 9 months with single-agent chemotherapy. In fact, 5% of patients have a complete, sometimes durable, remission.

CLINICAL STUDIES OF PD-1/PD-L1 INHIBITORS IN UROTHELIAL CARCINOMA

Two clinical trials of checkpoint inhibitors have reported preliminary efficacy in advanced/refractory metastatic UC. Remarkable efficacy and safety was seen in a phase I expansion cohort of 67 patients with heavily pretreated metastatic bladder cancer. Patients received 15 mg/kg of MPDL3280A, a human monoclonal antibody to PD-L1 containing an engineered Fc-domain, later revised to a flat dose of 1,200 mg intravenously every 3 weeks.[89] Response rates were reported by PD-L1 positivity status, defined as 5% or higher of tumor-infiltrating immune cells staining for PD-L1 by IHC.[1] In this study, 27% of tumors were IHC 2- or 3-positive, as defined by expression of PD-L1 on tumor-infiltrating immune cells. The overall response rate for all patients by Response Evaluation Criteria in Solid Tumors (RECIST) v1.1 was 26%, and was even more remarkable (43%) among patients with PD-L1$^+$ tumor-infiltrating cells. Even among patients whose tumor infiltrating immune cells were PD-L1$^-$, the response rate was 11% as measured by RECIST v1.1. The median time to first response was 42 days (range, 38 to 85 days). Based on these results, MPDL3280A received breakthrough designation by the FDA in June 2014.

A phase I trial of pembrolizumab/MK-3475, a PD-1 inhibitor, studied 33 patients with advanced UC expressing PD-L1 in at least 1% of tumor cells by IHC. Patients received 10 mg/kg of pembrolizumab every 2 weeks. A response was seen in 7 out of 29 (24%) evaluable patients, and 64% of patients experienced a decrease in target lesions.[90] With a median follow-up of 11 months, six patients have ongoing responses (median duration 16 to 40 weeks; median not reached).

Multiple PD-1/PDL-1 agents are currently being tested alone or in combination in advanced/refractory UC. Many more trials are in development in earlier disease states, testing agents such as MPDL3280A (NCT02302807) in the first-line setting in cisplatin-ineligible patients with metastatic bladder cancer, nivolumab in the maintenance setting after first-line cisplatin-based chemotherapy, and pembrolizumab in patients with NMIBC (NCT02324582).

Nonsurgical Management of Cervical Cancer: Locally Advanced, Recurrent, and Metastatic Disease, Survivorship, and Beyond

Helen J. Mackay, MD, Lari Wenzel, PhD, and Linda Mileshkin, MD

OVERVIEW

Despite the declining incidence of cervical cancer as a result of the introduction of screening programs, globally it remains a leading cause of cancer-related death in women. Outcomes for patients who are diagnosed with anything but early-stage disease remain poor. Here we examine emerging strategies to improve the treatment of locally advanced disease. We discuss emerging biologic data, which are informing our investigation of new therapeutic interventions in persistent, recurrent, and metastatic cervical cancer. We recognize the importance of interventions to improve quality of life and to prevent long-term sequelae in women undergoing treatment. Finally, and perhaps most importantly, we recognize the need for global collaboration and advocacy to improve the outcome for all women at risk of and diagnosed with this disease.
