Cervical cancer remains one of the leading causes of cancer-related morbidity and mortality worldwide and is the fourth leading cause of cancer death in women.[1] Human papillomavirus (HPV), particularly types 16 and 18, is associated with subsequent development of cervical cancer, with an increased risk also seen among smokers.[2] The incidence and mortality rates of cervical cancer are substantially higher in resource-poor regions of the world; the age standardized incidence of cervical cancer being 1.6 times higher in less developed countries. These regional discrepancies are attributable to reductions made in the incidence of cervical cancer in resource-rich countries with the introduction of widely accessed screening programs.[3] This decline is expected to continue as a result of the implementation and increased availability of vaccination against HPV.[4] These gains, however, remain challenging to replicate in resource-poor regions, which lack the infrastructure and funding to implement screening and vaccination programs, and where access to treatment remains an important problem. Within the United States, over 12,000 women will be diagnosed with cervical cancer in 2015 with approximately 4,000 women expected to die from their disease. Cervical cancer is disproportionately more common in women of African American or Hispanic ethnicity and in patients with limited access to health care.[3] Despite the advances in cervical cancer prevention and diagnosis, the outcome for patients diagnosed with later-stage and recurrent disease remains poor.

NONSURGICAL MANAGEMENT OF LOCALLY ADVANCED CERVICAL CANCER

The use of low-dose chemotherapy concurrent with pelvic radiation has been proven to improve survival, and became the established standard of care for locally advanced cervical cancer after the National Cancer Institute issued a clinical alert in 1999 about the benefit of chemoradiation compared with radiation alone as observed in five randomized clinical trials.[5] The Medical Research Council (MRC) individual patient data meta-analysis found that the addition of concurrent chemotherapy to radiation increased the 5-year overall survival (OS) rate by 6% (hazard ratio [HR], 0.81; 60% vs. 66%).[6] On the basis of the studies in this analysis, weekly cisplatin at a dose of 40 mg/m^2 during pelvic radiation has been adopted as the standard of care for the treatment of locally-advanced disease. However, the 5-year disease-free survival rate was only 58% in the chemoradiation group, which although superior to 50% with radiation alone, still leaves substantial room for improvement.

Identifying Patients Most at Risk of Recurrent Disease

The main prognostic factor for outcome in cervical cancer has traditionally been the International Federation of Gynecology and Obstetrics (FIGO) staging system, which is based on clinical examination alone. In those with FIGO stage 1B2 or higher, treatment with primary chemoradiation in the recommended approach.[7] In the meta-analysis, the additional benefit of chemotherapy was seen regardless of age, tumor histology, or grade. However, there appeared to be a lesser degree of benefit in higher staged tumors, with an absolute 5-year survival benefit of 10% for women with stages Ib to IIa cervical cancer, 7% for those with stage IIb, and 3% for women with stage III to IVa disease.[6]

In the meta-analysis, a benefit of adding chemotherapy was also seen regardless of nodal involvement, although it was only possible to look at this in five of the 18 included trials. However, Narayan et al and others have highlighted the important prognostic role of both nodal and uterine corpus involvement as detected by imaging, with MRI and PET now accepted modalities for noninvasively determining these features.[8-10] Nodal involvement has been documented to predict disease relapse in multiple studies, but is not part of the current FIGO staging system.[8,11-14] Uterine corpus invasion tends to be associated with tumors that grow endophytically rather than exophytically, and has also been shown to predict worse outcomes, in part because it predicts nodal metastasis (Fig. 1).[15-20] The relapse rate in those with PET-positive node disease has been reported to be approximately 50% after standard chemoradiation.[17,21,22] Some suggest that a follow-up fludeoxyglucose (FDG)-PET scan done 3 to 4 months postchemoradiation can predict patient outcome and may help to determine the intensity of follow-up needed.[23]

Optimizing Local Therapy

Although the development of distant disease after chemoradiation is the predominant cause of mortality, local relapse may also be a problem that causes substantial morbidity. Although the patterns of treatment failure have not been well described in all studies, in the meta-analysis, locoregional treatment failure was responsible for 35% of the failure events across trials.[6]

Standard radiation treatment involves 40 to 50.4 Gy of external beam radiation therapy (EBRT) delivered in fractions of 1.8 to 2 Gy to the pelvis. The upper border for treatment is usually L4-S1, unless an extended field is required to cover involved node disease. Parametrial or nodal boost may also

KEY POINTS

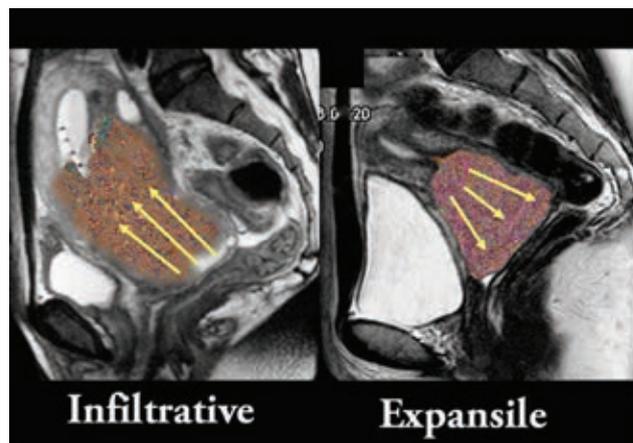
· Cervical cancer remains one of the leading causes of cancer-related morbidity and mortality in women worldwide.

· A number of ongoing clinical trials are examining the role of adjuvant chemotherapy in addition to the standard-of-care treatment, low-dose chemotherapy (cisplatin) concurrent with pelvic radiotherapy for locally advanced cervical cancer.

· Women undergoing treatment for locally advanced cervical cancer experience significant psychosocial distress. Multidisciplinary supportive care may reduce the magnitude of long-term sequelae and improve quality of life.

· Outcome for women diagnosed with metastatic or recurrent cervical cancer remains poor; there are a number of potential therapeutic targets actively under investigation. The first biologic agent, in combination with chemotherapy, to show a survival benefit was bevacizumab.

· International collaboration and engagement of medically underserved communities are essential to making progress in the treatment of cervical cancer.

FIGURE 1. Infiltrative versus Expansile Cervical Cancer


Infiltrative corpus invasive cervix cancer has higher local failure rates, increased frequency of nodal metastases at presentation, and poor survival compared with exophytic tumor of similar volume.

be given if these areas are involved. In addition to EBRT, brachytherapy direct to the primary tumor is considered to be an essential component of therapy. It is recommended that the overall treatment time for chemoradiation should not exceed 8 weeks. The role for intensity modulated radiation therapy (IMRT) is controversial and an area of active research because of the recognition that the cervix moves as a result of changes in bladder and bowel filling, and uterine movement.

There is also ongoing controversy about the best approach to delivery of brachytherapy. Traditionally, brachytherapy has been planned to give a recommended cumulative dose of 80 to 90 Gy EBRT and brachytherapy to "point A," which is an anatomic landmark 2 cm lateral to the central canal of the uterus and 2 cm up from the mucous membrane of the lateral fornix in the axis of the uterus.[24] There has also been increased interest in the value of using conformal brachytherapy, in which the dose is prescribed to the residual tumor volume at the end of EBRT rather than to point A. Proponents report that this approach may increase the effectiveness of local treatment and also reduce toxicity.[25] It is also recommended that image-guidance using either MRI or ultrasound is used to ensure that the tandem and ovoids used for the delivery of brachytherapy are correctly positioned within the uterus (Fig. 2).

A variety of approaches to intensifying the concurrent chemotherapy component of chemoradiation have been tested including the addition of cytotoxic agents. To date, no chemotherapy regimen has been found to be superior to 40 mg/m^2 (for most of the GOG studies, the does was capped at a maximum of 70 mg) of cisplatin weekly. However, the meta-analysis does suggest that substituting other agents that have demonstrated efficacy such as carboplatin or 5-flurouracil (5-FU) should be considered for women with a contraindication to cisplatin.[6] Addition of biologic agents to chemoradiotherapy is an active area of research. Despite suc-

FIGURE 2. Ultrasound and MRI Images for Delivery of Brachytherapy

cess in head and neck cancers, the combination of the epidermal growth factor receptor (EGFR) inhibitor cetuximab, cisplatin, and radiotherapy proved toxic in patients with cervical cancer.[26] RTOG 0417 investigated 10 mg/kg of intravenous bevacizumab every 2 weeks (for three doses only) in combination with chemoradiation in 47 patients.[27] Results were promising and the toxicity profile was acceptable with no perforations or fistulas observed; further investigation is warranted.[28]

Multidisciplinary care is essential during chemoradiation for cervical cancer. In addition to monitoring side effects such as diarrhea and nausea, given the nature of the disease and the patient demographic, financial and psychosocial concerns are common. Early involvement of social work and psychology may assist women to cope with these issues. Younger women may require referral to discuss options for fertility preservation and hormone-replacement therapy. Smoking cessation is highly encouraged as ongoing smoking during chemoradiation may reduce the effectiveness of treatment, as well as increase the risk for the development of a second malignancy.[29] Treatment of anemia may also be required and it is generally recommended that the hemoglobin is maintained at 10 g/dL or higher during treatment.[30] Erythropoietin during chemoradiation, however, is not recommended because of an increased risk of thromboembolic events.[31]

Adjuvant Chemotherapy

Although chemoradiation is effective treatment for the primary disease, relapsed disease most commonly develops as distant metastatic disease.[32] It is therefore reasonable to predict that the addition of further cycles of adjuvant chemotherapy following completion of chemoradiation may decrease the development of distant metastases and thus improve survival. GOG109 was a U.S. study that randomly assigned patients who had been initially treated with radical hysterectomy and pelvic lymphadenectomy, and subsequently found to have positive pelvic nodes and/or positive margins and/or microscopic parametrial involvement, to receive adjuvant radiation alone or adjuvant chemoradiation. The chemotherapy consisted of four cycles of cisplatin and 5-FU, given as two cycles concurrent with radiation and two

cycles post radiation. Progression-free survival (PFS) and OS rates were substantially improved for patients who received the additional chemotherapy. Although only 60% completed all planned chemotherapy, a higher number of chemotherapy courses was positively associated with improved survival rates.[33] This trial was one of two trials considered in a subset analysis of the MRC meta-analysis that considered the potential value of giving additional adjuvant chemotherapy. In this subset, there was an impressive absolute improvement of 19% in 5-year survival (from 60% to 79%) compared with radiation alone.[33,34]

More recently, Duenes-Gonzalez et al demonstrated a benefit of adding concurrent gemcitabine to the standard regimen of weekly cisplatin during radiation, followed by two further cycles of adjuvant cisplatin/gemcitabine. This multicenter, randomized, phase III trial showed a significant 9% improvement in the primary outcome of PFS at 3 years (65% to 74%; p = 0.029).[35] Toxicity, however, was a concern with two deaths in the experimental arm and a doubling of grade 3 to 4 adverse events (86.5% vs. 46.3%). In addition, prior investigators had been unable to safely deliver similar doses of drugs combined with radiotherapy in a North American population. Furthermore, it remains unclear how much of the benefit observed in this trial was a result of the additional chemotherapy given following the chemoradiation. Finally, follow-up data were truncated at 1 year, and as a result, an accurate measure of the effect on OS or rate of serious late complications cannot be properly assessed.[36]

Although not practice changing, these studies do raise important and unresolved questions regarding the potential value of adjuvant chemotherapy for women with locally advanced cervical cancer.

Current Clinical Trials

The Gynecologic Cancer InterGroup (GCIG) has an ongoing series of international, randomized, phase III trials aiming to test the effect of different chemotherapy strategies during chemoradiation on OS rates. The OUTBACK trial, led by the Australia New Zealand Gynaecological Oncology Group (ANZGOG) in collaboration with NRG Oncology, is testing the value of administering additional adjuvant chemotherapy after standard cisplatin-based chemoradiation compared with chemoradiation alone (ACTRN12610000732088). The primary aim is to determine if the addition of four cycles of adjuvant carboplatin and paclitaxel to standard cisplatin-based chemoradiation can improve OS.

The TACO trial, led by the Korean Gynecologic Oncology Group (KGOG) and Thai Cooperative Group, is comparing standard treatment with weekly cisplatin during chemoradiation to 3-weekly cisplatin (NCT01561586). This is based on a prior phase II trial from the KGOG, which suggested that the triweekly cisplatin maybe more effective and feasible to deliver.[37] It may also be an attractive regimen to use in low-resource countries because of the reduced number of chemotherapy treatments required.

Finally, INTERLACE, a trial led by the National Cancer Research Institute in the United Kingdom, is testing the value of

administering additional neoadjuvant chemotherapy before chemoradiation compared with chemoradiation alone (NCT01566240). Although a previous meta-analysis suggested no improvement in OS with neoadjuvant chemotherapy in locally advanced cervical cancer, there was a suggestion of improved outcomes in those trials with a shorter cycle length of 14 days or less or higher dose intensity of cisplatin.[38] The regimen being tested of six doses of weekly carboplatin and paclitaxel before standard chemoradiation has been shown to be feasible to deliver in a prior phase II study.[39]

QUALITY OF LIFE FOR PATIENTS WITH CERVICAL CANCER AFTER TREATMENT

Cervical cancer survivors often experience substantial quality of life (QOL) disruptions associated with the disease and treatment, many of which persist long into survivorship.[40-45] A recent analysis of health-related QOL data among U.S. cancer survivors indicates that cancer survivors are more likely to have poor physical and mental health–related QOL (25% and 10%, respectively > 1 standard deviation above the U.S. population mean) compared with adults with no cancer history (10% and 5%, respectively). Furthermore, cervical cancer survivors and short-survival cancer survivors report the worst mental health–related QOL.[46]

Persistent sequelae include pain, bladder and bowel dysfunction,[47-51] sexual dysfunction,[52-56] lymphedema, and menopausal symptoms,[57] as well as reproductive concerns among women of childbearing age.[45,58-62] Adverse psychologic consequences are shared with women diagnosed with other gynecologic tumors, and include depression and anxiety,[63] sleep disturbance, and concentration difficulties to a greater magnitude than many other populations of patients with cancer.[41,42,64-68] Despite challenges inherent in this cancer survivor population, supportive interventions may assist in substantially improving QOL, with potential to also improve stress-related biomarkers.[69] This could, in turn, improve disease outcomes.[70-72]

A recent study indicated that of patients with cervical cancer diagnosed 9 to 30 months earlier, patients who reported the worst QOL also reported more gynecologic problems and less social support.[73] Gynecologic problems were substantially worse in patients treated with radiation with or without chemotherapy compared with those treated with surgery only, with a moderate-to-large effect size which is both statistically significant and clinically relevant (FACT-Cx, p = 0.014; FACT-TOI, p = 0.006). Treatment with radiation with or without chemotherapy also contributed to substantially poorer QOL, higher perceived stress, and greater depression, with modest-to-moderate effect sizes. Further, patients with three or more comorbidities before cancer diagnosis have also been reported to have substantially worse QOL, higher perceived stress, more depression and anxiety, and lower social support. In identifying subpopulations who are likely to benefit from supportive care interventions, it appears that a brief screening of type and number of premorbid medical problems, including mood disorders, could target the patients who have the greatest need for more immediate care and attention, as well as future cancer control studies. Therefore, further study of supportive care interventions to improve distress and decrease gynecologic problems in this vulnerable population appear warranted, particularly for women whose cancer treatment extends beyond surgery.

A recent supportive care study examined the effect of a psychosocial telephone counseling (PTC) intervention on QOL domains and associations with biomarkers. In this randomized clinical trial, after adjusting for age and baseline scores, participants receiving PTC had significantly improved depression and improved gynecologic and cancer-specific concerns at 4 months compared with usual care participants (all p < 0.05); significant differences in gynecologic and cancer-specific concerns (p < 0.05) were sustained at 9 months. Participants with decreasing interleukins-4, -5, -10, and -13 had substantially greater improvement in QOL than patients with increasing cytokine levels. This trial confirms that PTC benefits mood, QOL regarding cancer-specific and gynecologic concerns, for a multiethnic underserved cancer survivor population. The improvement in patient-reported outcomes with decreases in T-helper type 2, and counter-regulatory cytokines support a potential bio-behavioral pathway relevant to cancer survivorship.[74] Providing supportive care during treatment, and evaluating the effects of supportive care, may reduce the prevalence and magnitude of long-term sequelae of cervical cancer, which will in turn improve QOL and quality of care.

TREATMENT OF METASTATIC OR RECURRENT CERVICAL CANCER

Patients with distant metastases and/or with recurrent disease not suitable for local control have a very poor prognosis, with 5-year survival rates between 5% and 15%.[75] In this setting, any treatment is palliative, aiming to prolong survival but also to maintain or improve QOL. Platinum-based combinations have shown the most promising response rates with the combination of cisplatin (or carboplatin) with paclitaxel considered the standard of care. Responses to platinum-based chemotherapy are short-lived; median OS is around 12 months[76] and can be less than 6 months for those women who have poor prognostic features.[77] Response to chemotherapy is influenced by site of recurrence in relation to previous treatment, with progressive disease within a previously irradiated field being particularly resistant to cytotoxic agents.[78] Receipt of prior platinum-based chemoradiation and a short time to relapse after primary treatment are also important negative prognostic factors. There are no effective second-line chemotherapy options for women whose disease progresses.

Targeting Angiogenesis

Persistent HPV infection leads to neovascularization and tumor growth promotion, with many studies having demon-

strated a prognostic role for vascular endothelial growth factor (VEGF) and other markers of increased angiogenesis in cervical cancer (Fig. 3).[79-89] Targeting angiogenesis has therefore emerged as a rational therapeutic strategy in the treatment of cervical cancer. Early phase clinical studies with the anti-VEGF antibody bevacizumab, either alone or in combination with chemotherapy, suggested promising activity. Toxicity was acceptable and responses seen even in previously irradiated sites of disease.[89-91] As a result, a four-arm prospective, randomized clinical trial, GOG 240, was conducted. Over 400 patients were randomly assigned to receive treatment with one of two chemotherapy regimens: cisplatin plus paclitaxel versus paclitaxel plus topotecan with or without bevacizumab. Although there was no difference in outcome noted between the two chemotherapy regimens, the addition of bevacizumab led to a significant improvement in median OS, 17 months compared with 13.3 months in the chemotherapy alone arms (HR 0.71; 98% CI, 0.54 to 0.95; p = 0.004). Response rates were also higher for bevacizumab-containing arms (48% vs. 36%; p = 0.008). The benefit from bevacizumab was maintained in women with prior platinum exposure, recurrent/persistent disease, and responses were seen in previously irradiated fields. Toxicity, however, was increased by the addition of bevacizumab with an increased risk of fistula formation in gastrointestinal and genitourinary tracts (10.9% vs. 1%), grade 2 hypertension (25% vs. 2%), neutropenia (35% vs. 26%), and thromboembolism (8% vs. 1%). As a result of this study bevacizumab received a U.S. Food and Drug Administration label for the treatment of cervical cancer in combination with chemotherapy. This has become a new standard of care for women with cervical cancer in resource-rich populations, but expense precludes its use in most parts of the world.[70] A better understanding of the risk factors for fistulae development and identification of predictive biomarkers for response would help us to further refine the use of this drug by identifying the subgroups of women who may derive benefit while minimizing toxicity risk.

Antiangiogenic agents targeting other parts of the pathway have also been investigated in cervical cancer. Single agent, orally administered, multitargeted receptor tyrosine kinases inhibitors pazopanib (VEGFR 1, 2, and 3; PDGFR-α and β; and c-KIT) and sunitinib (VEGFR 1, 2 and 3; PDGFR, c-KIT, and FLT3) were studied in phase II trials. Sunitinib did not display sufficient activity to warrant further investigation and was associated with an unacceptably high (26%) rate of fistula formation.[92] In the second, larger study, 230 patients were randomly assigned to one of three arms: pazopanib alone, lapatinib (a tyrosine kinase targeting EGFR and HER2/neu) alone, or a combination of the two agents. Pazopanib improved PFS (HR 0.66; 90% CI, 0.48 to 0.91; p = 0.013) and OS (HR 0.67; 90% CI, 0.46 to 0.99; p = 0.045) compared with lapatinib alone. Median OS was 50.7 weeks compared with 39.1 week for pazopanib and lapatinib, respectively. Pazopanib alone was well tolerated, but the combination of the two drugs lacked efficacy and was associated with more serious adverse events.[93]

Clearly, targeting angiogenesis in cervical cancer has benefits in terms of efficacy, but patient selection is key and consideration of maintenance of QOL essential when considering future investigation of this therapeutic approach.

TABLE 1. Agents Currently under Investigation for the Treatment of Recurrent, Persistent, and Metastatic Cervical Cancer

Target	Phase of Study	Agent(s)	Clinical Trials No.
Immunotherapy			
CTLA	II	Ipilumimab	NCT01693783
PD-1	II	Nivolomab	NCT02257528
TiLs		TiLs	NCT01585428
T-cell immunotherapy	HPV16 only	T cells	NCT02280811
Pathway-Targeted Therapy			
RAS/ERK/PI3K/AKT/MTOR	II	Trametanib (MEK inhibitor)/GSK2141795 (AKT inhibitor)	NCT01958112
PI3K	II	BKM120	NCT01613677
RTK/Angiogenesis	II	Pazopanib/topotecan	NCT02348398
RTK/Angiogenesis	II	Carboplatin/paclitaxel ± nintedanib or placebo followed by maintenance	NCT02009579
HPV-Related Therapy			
HPV 16 and 18-positive cancer	II	VGX-3100 (plasmids encoding E6 and E7 protein)/INO-9012 (plasmid encoding interleukin 2) delivered via electroporation	NCT01693783
Therapeutic vaccine	I-II	ADXS11-001 high dose (therapeutic vaccine)	NCT02164461
	I-II		
	HPV 16 only	ISA101 (HPV 16 E6/E7 long peptides vaccine) with or without interferon alpha with carboplatin paclitaxel	NCT02128126
Cytotoxic Agents	II	Albumin-bound paclitaxel/nedaplatin	NCT01667211
	II	Eribulin mesylate	NCT0167818
Other			
Chromosome Region 1 Maintenance Protein	II	Selinexor	NCT02025985

Abbreviations: TiLs, tumor-infiltrating lymphocytes; HPV, human papillomavirus.
Studies are single arm unless otherwise indicated.

Targeting the EGFR

EGFR is expressed at moderate to high levels in cervical carcinoma. However, activating mutations are rare and studies evaluating the association of EGFR protein expression and prognosis in cervical cancer have yielded conflicting results.[95-96] Trials investigating the monoclonal antibody cetuximab, either alone or in combination with chemotherapy, failed to demonstrate sufficient clinical activity to warrant further investigation and reports of increased toxicity in combination with chemotherapy are concerning.[97-99] Clinical studies with the EGFR tyrosine kinase inhibitors gefitinib, erlotinib, and lapatinib were also disappointing.[100,101]

Molecular Profiling and Potential Therapeutic Targets

Our understanding of cervical cancer biology has focused around the role of HPV infection in the development of this disease.[102] The HPV oncoproteins E5, E6, and E7 are the primary viral factors responsible for initiation and progression of cervical cancer, and act largely by overcoming negative growth regulation by host cell proteins, including downstream effects that increase angiogenesis (Fig. 3).

Recent emerging data, however, are helping us to understand more about the genomic profile of cervical cancer. These data are helping to identify potentially "drugable targets" and thus new therapeutic approaches for investigation.

Activating mutations and amplification of *PIK3CA* (the gene encoding phosphoinositol-3-kinase) have been reported for some time, occurring in 23% to 36% of cervical cancer cases. Reports of somatic mutations in other genes including *PTEN*, *TP53*, *STK11*, and *KRAS* were also reported.[103-105] A more comprehensive analysis was published in 2014, which included whole-exome sequencing. Previously unknown somatic mutations were identified in 79 primary squamous cell cervical carcinomas (SCC), including recurrent substitutions in *MAPK* and inactivating mutations in *HLA-A*, *-B* and *B2M*, suggesting a role for immune evasion in cervical cancer (Table 1). HPV integration appeared to be a common mechanism for gene overexpression, including *ERBB2*, which also appears to occur as a result of somatic mutation and amplification.[106] A further paper from Wright et al focused on the differences between adenocarcinoma, which account for 10% to 20% of cervical cancers but have a worse prognosis, and SCC.[107] Although *PIK3CA* mutations and *PTEN* loss were observed in both histologic subtypes, *KRAS* mutations were detected only in adenocarcinomas (17.5% vs. 0%), and *EGFR* mutations only in SCC (0% vs. 7.5%).[108]

The prevalence of mutations within the PI3K/AKT/mammalian target of rapamycin (mTOR) pathway, regardless of histologic subtype, make this an attractive therapeutic target in cervical cancer. An initial phase II study of the mTOR in-

hibitor temsirolimus for the treatment of women with metastatic or recurrent cervical cancer demonstrated limited activity.[109] However, further investigation of newer agents (such as PI3K inhibitors) alone or in combination are warranted, potentially in patient populations enriched for *PIK3CA* mutations. Other potential therapeutic directions include exploring MAPK1 inhibition or ERBB2 inhibition in patients with activating mutations and mitogen-activated protein kinase/extracellular signal-regulated kinase (MEK) inhibitors in patients with *KRAS* mutations (extrapolating from the experience in low-grade serous ovarian cancer).

Immunotherapy

There is a strong rationale for investigating immunotherapy in cervical cancer given the host/HPV-induced immune evasion, which leads to persistent infection and carcinogenesis. Regulatory T cells are known to modulate the maintenance of an immunologically tolerant environment to HPV-associated preinvasive and malignant lesions.[110,111] Furthermore, the presence of tumor-infiltrating lymphocytes (TiLs) in tumor specimens has been associated with improved outcomes.[112,113] Currently, investigation of immunomodulating agents and strategies which either enhance the innate immune response to cervical cancer or repress immune-protective pathways are a very active area of cervical cancer research (Table 1). Upregulation of cytotoxic T lymphocyte-associated molecule-4 (CTLA-4) receptor on T lymphocytes is a negative regulator of T-cell activation. Ipilimumab is a fully human immunoglobulin (IgG1 kappa) that blocks CTLA-4. CTLA-4 blockade results in the expansion of activated T-cell clones directed at tumor epitopes, theoretically increasing immunovigilance and eradication of tumor cells.[114-116] Ipilimumab has demonstrated substantial clinical activity in patients with metastatic melanoma and is currently being investigated in two clinical trials enrolling women with advanced cervical cancer with results expected soon. (GOG 9929/NCT01711515; NCT01693783). A second attractive immunomodulatory strategy under investigation utilizes antibodies directed against another coinhibitory pathway on activated T-cells, the inhibitory receptor programmed cell death 1 (PD-1) and its ligand PD-L1. It remains to be seen if this approach will yield results in cervical cancer.[117] The use of bacterial vectors directed against E7 has been shown to induce tumor regression in preclinical models, and a phase II trial conducted in India with a live-attenuated *Listeria* monocytogenes vaccine suggests that this approach may be successful with further studies ongoing (GOG 265/NCT01266460).[118] Finally, patients with cervical cancer are being included in adoptive immunotherapy programs exploring the potential of TiLs harvested from patient tumor samples and then reinfused after immunodepletion (NCT01266460).

Targeting DNA Repair

Repair of DNA damage occurring in cells is essential for their survival. Therefore, inhibition of DNA repair following radio-

therapy is a potentially interesting strategy in cervical cancer. Furthermore, there are reports that a subgroup of cervical cancers may have defective homologous recombination as a result of epigenetic modification of the Fanconi anemia (FA) complementation group F (*FANCF*).[119,120] As a result, investigation of the poly (adenosine diphosphate-ribose) polymerase (PARP) inhibitors, which block base excision repair of single stranded DNA breaks, in cervical cancer a potentially interesting idea.[121] Other proposed strategies inhibiting the repair of DNA damage include inhibition of ribonucleotide reductase (RNR)[122,123] and agents which abrogate the G2/M arrest induced by radiation or chemotherapy, such as the Wee1 inhibitor MK1774 (NCT01076400).[124]

CHALLENGES IN CERVICAL CANCER RESEARCH

The majority of women affected globally by cervical cancer are unlikely to have access to trials or be able to afford new biologic therapies. Conducting clinical trials in patients with cervical cancer in the developed world is becoming increasingly challenging. Ironically, the falling incidence of cervical cancer in the developed world not only results in fewer women who are eligible for clinical trials, but may also result in a lack of interest by pharmaceutical companies to explore new agents in this patient population, despite the major mortality the disease causes worldwide. International collaboration is increasingly required to complete studies in a timely fashion, which, despite efforts in harmonization by organizations such as the GCIG, continue to pose substantial logistical barriers between countries. Within the United States, the patient demographic makes trial enrollment challenging.[125] The participation of ethnic minorities and medically underserved populations in clinical trials is critical to making progress. However, multiple well-documented factors account for disproportionally low enrollment rates among minority patients in clinical trials.[126-128] These include patients and their families being unaware of clinical trials, a fear of being "treated like a guinea pig,"[129-131] and the presence of mistrust of medical research and researchers among certain ethnic groups including American Indian, Asian American, and African American communities.[126,132,133] Furthermore, patients with cancer who are immigrants, live in rural areas, have a poor socioeconomic status, and work frequently cite practical concerns, including issues with transportation, family responsibilities, and out-of-pocket expenses as factors that inhibit their ability to participate in research.[126,134,135] It is imperative that clinical researchers of cervical cancer acknowledge these issues and reach out to our most vulnerable patients to provide assistance in helping them to become aware of all of their treatment options.

Given the relatively small numbers of patients available to enroll in clinical trials, it is essential that studies are rationally designed and based on biologically sound hypotheses. To limit the administrative burden and maximize participation, creative trial design is essential. Trial designs such as multiarm (or umbrella) or rolling phase II studies are essential if we are to investigate multiple agents in a time- and resource-efficient manner. Incorporation of translational substudies and functional imag-

ing studies will allow us to gain the maximum information from each trial. Commonality with other HPV-induced malignancies, such as cancers of the oropharynx and anal canal, suggest there might be underdeveloped routes of collaboration. Patients with cervical cancer may be eligible for studies requiring the presence of specific mutational profiles which are not limited to a particular cancer type.[125]

FINAL REMARKS

Much progress is still needed in the treatment of cervical cancer. It is important that we remember that the majority of women affected globally by cervical cancer are unlikely to be able to access new biologic therapies or have access to clinical trials. If we are to achieve maximum benefit for women with this disease, we need to reach out and form partnerships that allow us to raise the standards for all women. Costs must be considered in the development of new agents so that our results may be globally relevant, and advocacy is essential. Data from randomized trials exploring the role of adjuvant chemotherapy are expected soon that may change our approach to the front-line management of women with locally-advanced cervical cancer. However, the key to ensuring truly improved quality of care for patients is to recognize and identify patients who require supportive interventions both during and following therapy.

Epithelial Ovarian Cancer in Older Women: Defining the Best Management Approach

Linda R. Duska, MD, William P. Tew, MD, and Kathleen N. Moore, MD

OVERVIEW

Epithelial ovarian cancer is a cancer of older women. In fact, almost half of women diagnosed with ovarian cancer will be older than age 64, and 25% will be older than age 74. Therefore, it is crucial to examine the available data in older populations to optimize the therapeutic approach without negatively affecting the quality of life permanently. Unfortunately, little prospective data are available in this under-represented population of women. Although ovarian cancer traditionally has been approached with aggressive cytoreductive surgery, older patients may benefit from a less aggressive surgical approach and, in some cases, may be candidates for neoadjuvant chemotherapy followed by an interval cytoreduction. Modalities do exist for assessing an older woman's ability to tolerate surgery and chemotherapy, and these tools should be familiar to clinicians who are caring for this population of women in making treatment decisions. Ongoing planned trials to evaluate pretreatment assessment for older patients will provide objective, feasible, clinical tools for applying our treatment-based knowledge. Future trials of both surgery and chemotherapy, including a focus on the sequence of these two treatment modalities, are crucial to guide decision making in this vulnerable population and to improve outcomes for all.

Close to half (45%) of women diagnosed with ovarian cancer will be older than age 64, and 25% will be older than age 74 (20.7%, age 65 to 74; 16.6%, age 75 to 84; and 8.1%, older than age 84).[1] The mean age at diagnosis of ovarian cancer is 63 years.[1,2] In addition, the percentage of older women with ovarian cancer is expected to increase in the coming decades as our population ages and life expectancy improves.[3,4] Unfortunately, as the age of the patients increases, cancer outcomes steadily worsen. One report showed age-standardized relative survival rates at 1 year of 57% for women age 65 to 69, 43% to 45% for those age 70 to 79, and 25% to 33% for those age 80 to 99.[5] There have been various theories put forward to account for the decreased survival in older women, including the following: (1) more aggressive tumor biology, including higher grade and more advanced stage, (2) inherent resistance to chemotherapy, (3) individual patient factors, such as multiple concurrent medical problems, functional decline, and malnutrition leading to greater anticipated treatment toxicity, and (4) physician and health care biases toward older adults that lead to inadequate surgery, and suboptimal chemotherapy.[6]

To improve the outcomes of older women with ovarian cancer, we need to develop better decision aids to discriminate those patients who will and will not tolerate standard cytoreductive surgery (CRS) and chemotherapy. Our trials cannot continue to focus exclusively on younger, fit women and the healthiest subsection of older women. In the South-west Oncology Group (SWOG) analysis of data on 16,396 patients enrolled in 164 trials during the 1990s, patients older than age 65 accounted for only 30% of all included patients.[7] Similarly, in a recent Surveillance, Epidemiology, and End Results (SEER) survey, only 9% of patients older than age 75 who had cancer were included in clinical trials of new therapies.[8] With a focus on improving under-represented populations, cooperative groups in the U.S. (Elderly Working Group in the NRG Gynecologic Oncology Group [GOG]) and Europe (Groupe d'Investigateurs Nationaux pour l'Etude des Cancers Ovariens, GINECO) are developing trials specific for older women with gynecologic cancer.

In this review, we will discuss currently available data regarding results of surgery and chemotherapy in the older woman with ovarian cancer as well as review geriatric assessment (GA) tools being developed to aid decision making regarding both surgical and chemotherapeutic interventions.

Ovarian Cancer Surgery in Older Women

The data for surgery in epithelial ovarian cancer (EOC), although retrospective, is clear: patients with advanced (stages III to IV disease) will experience an improved overall survival if they undergo an optimal CRS.[9,10] The meaning of optimal has changed over time, with an accepted current definition in the platinum era of less than 1 cm of residual disease.[11] Most recently, it has been suggested that no visible residual should be the goal of a cytoreductive surgery. The improved survival

associated with optimal CRS has been confirmed in recent prospective, randomized trials of chemotherapy.[12-14]

There remains, however, controversy regarding the role of neoadjuvant chemotherapy (NACT) followed by an interval cytoreduction (iCRS) as a primary strategy for the treatment of ovarian cancer. The aggressive surgical effort that is required for an optimal primary surgery may result in postoperative morbidity; the interval surgery associated with NACT may be less extensive and, therefore, better tolerated.[15] The idea that all patients, regardless of comorbidities, should be approached with a primary surgical effort has transformed into consideration of NACT with iCRS for those patients who may not tolerate an up-front maximal surgical effort.

Risk factors for postoperative morbidity after primary surgery for ovarian cancer have been identified. These include older age (older than age 75), poor performance status (PS), low serum albumin, the presence of ascites, and high preoperative CA 125.[16] Thus, age becomes an important factor in determining the best first therapy for women who present with advanced disease when surgery and the timing of surgery are being considered.

Older studies noted that older women with ovarian cancer have a worse prognosis than younger women and suggested that this worse prognosis may be due to a less aggressive surgical approach to the disease. The American Cancer Society analysis from Hightower et al,[17] for example, noted a significant reduction in survival for patients older than age 80 compared with their younger counterparts; this decrease was attributed to a less aggressive surgical approach.[17] The older women were more likely to see a general surgeon rather than a gynecologic oncologist for their surgery and also were more likely to have a suboptimal CRS performed. In addition, older patients in this series were less likely to receive adjuvant chemotherapy (42% vs. 69%, p < 0.0001). The finding that older women are less likely to have an aggressive surgical effort also has been confirmed by other series.[18-21] In part, this finding may be due to the observation that women older than age 70 are less likely to be seen by a gynecologic oncologist.[22]

More recent studies consist of a series of single tertiary institution findings, reported by gynecologic oncologists, that are retrospective in nature and consequently affected by selection bias. The majority of these studies suggest that older women tolerate aggressive surgical effort well, with a conse-

quent similar overall survival to their younger counterparts.[23-25] However, a select few have noted significant morbidity in the cohort of very older ages (greater than 80).[16,26,27] In particular, the report from Oklahoma noted a significant rate of death before hospital discharge and within 30 days of surgery in women older than age 80 who underwent primary cytoreduction.[26] Although the authors were able to achieve a 74% rate of optimal cytoreduction in this group of patients (defined in this study as less than 1 cm of disease remaining), postoperative complications were common. In addition, and perhaps more significant, 13% were unable to receive adjuvant chemotherapy and, of those who were treated, only 57% completed more than three cycles.

Population-based studies have confirmed age as an independent risk factor for surgical morbidity. In the SEER analysis reported by Thrall et al,[28] advancing age was associated with a significant increase in 30-day mortality. Among their sample of 5,475 patients, patients older than age 85 had five times the mortality risk as those age 65 to 69 (17.52% vs. 3.19%, respectively). When age was evaluated as a continuous variable, each year over age 65 was associated with a 7.5% increase in the risk of 30-day mortality. The authors performed further risk modeling, including stage and comorbidity, and found that women at the highest risk (more than 10%) for 30-day mortality after CRS were those older than age 75 with stage IV disease or those older than age 75 with stage III disease and a comorbidity score of +1.[28] Another study using data from the Nationwide Inpatient Sample registry of patients admitted for ovarian cancer surgery also found that perioperative complications increased with age.[29] Among the 28,651 patients included, those patients younger than age 50 had a 17.1% complication rate compared with rates of 29.7% in patients age 70 to 79 and 31.5% in patients older than age 80. Discharge to a facility also increased with age, from only 1.0% of patients younger than age 50 to 14.0% of patients age 70 to 79 and 33.3% of patients older than age 80. In the multivariate analysis, age, number of medical comorbidities, and number of radical procedures performed were the most important predictors of morbidity and mortality.

Finally, Wright et al[30] reported SEER data for women age 65 years or older, this time with the primary goal of assessing reception of adjuvant therapy after primary surgery.[30] In a multivariate model, older patients and those with comorbidities, mucinous tumors, and stage IV cancers were more likely to not receive chemotherapy after surgery, and age remained a predictor of delay of initiation of chemotherapy.[30] These studies are shown in Fig. 1.

Likely, age alone cannot suffice as a measure of postoperative surgical morbidity and mortality. Instead, a combination of factors should be used to identify a group of patients for whom an up-front surgery will not be of benefit. The ability to assess who is fit enough to undergo aggressive CRS followed by chemotherapy and who should be offered an alternative pathway, such as NACT and iCRS or primary chemotherapy alone, is an unmet need. In the study from Aletti et al,[16] when tumor distribution, age, and nutritional status were combined, the authors were able to identify a subgroup

KEY POINTS

- Almost half of women with ovarian cancer are older than age 64 years, and 25% are older than 74 years.
- Older patients may benefit from a less aggressive surgical approach and, in appropriate cases, may be candidates for neoadjuvant chemotherapy.
- Validated modalities exist for assessing an older woman's ability to tolerate surgery and chemotherapy, and these tools should be utilized when caring for this population in making treatment decisions.

FIGURE 1. Risks of Cytoreductive Surgery in Advanced Ovarian Cancer Increase with Age

Complication	Younger than Age 50	Age 50 to 59	Age 60 to 69	Age 70 to 79	Age 80 and Older
30-Day Postoperative Mortality[28]			4.6%*	Age 70-74: 5.4% Age 70-79: 9%	Age 80-84: 12% Age 85+: 21%
Postoperative Morbidity[29]	17.1%	20.2%	25.5%	29.7%	31.5%

* Data for age > 65.

of patients for whom the benefits of an aggressive up-front surgery did not outweigh the risks.[16] In addition, in this group of patients, aggressive surgery did not result in improved overall survival.

Further prospective study is warranted to identify those women for whom primary CRS is not indicated. If we use a generalized preoperative assessment for all patients, we may exclude many who might benefit from aggressive primary CRS. However, by not validating a preoperative tool in this vulnerable population, we risk excess morbidity and mortality in those patients with too little reserve to tolerate primary CRS followed by chemotherapy.

OVARIAN CANCER CHEMOTHERAPY IN OLDER WOMEN
Timing of Chemotherapy: NACT

NACT is the delivery of chemotherapy before a CRS. NACT use is gaining popularity in both the United States and Europe, particularly for older and frail patients. By shrinking cancer before surgery, several reports suggest that NACT increases the chance of an optimal CRS (defined as no gross residual disease postsurgery) with less surgical morbidity and no significant effect on survival.[31,32]

The only published prospective, randomized study of NACT versus primary CRS followed by adjuvant chemotherapy is study 55971 from the European Organization for Research and Treatment of Cancer (EORTC).[31] The 632 patients with newly diagnosed stage IIIC or IV EOC were randomly assigned to either primary CRS followed by six cycles of platinum-based chemotherapy or to three cycles of NACT platinum-based followed by an iCRS followed by an additional three cycles of platinum-based chemotherapy. The two cohorts had similar baseline characteristics (age, PS, histology type, grade, and stage). The median ages were 62 (range, ages 25 to 86) in the primary surgery group and 63 (range, ages 33 to 81) in the NACT group. No subgroup analysis was reported based on older age.

NACT was not inferior to primary surgery; the median overall survival times were 29 months in the primary debulking group and 30 months in those assigned to NACT. Although outcomes were equivalent, the median survival in each arm was relatively short, which suggests that the trial may have selected for a poor prognostic group of patients. The authors found that one of the main predictors of survival was no gross residual disease, so the question of NACT versus primary CRS remains controversial as it pertains to those patients for whom no gross residual disease is a reasonable expectation.

The CHORUS trial is another randomized, phase III trial with identical eligibility criteria to that of EORTC 55971.[33] This study has only been reported in abstract form, but the primary endpoint of overall survival was not statistically different, at 22.8 versus 24.5 months for the pCRS and iCRS groups, respectively. These two studies were meant to be evaluated together; with combined data for this selected population, the overall estimate of the hazard ratio (HR) was 0.93 (95% CI, 0.81 to 1.06).

Several things are notable about these studies compared with the GOG studies, not specific to older women, that were described previously.[34] First, the median age of the patients enrolled in EORTC 55971 and CHORUS were almost a decade older than those patients enrolled in the GOG studies. On the EORTC and CHORUS studies, 20% to 32% of patients had a PS of 2 to 3 compared with 8.5% of patients on the prior GOG studies, and approximately 25% of patients on the EORTC and CHORUS studies had stage IV disease compared with none in the prior GOG studies cited, which makes this a highly selected, poor-prognosis group of patients (Fig. 2).[33,34]

Older women, particularly those with high comorbidities and frailty, are at the highest risk of surgical morbidity and may be the most appropriate candidates for NACT. Although each patient plan must be individualized, these criteria are reasonable to use as guidelines for an NACT approach.

Timing of Chemotherapy: After Primary Surgery

EOC is one of the most chemotherapy-sensitive diseases, with high initial response rates. The standard of care has evolved into taxane and platinum-based regimens that vary in schedule and route of administration. However, the studies that established these standards of care contained few older patients (here defined as age 70 or older), and the vast majority of those included would have been the most fit and had a high PS. For example, in GOG 158, which established paclitaxel and carboplatin as a standard of care, and GOG 172, which established intraperitoneal cisplatin and paclitaxel-based therapy as a standard for patients after optimal cytoreduction, only 12% of patients enrolled were older than age 70.[13,35] Similarly, both GOG 218 and ICON 7, which evaluated the addition of bevacizumab to every-21-day paclitaxel and carboplatin, enrolled 23% and 10%, respectively, older than age 70.[36,37] GOG 182, one of the largest randomized trials in EOC completed, with more than 4,000 enrolled patients, included 23% who were older than age 70.[14] Although no subset analyses were done in the older population of patients in these trials, a post hoc analysis of the 620 patients age 70 or older enrolled in GOG 182 found that this group had a poorer PS, lower chemotherapy completion rates, increased toxicities (neuropathy and cytopenias) and an 8-month shorter overall survival after adjusting for other prognostic factors.[38]

These adverse outcomes, among highly selected older patients who were deemed fit enough to enroll in a prospective clinical trial, are significant and reflect the difficulty in assessing reserve for treatment in an older population. The uncertainty surrounding how much an older woman can tolerate, combined with competing comorbid and social conditions may explain the low percentage of older women receiving standard of care chemotherapy for ovarian cancer. In one SEER review of the use of chemotherapy in advanced EOC, the odds of chemotherapy being administered dropped with age compared with the reference group of ages 65 to 69.[39] For example, women age 75 to 79 had a odds ratio (OR) of 0.65, women age 80 to 84 had an OR of 0.24, and women age 85 and older had an OR of 0.12.[39] A second SEER analysis found that the women at greatest risk of incomplete chemotherapy (either not given or received an incomplete course) were those older than age 76 (OR, 1.64) and/or two or more medical comorbidities.[40]

Designated clinical trials for older women and PS–challenged women have been completed outside the United States. The first designated trial for this population (GOG 273) was completed in the United States and presented in abstract form in 2014, giving us useful guidelines on the selection of the best therapies for these patients.[41]

Front-line chemotherapy options. Because of concerns related to excess toxicity among older women, investigations have focused on improving tolerance while maintaining efficacy. There are three main foci of investigation: (1) initial dose modifications, (2) variations in scheduling, and (3) timing (neoadjuvant vs. primary chemotherapy). NACT is addressed above and will not be readdressed in this section.

Initial dose modification. In 1997, the GINECO group in France launched a dedicated older women ovarian cancer (EWOC) program. Between 1998 and 2003, two prospective studies were conducted to assess the tolerability of the current standard platinum-based chemotherapy regimens. Both studies enrolled women age 70 or older, with liberal inclusion

criteria, and a baseline GA was performed. In the first study (EWOC 1), 83 patients (median age, 76) with stage III/IV EOC received carboplatin (area under the curve [AUC] 5) and cyclophosphamide (600 mg/m^2) in combination (i.e., CC) on day one every 28 days for six cycles. The rate of the completion of all six cycles of the CC regimen was 72%, with minimal toxicities.[42] Moreover, GA predicted toxicity and overall survival. In the multivariate analysis, three factors appeared to have a prognostic value of toxicity: symptoms of depression at baseline (p = 0.006), dependence (p = 0.048), and PS of 2 or greater (p = 0.026). Independent prognostic factors identified for overall survival (Cox model) were depression (p = 0.003), International Federation of Gynecology and Obstetrics (FIGO) stage IV (p = 0.007), and more than six medications per day (p = 0.043). The second study (EWOC 2) assessed the feasibility of carboplatin (AUC 5) with paclitaxel (175 mg/m^2) (CP) once every 3 weeks for six cycles in 75 older patients. The feasibility of completing all six cycles for patients receiving CP was 68%.[43]

These two studies were pooled in a retrospective, multivariate analysis (EWOC 1 plus EWOC2) to assess predictive factors of survival.[43] Patients in the EWOC 2 study appeared to be younger and had better PS than those in the EWOC 1 study, which indicated a selection bias because of a concern that the CP regimen could be associated with higher toxicity. The CP regimen had more hematologic (grade 3 to 4) and neurologic toxicities. Despite the inclusion of a higher proportion of patients with optimal CRS (1 cm or less of residual disease) in the CP regimen (40% vs. 21% in the CC regimen), the survival curves were similar. Predictive factors of poor prognosis were advanced age, depression symptoms at baseline, and FIGO stage IV. The use of paclitaxel was found to be an independent factor for poor survival (HR = 2.42, p = 0.001).

However, given that this was a small, nonrandomized study, the validity of this finding is unclear. GOG 273 may address this issue when survival analyses are available. This study enrolled women older than age 70 with newly diagnosed EOC and allowed physicians to select treatment either with every-3-week paclitaxel (135 mg/m^2) and carboplatin (AUC 5) plus pegfilgrastim support or with every-3-week carboplatin alone (AUC 5). The primary endpoint was the ability of independent activities of daily living (IADL) score to predict completion of four cycles of chemotherapy.

This study enrolled 153 women onto the combination arm and 59 onto the single-agent carboplatin arm. The study was not randomized, so it is not unexpected that the women in the single-agent arm were older (median age, 83 vs. 77), had a lower PS (PS of 2 to 3: 37% vs. 11%), were more likely to receive NACT (58% vs. 49%), and were less likely to complete all four cycles without a dose reduction or a more than 7-day delay (54% vs. 82%). However, overall completion of four cycles was high in both arms (92% and 75% in the combination and single-agent arms, respectively). Although the primary endpoint of the ability of IADL to predict completion of four cycles of chemotherapy was not met, patients in both arms reported improved quality of life, social activity, and function

(i.e., activities of daily living [ADL]) with increasing cycles of chemotherapy.[41]

The EWOC 3 study evaluated the use of single-agent carboplatin AUC 5 in a highly selected, frail population. This study was used to validate the geriatric vulnerability score (GVS) developed during evaluation of the baseline GAs done for EWOC 1 and 2. The GVS will be discussed more in the section on GAs later in this chapter.[44]

Variations in scheduling. The MITO-5 (Multicenter Italian Trial in Ovarian cancer) phase II study assessed the tolerability of a weekly combination of carboplatin (AUC 2) plus paclitaxel (60 mg/m^2) on days 1, 8, and 15, every 4 weeks for six cycles in a small trial of 26 patients age 70 or older with stage IC to IV disease and performance status up to or less than PS 2.[45] In this study, 54% patients had at least two comorbidities and high functional dependency (ADL, 31%; IADL, 69%). The RECIST response rate was 38.5%, and the median overall survival was 32.0 months. Toxicity was low; 23 patients (89%) were treated without any defined-as-unacceptable toxicity (primary study endpoint).

The larger randomized, phase III trial (MITO-7) evaluated the same weekly regimen used in MITO-5 versus standard carboplatin (AUC 6) with paclitaxel (175 mg/m^2) every 3 weeks in women with newly diagnosed EOC.[46] Although this trial was not specifically for older women, it did confirm the possible advantages of the weekly regimen, because it was associated with better quality of life scores and lower toxicity, including lower incidence of neuropathy worse than grade 2 and fewer incidences of grade 3 to 4 hematologic toxicity. There was no survival advantage to the weekly regimen but no decrement either (median progression-free survival, 17.3 vs. 18.3 months), which supports this regimen as an alternative to every-21-day paclitaxel and carboplatin, especially among more vulnerable patients.

Because of the interest in weekly dosing generated by this and other phase III trials, GOG 273 added a weekly arm to evaluate carboplatin AUC 5 with weekly paclitaxel 60 mg/m^2. For this arm of the trial, the primary endpoint is to determine if an eight-point GA score could predict the ability to tolerate chemotherapy.[47] This study has completed enrollment, and follow-up care is ongoing. In France, the most recent EWOC trial is enrolling as well. This randomized, phase II trial (NCT02001272) plans to enroll 264 patients, and treatment arms will encompass both initial dose modification strategies and weekly strategies (single-agent carboplatin, combination carboplatin and paclitaxel, and a weekly paclitaxel and carboplatin arm, similar to MITO-7). Eligibility for EWOC is defined by a GVS score greater than 3, again selecting for a very vulnerable population of older patients. A summary of clinical trials performed in the older patient with ovarian cancer is provided in Fig. 3.

Is intraperitoneal chemotherapy a consideration for the older patient? Cisplatin-based intraperitoneal chemotherapy has a demonstrated significant survival benefit for patients with an optimal CRS for stage III ovarian cancer and is a standard of

FIGURE 3. Chemotherapy Trials in the Older Patients

Study	Inclusion	Agents Used	Overall Survival (Median Months)	Discovery
EWOC-1 (83 patients, phase II, single arm)	> 70, stage III/IV Enrolled: (Age 70-90) Phase ≥ 2: 44% Stage IV: 24%	Carboplatin AUC 5 + cyclophosphamide 600 mg/m2 q 28 days for 6 days	21.6	OS associated with: (1) depression (p = 0.003), (2) stage IV (p = 0.007), (3) > 6 medications/day (p = 0.043). Toxicity associated with: (1) depression (p=0.006), (2) dependence of ADL or IADL (p=0.048), (3) PS ≥ 2.
EWOC-2 (75 patients, phase II, single arm)	Age > 70, stage III/IV Enrolled: (Age 70-89) Phase ≥ 2: 26% Stage IV: 22%	Carboplatin AUC 5 + paclitaxel q 21 days	25.9	OS associated with the HADS > 15*
EWOC-3 (111 patients, phase II, single arm)	Age > 70, stage III/IV	Carboplatin AUC 5	17.4	Validated the GVS**
MITO 5 (phase II, single arm)	Age ≥ 70, stage IC-IV	Carboplatin AUC 2 + paclitaxel 60mg/m2 day 1, 8, 15 every 28 days	32	89% of patients were treated without protocol defined unacceptable toxicity
GOG 273 (212 patients; includes only arms I and 2; phase II; multi-arm; not randomized)	Age ≥ 70, stage IC-IV	Physician choice: (1) carboplatin AUC 5 + paclitaxel 135mg/m2 + G-CSF q 21 days, (2) carboplatin AUC 5 q 21 days, (3) carboplatin AUC 5 every 21 days + paclitaxel 60mg/m2 day 1, 8, 15 (results for this arm have not been presented)		Endpoint was trying to correlate IADLs with ability to complete 4 cycles of chemotherapy without delay >7 days or dose modification. Arm 1: 82% completed without delay or dose mod. Arm 2: 54% completed without delay or dose mod. Patients in both arms reported improved quality of life, social activity, and ADL with increasing cycles of chemotherapy.

** GVS (Geriatric Vulnerability Scale).

care at many U.S. cancer centers. Despite growing acceptance of its superior survival advantages, several concerns remain, including technical difficulties (intraperitoneal catheter placement and complications) and increased toxicities (renal dysfunction, neuropathy, hearing loss). In GOG 172, 39% of the 205 women who received intraperitoneal cisplatin/paclitaxel were older: 26% were age 61 to 70), 12% were age 71 to 80, and 1% were older than age 80.[35] Their functional status was good (92% with a GOG PS of 0 to 1). Regardless of age, less than 50% of all patients were able to complete four or more cycles of the intraperitoneal regimen because of toxicity.

How does an oncologist apply these results to their older population? First, the major limitation to the study was that patients received intraperitoneal cisplatin. By age 70, renal function may have declined by as much as 40%, and this reduction in glomerular filtration rate may lead to enhanced toxicity of drugs, particularly those with significant renal excretion, such as cisplatin. On GOG 172, patients were re-

quired to have a serum creatinine less than 1.2 mg/dL; however, creatinine clearance is a more sensitive marker for renal dysfunction and should be used.[48] The second limitation was the use of paclitaxel, because its drug clearance declines with age and its toxicities, such as neuropathy and cytopenias, heighten.[49] Even with the overall survival benefit demonstrated with intraperitoneal therapy, widespread adoption of this modality has been slow secondary to the limitations discussed.

If intraperitoneal chemotherapy is offered as an option to older women, one needs to carefully select patients with good functional status, adequate kidney and hearing function, and an understanding that toxicities may arise earlier in the course of treatment compared with intravenous chemotherapy alone.

Chemotherapy for recurrent disease. Treatment for recurrent ovarian cancer is divided into relapse at 6 months or fewer since the last platinum-containing chemotherapy administration, as platinum resistant, and at greater than 6 months as platinum sensitive. For platinum-sensitive disease, trials show the survival advantage of a doublet combination with carboplatin and either paclitaxel, liposomal doxorubicin, or gemcitabine.[50,51] The combination of carboplatin and paclitaxel (in CALYPSO) was significantly associated with a higher incidence of neurologic toxicity (neuropathy greater than grade 2) among patients older than age 70 (25% vs. 16%, respectively; p = 0.006).[52] Although the proportion of older patients (median age, 73) comprised only 16% of the study population, the prevention of severe neurologic toxicity would advocate for the use of pegylated liposomal doxorubicin rather than paclitaxel in older women.

For platinum-resistant disease, chemotherapy is typically given as single agent, with responses from 10% to 25% and a median duration of 4 to 8 months. Common options include liposomal doxorubicin, topotecan, gemcitabine, weekly paclitaxel, and single-agent bevacizumab.[53] Unfortunately, few studies have been reported in older patients with ovarian cancer. Based on extensive studies from lung and breast cancer in older patients, most of these single-agent drugs are well tolerated.[54,55] Gronlund et al[56] described their experience with topotecan (1 mg/m^2 over 5 days) in 57 older patients with platinum-resistant ovarian cancer and found no significant differences in the toxicity profile or response between an older (older than age 65) or younger (younger than 65) cohort.[56] PS was a better predictor of response and survival in both cohorts. Currently, most oncologists use liposomal doxorubicin or weekly topotecan for older patients with platinum-resistance, given its improved toxicity profile.[57,58] The recent publication of the AURELIA trial and the subsequent U.S. Food and Drug Administration (FDA) label for bevacizumab 10 mg/kg every 2 weeks with either pegylated liposomal doxorubicin (PLD) 40 mg/m^2, weekly paclitaxel 80 mg/m^2 for four doses, or topotecan 4 mg/m^2 weekly for three doses has created yet another option for the platinum-resistant population. The median age of patients on the chemotherapy/bevacizumab arm was 62, but the range was ages 25 to 80.[59] There was criticism of this study because of the lack of a bevacizumab-alone arm, which is considered an effective agent but is not FDA approved for this indication on the basis of only phase II data.[60] Hypertension and arterial thrombosis risk may be heightened in an older patient who has more comorbidities. Previously reported high bowel perforation rates (as high as 11%) have been greatly diminished, and recent data from a prospective, phase III trial demonstrated a 2.8% rate of perforation among those treated with bevacizumab compared with 1.2% in those treated without. Age was not mentioned as a risk for bowel perforation in this study.[36]

Because these chemotherapy options offer primarily palliation, many argue for a focus on better supportive measures rather than more chemotherapy. In one study, there was a significant cost difference, with no appreciable improvement in survival in a comparison of patients with ovarian cancer treated aggressively with chemotherapy with those enrolled in hospice at the final months of their life. The authors suggest that earlier hospice enrollment is beneficial, particularly in the older frail patients who have poor prognoses.[61]

Assessment of the Older Woman for Ovarian Cancer Treatment: Making Data Driven Decisions

Geriatric assessment (GA) provides information about a patient's functional status (i.e., ability to live independently at home and in the community), comorbid medical conditions, cognition, psychologic status, social functioning support, and nutritional status. In the cancer setting, several studies have demonstrated the predictive value of GA for estimating the risk of severe toxicity from chemotherapy.[47,62,63] A validated instrument for assessment specifically for the older patient with ovarian cancer does not yet exist. There are several assessments used in the older adult with cancer (Fig. 4), but further prospective studies are imperative to remove the guesswork from assessing a patient's fitness for surgery or chemotherapy.

Presurgery assessment. Traditional models of preoperative assessment (e.g., Lee, Eagle, American Society of Anesthesiologists) do not consider the multisystem assessment needed to evaluate an older patient. The Preoperative Assessment of Cancer in the Elderly (PACE) tool was developed to combine elements of the comprehensive GA with surgical risk assessment tools in an older cancer population, although no gynecologic patients were included (Fig. 4). The authors found no significant association of age with postoperative complications. However, 30-day morbidity was predicted by IADL (i.e., more complex activities, such as managing finances and shopping), moderate to severely elevated scores on the Brief Fatigue Inventory (BFI), and abnormal PS. An extended hospital stay was predicted by lower scores in ADL (i.e., basic activities, such as eating, bathing, dressing), IADL, and worse PS.[64,65]

A position paper was released in 2012 by the American College of Surgeons that outlined the best practices for optimal preoperative assessment of the geriatric patient with a

FIGURE 4. Geriatric Assessment in Older Adults with Cancer

Variables	1) Mini-mental state inventory 2) Activities of daily living (ADL) 3) Instrumental activities of daily living (IADL) 4) Global depression scale (GDS) 5) Brief fatigue inventory (BFI) 6) Performance status (PS) 7) ASA 8) Satariano's index of co-morbidities	If yes to below— a graded value is added to a toxicity score: 1) Age ≥ 72 2) Cancer type (GI or GU) 3) Standard dosing 4) Poly-chemotherapy 5) Anemia 6) Renal dysfunction (CrCl b 34 mL/min) 7) Decreased hearing 8) Falls in last 6 months 9) Assistance with taking medication 10) Limited walking 1 block 11) Decreased social activity	Measures to be collected: 1) Function (ADL, IADL, PS, Fall Hx) 2) Comorbidity (Physical Health Section of OARS) 3) Psychological (Mental Health Inventory-17) 4) Social Activity/Support— MOS Surveys 5) Brief Fatigue Inventory 6) Nutrition (BMI, weight loss) 7) Medication list	Measures to be collected: 1) Function (ADL, IADL, PS) 2) Comorbidity (Charlson Score, Hearing Loss, Fall Hx) 3) FACT-O 4) FACT/GOG-NTX-4 5) Nutrition (BMI, weight Loss)	If yes to below— a graded value is added to a toxicity score (GVS): 1) Low albumin 2) Low ADL 3) Low IADL 4) Lymphopenia 5) High Hospital Anxiety and Depression (HADS) score
Conclusion	1) IADL, BFI and PS predicts 30 day morbidity 2) ADL, IADL and PS associated with extended hospital stay.	A toxicity score ranging from 0 to 23 identified patients at greatest risk of grade 3–5 chemotherapy toxicity.	Accrual underway	Final report pending	Accrual underway.

standard checklist.[66] Timed Up & Go has been reported to predict 30-day surgical morbidity in patients age 70 or older who were undergoing cancer surgery (61% involved laparotomy). This was part of the PREOP study that was designed to assess a number of different presurgical assessments in older patients who had a variety of cancers and were undergoing a variety of different operations.[67]

A unique multicenter study (NRG-CC002) under accrual is focused exclusively on women older than age 70 at the time of diagnosis of a gynecologic cancer (advanced ovarian or en-

dometrial serous cancer). Before surgery or NACT, geriatric measures will be collected, to include the following: (1) function (ADL, IADL, PS, fall history), (2) comorbidity (physical health section of Older Americans Resources and Services), (3) psychologic (Mental Health Inventory-17), (4) social activity/support (Medical Outcomes Study survey), (5) nutrition (body mass index, weight loss), (6) Brief Fatigue Inventory, and (7) medications. A risk score will be calculated to determine its ability to predict major postoperative complications.

Prechemotherapy assessment. A simple and short screening test to assess toxicity risk for older vulnerable women with ovarian cancer undergoing chemotherapy is clearly needed, and a variety have been or are being tested (Fig. 4). Examples of short surveys used in various cancers are the Vulnerable Elders Survey (VES-13) and the Cancer and Aging Research Group (CARG)–GA and toxicity score. VES-13 is a self-administered survey that consists of one question for age and 12 additional questions that assess self- rated health, functional capacity, and physical performance. CARG-GA is a feasible assessment (mean time to completion is 27 minutes, mostly self administered) with an 11-variable toxicity score (Fig. 4). The score predicted grade 3 to 5 chemotherapy toxicity far better than PS.[47] The CARG study did include a small proportion of women who had ovarian cancer (50 patients, 10%), and a retrospective subgroup analysis showed that grades 3 to 5 toxicity occurred in 19 patients (37%). Abnor-

mal CA125 was associated with assistance with IADL, low PS, chemotherapy toxicity, and dose reductions.[68]

The French GINECO group has developed a GVS from a series of up-front trials in older women with ovarian cancer. The GVS includes the high-risk variables of low albumin (less than 35 g/L), low ADL score (less than 6), low IADL score (less than 25), lymphopenia (less than 1G/L), and a high hospital anxiety and depression (HADS) score (greater than 14).[44] Women with a high GVS score (3 or greater) had a worse overall survival (11.5 vs. 21.7 months; HR, 2.94; p < 0.001), experienced a lower rate of chemotherapy completion (65% vs. 82%; OR = 0.41; p = 0.04), had higher incidences of severe adverse events (53% vs. 29%; OR = 2.8; p = 0.009), and more unplanned hospitalizations (53% vs. 30%; OR = 2.6, p = 0.02). The use of the GVS appears helpful in selecting those at greatest risk; validation studies with larger cohorts are underway.

CONCLUSION

As designated treatment trials for the older and performance-challenged woman with ovarian cancer increase, our understanding of and ability to discern best practices for treatment planning increase. In addition, the ongoing planned trials evaluating pretreatment assessment for older patients will provide objective, feasible, clinical tools for applying our treatment-based knowledge. These important works will hopefully eliminate much of the gestalt decision making in this potentially vulnerable population and improve outcomes for all.

Chemotherapy for Patients with *BRCA1* and *BRCA2*-Mutated Ovarian Cancer: Same or Different?

David S.P. Tan, PhD, MBBS, BSc, MRCP, and Stanley B. Kaye, MD, FRCP, FRSE

OVERVIEW

Retrospective studies have shown an improved prognosis, higher response rates to platinum-containing regimens, and longer treatment-free intervals between relapses in patients with *BRCA 1* and *BRCA 2* (*BRCA1/2*)–mutated ovarian cancer (BMOC) compared with patients who are not carriers of this mutation. These features of BMOC are attributed to homologous-recombination repair (HR) deficiency in the absence of *BRCA1/2* function, which results in an impaired ability of tumor cells to repair platinum-induced double-strand breaks (DSBs), thereby conferring increased chemosensitivity and increased sensitivity to poly(ADP-ribose) polymerase (PARP) enzyme inhibition and other DNA-damaging chemotherapeutic agents such as pegylated liposomal doxorubicin (PLD). Therefore, the chemotherapeutic approach for patients with BMOC should focus on treatment with platinum-based chemotherapy at first-line and recurrent-disease settings and measures to increase the platinum-free interval following early platinum-resistant relapse (i.e., progression-free survival of less than 6 months from last platinum-based chemotherapy) by using nonplatinum cytotoxic agents, with the aim of reintroducing platinum again at a later date. The role of first-line intraperitoneal platinum-based therapy in the specific context of BMOC also merits further analysis. Other than platinum, alternative DNA-damaging agents (including PLD and trabectedin) also may have a therapeutic role in patients with recurrent BMOC. The recent approval of olaparib for clinical use in Europe and the United States will also affect chemotherapeutic strategies for these patients. Further work to clarify the precise relationship between *BRCA1/2* mutation genotype and clinical phenotype is crucial to delineating the optimal therapeutic choices in the future for patients with BMOC.

The *BRCA1/2* tumor suppressor genes are critical for the maintenance of cellular genomic stability through the error-free repair of DNA double-strand breaks (DSBs) via the high-fidelity homologous-recombination repair (HR) pathway.[1,2] Loss of *BRCA1/2* function may occur because of somatic mutations or epigenetic silencing, which results in a dependency on alternative error-prone (low-fidelity) DNA repair pathways and potential genomic instability.[2] The absence of *BRCA1/2* function is associated with a cumulative lifetime risk for developing epithelial ovarian cancer (EOC) of 40% to 50% in patients who are *BRCA1*-mutation carriers and 20% to 25% in patients who are *BRCA2*-mutation carriers.[3] Germ-line mutations in *BRCA1/2* have been observed in 14% of patients with nonmucinous EOC, including 17% of patients with high-grade serous histology, with 44% of these patients having no reported family history of breast or ovarian cancer, whereas somatic mutations in *BRCA1/2* have been found in 6% of patients with high-grade serous EOCs.[4,5]

PLATINUM SENSITIVITY AND IMPROVED SURVIVAL ARE HALLMARKS OF BRCA-NESS IN EOC

Improved prognosis in terms of progression-free survival (PFS) and overall survival (OS), with higher partial response (PR) and complete response (CR) rates to platinum-containing regimens and longer treatment-free intervals, has been observed in retrospective studies of patients who are *BRCA1/2*-mutant carriers with ovarian cancer compared with patients who are non-BMOC.[5-10] This "BRCAness" phenotype, with superior outcomes following platinum-based therapy in patients with BMOC, has been attributed to HR deficiency in the absence of *BRCA1/2* function. This results in an impaired ability of *BRCA*-deficient tumor cells to repair platinum-induced DSBs, which confers increased sensitivity to chemotherapy.[8,9,11] Similarly, inhibition of poly(ADP-ribose) polymerase (PARP) enzymes (which repair single-stranded DNA breaks mainly through the base-excision repair pathway) in HR-deficient cells by PARP inhibitors (PARPi) results in DSBs that are subjected to low-fidelity repair by nonhomologous end joining.[2,12] The absence of high-fidelity DNA-repair mechanisms following PARPi treatment in HR-deficient cells leads to synthetic lethality through an accumulation of DNA damage that results in mitotic catastrophe and cell death.[13] PARP inhibitors are active agents in patients with BMOC, but they also may be effective in a subset of sporadic ovarian cancers.[14] Mutations

in other genes, such as *ATM, CHEK1, CHEK2, NBN,* and *RAD51D,* can also affect HR function and increase sensitivity to DNA-damaging agents and PARPi.[11]

WHAT ARE THE MECHANISMS OF PLATINUM RESISTANCE IN BMOC TUMORS?

Recent evidence suggests that secondary (reversion) *BRCA1/2* mutations are a mechanism of acquired resistance to platinum and PARPi in *BRCA1/2*-mutated cancer cells.[15,16] Reversion of *BRCA1/2* germ-line mutations also have been found in platinum-resistant tumors,[17] but it is unclear which functions of BRCA1/2 proteins are required for therapy resistance and which *BRCA1/2* genotypes are more likely to undergo reversion mutations. Furthermore, it is unclear if a spectrum of platinum and PARPi sensitivity exists among *BRCA1/2* mutant cancers, such that, independent of reversion mutations, certain *BRCA1/2* genotypes may be associated with a phenotype that is intrinsically less sensitive to these therapies than others or may be associated with heterogeneity in their response to these therapies, such that the tumors are platinum resistant but still retain sensitivity to PARPi and vice versa. Heterogeneity in clinical response also may be explained by other mechanisms of (PARPi) resistance, including enhanced P-glycoprotein-mediated drug efflux or reduced 53BP1 expression.[18]

Evidence to support the notion that all *BRCA1/2*-mutated cancers may not have a uniform clinical phenotype has emerged from survival data showing that patients with EOC who carry a germ-line *BRCA2*-mutation have a better prognosis than patients with EOC who carry a germ-line *BRCA1*-mutation.[6] Furthermore, recent in vivo data from a *BRCA1*-deficient mouse mammary carcinoma model suggest that the *BRCA1C61G* mutation (a common pathogenic missense variant) may be associated with poor response and rapid development of resistance to platinum drugs and PARP inhibition but still retain the *BRCA1C61G* mutation.[19] This suggests that ab initio resistance to specific chemotherapeutic agents may also exist in certain *BRCA1/2*-mutated breast and ovarian cancers depending on the patient's *BRCA1/2* genotype. In a recent meta-analysis of clinical outcome data in patients with BMOC, *BRCA1/2* mutations and low *BRCA1* expression by immunohistochemistry or reverse transcription polymerase chain reaction were statistically significantly better prognostic factors for survival (hazard ratio [HR] 0.51 to 0.67), whereas *BRCA1*- promoter methylation was not associated with improved prognosis (HR 1.59).[10] Therefore, given the potential effect of the mechanisms of *BRCA1/2* inactivation and genotype on the heterogeneity of treatment responses and outcome, the ability to correlate *BRCA* genotype with its clinical "BRCAness" phenotype will be crucial to facilitate patient stratification according to underlying *BRCA1/2* deficiency in each patient to optimize management in the future.

WHAT DATA EXIST FOR INCREASED SENSITIVITY TO SINGLE AGENT CHEMOTHERAPEUTIC DRUGS OTHER THAN PLATINUM COMPOUNDS IN PATIENTS WITH BMOC?

Limited data are available presently to fully address the question of whether chemosensitivity to platinum salts observed in patients with BMOC can be extended to other nonplatinum agents, including pegylated liposomal doxorubicin (PLD), paclitaxel, topotecan, and gemcitabine, which commonly are used as monotherapy in the platinum-resistant/refractory setting (Table 1).

The most convincing information comes from two retrospective analyses on patient outcomes following treatment with PLD in BMOC. Both have demonstrated improved response rates and PFS when compared with patients who are non-BMOC.[22,28] Safra et al combined the outcomes of patients who received either PLD as a single agent or in combination with platinum-based chemotherapy and demonstrated improved median time to treatment failure (15.8 vs. 8.1 months; p = 0.009) and OS (56.8 vs. 22.6 months; p = 0.002) for patients with BMOC vs. patients who are non-BMOC.[28] Adams et al examined the response rates of 23 patients with BMOC following treatment with single-agent PLD and reported an improved response rate of 56.5% (3 by RECIST criteria and 10 by CA125 levels) in patients with BMOC compared with only 19.5% (2 by RECIST criteria and 6 by CA125 levels; p = 0.004) in patients who are non-BMOC.[22] Notably, 71% (10/14) of BMOC patients with platinum-resistant disease in this study responded to PLD,

KEY POINTS

- Improved prognosis and response to platinum-based chemotherapy are hallmarks of *BRCA1/2*-mutated ovarian cancer (BMOC).
- Increased platinum sensitivity is attributed to underlying homologous-recombination repair deficiency in BMOC, leading to impaired ability to repair platinum-induced double-strand breaks, thereby conferring increased sensitivity to chemotherapy.
- Chemotherapeutic strategies for patients with BMOC should focus on platinum-based chemotherapy at first-line and recurrent-disease settings, and include measures to increase the platinum-free interval in patients with early platinum-resistant relapse (i.e., progression-free survival of < 6 months from last platinum-based chemotherapy) by using nonplatinum cytotoxic agents, with the aim of reintroducing platinum at a later date.
- In recurrent disease, patients with BMOC appear to have increased sensitivity to pegylated liposomal doxorubicin and other DNA-damaging agents, including trabectedin and mitomycin C, also may have a therapeutic role.
- With recent approval for the use of the poly(ADP-ribose) polymerase (PARP) inhibitor (PARPi) olaparib in BMOC in Europe and the United States, further work to define the optimal choice, timing, and sequence of chemotherapy and/or PARPi therapy will be crucial to improve outcomes for patients with BMOC.

TABLE 1. Overall Response Rates following Chemotherapy in Patients with BMOC

Chemotherapy Regimen	ORR in Platinum-Sensitive BMOC	ORR in Platinum-Resistant BMOC	References
Platinum-Based Chemotherapy	**First Line**		
	87%[a] *BRCA1* (83 patients)	-	Vencken et al[9]
	92%[a] *BRCA2* (13 patients)	-	Vencken et al[9]
	96%[b] (21/22 patients)	-	Tan et al[8]

[a] World Health Organization criteria were used to evaluate response to chemotherapy.
[b] Response Evaluation Criteria in Solid Tumors (RECIST) criteria.
[c] Response defined as a 50% decrease in CA-125, maintained for 28 days.
[d] RECIST PR/CR and Gynecologic Cancer Intergroup (GCIG) CA-125 criteria.
[e] RECIST PR/CR or more than 50% reduction in CA-125.

and improved PFS and OS measured from the time of PLD administration also was observed.[22] Furthermore, the improved outcomes noted in both studies appeared to be independent of platinum sensitivity.[22,28] An improved response to PLD also was a striking feature in a randomized study of patients with BMOC with relapsed disease within 12 months of completing platinum-based therapy.[23] Patients were randomly assigned to (two dose levels of) olaparib or PLD; at 400 mg twice a day olaparib yielded the expected 59% RECIST/CA125 response rate with a median PFS of 8.8 months. PLD yielded an unexpectedly high level of 39% combined RECIST/CA125 response with a median PFS of 7.1 months.[23]

Given that doxorubicin is a topoisomerase II-alpha poison that causes DSBs in DNA by inhibiting the unwinding of DNA for transcription and replication,[29] the increased efficacy of PLD in patients with BMOC also could be directly related to defective HR in BMOC cells. Intriguingly, however, in a small study by Hyman et al, no responses were observed following treatment with the topoisomerase I inhibitor topotecan in nine patients with BMOC who received heavy pretreatment.[25] Likewise, Safra et al demonstrated no difference in PFS (median PFS of 4 months in both groups) between patients with BMOC or who are non-BMOC who were treated with topotecan.[30] It is unclear why the differences in outcomes observed for topoisomerase I and II inhibition exist. Possible explanations include the additional cytotoxic effects of doxorubicin beyond topoisomerase II inhibition (e.g., intercalation into DNA causing additional DSBs, inhibition of DNA synthesis, and generation of free radicals, coupled with the fact that PLD may have

improved drug delivery properties that could potentially enhance its antitumor effect).[31,32] Furthermore, a recent study demonstrated that although the cytotoxic response to PLD was similar in *BRCA1*-deficient and wild-type cells in vitro, *BRCA1* inactivation resulted in higher expression of Fas and MHC-I both before and after PLD exposure.[33] Additionally, PLD prolonged the survival of *BRCA1*-deficient tumor-bearing mice and increased intratumoral T-cell recruitment. Subsequent depletion of CD4$^+$ T cells combined with PLD treatment also substantially prolonged overall survival in *BRCA1*-deficient tumor-bearing mice.[33] Therefore, the increased efficacy of PLD also may be related to the amplification of its immunomodulatory effects in BMOC tumors, which may, in turn, enhance host antitumor responses.

Trabectedin, a minor groove DNA-binding agent derived from the marine organism Ecteinascidia turbinate, is approved in some countries for treating relapsed ovarian cancer in combination with PLD. Preclinical data suggest enhanced activity in HRD cells. Furthermore, at the 2014 American Society of Clinical Oncology Annual Meeting, Lorusso et al reported data on 88 patients with EOC with documented *BRCA1/2* mutation or BRCAness phenotype (defined as at least two previous responses to platinum) treated with single-agent trabectedin. An overall response rate of 41% was noted, with a median PFS of 18 weeks and a median OS not reached.[24] However, the significance of this is uncertain because the patient group was described as moderately or highly platinum-sensitive, and in previous phase II studies of single-agent trabectedin in unselected patients, the response

rate in platinum-sensitive patients was reported as 29% to 36%.[34,35] A second piece of clinical data has suggested a correlation between *BRCA1/2*-mutation status and the improved efficacy of trabectedin/PLD over PLD alone in a subgroup analysis of 41 patients in the OVA-301 trial. This observation may merit further exploration of that combination.[36]

Clinical data on smaller numbers of patients were reported in support of preclinical results suggesting increased sensitivity to other DNA-damaging agents such as mitomycin-C[37] and melphalan[38] for *BRCA1/2*-deficiency. Moiseyenko et al recently reported that administration of mitomycin-C (10 mg/m², 4 doses per week), which induces DNA cross-links, resulted in one CR (duration 36 weeks), two PRs (duration 36 and 48 weeks) and six instances of disease stabilization of between 12 to 24 weeks duration in patients with BMOC with recurrent disease.[26] Melphalan is a bifunctional alkylating agent that induces inter- and intrastrand DNA cross-links. It has been shown to be selectively toxic to *BRCA2*-deficient breast cancer cell lines.[38] Single doses of melphalan also have resulted in longer relapse-free survival in mice xenografted with *BRCA2*-deficient cells than with cisplatin or olaparib in vivo.[38] Osher et al reported a case of a patient who was a *BRCA2* mutation carrier with platinum-resistant EOC who responded to treatment with oral melphalan (8 mg per day, 5 days per month for 1 year) and has remained disease-free for more than 25 years.[27]

Paclitaxel is a well-established therapeutic agent for treating patients with EOC in the first-line[39] and relapsed settings.[40] In the context of patients with BMOC, however, the sensitivity of *BRCA1*-mutated cancer cells to platinum chemotherapy has been reported to correlate inversely with sensitivity to microtubule-interfering agents such as taxanes.[41] Furthermore, inhibition of *BRCA1*-expression in ovarian cancer cell lines has shown to increase cellular sensitivity to platinum compounds but reduce antitumor activity of taxanes.[42,43] Clinical data were also provided to suggest that overall survival for patients with higher *BRCA1*-expressing ovarian cancers improved following taxane-containing chemotherapy, albeit nonsignificantly (23.0 vs. 18.2 months; p = 0.12; HR, 0.53),[42] thus suggesting that higher *BRCA1*-expression levels may be required for a clinical response to taxanes. In vitro data suggest that *BRCA1*-mutated breast cancer cells are resistant to paclitaxel, in contrast to *BRCA1* wild-type cells,[44] and MCF-7 cells transfected with *BRCA1* siRNA display a significant 9-fold increase in resistance to paclitaxel (p ≤ 0.001).[45] Taken together, these data imply that patients with BMOC who harbor defects in *BRCA1/2* function through germ-line or sporadic mutations also may be potentially resistant to paclitaxel.[43] However, conflicting preclinical published studies indicate reduced *BRCA1* expression actually may confer increased sensitivity to paclitaxel.[46,47] In this context, a study by Tan et al of 26 patients with BMOC who received paclitaxel monotherapy for relapsed disease described an overall response rate of 46% (12 of 26 patients).[21] The clinical benefit rate (defined as RECIST PR or CR, or stable disease after 18 weeks of treatment) was significantly higher (80 vs. 36%, p = 0.04) in patients who are platinum sen-

sitive than in patients who are platinum resistant.[21] These data do not suggest any adverse effect of *BRCA1/2* mutation carrier status on the activity of paclitaxel. The study also showed that patients with BMOC who were platinum sensitive had significantly longer median PFS compared with patients who were platinum resistant (42 vs. 21 weeks, p = 0.003).[21] In the retrospective study by Safra et al, PFS for patients with BMOC following paclitaxel monotherapy was not significantly different from that of patients who are non-BMOC (p = 0.572).[30] Overall, the data suggest that equivalent paclitaxel efficacy is seen in both groups of patients, and taxanes should continue to have a therapeutic role in patients with EOC regardless of *BRCA1/2* carrier status.

ARE THERE ANY CHEMOTHERAPY COMBINATION DATA IN THIS CONTEXT?

In a retrospective single-institute review of 256 patients, the combination of PLD and platinum or gemcitabine and platinum was associated with significantly improved PFS in patients with BMOC compared with patients who are non-BMOC (p = 0.001 and p = 0.02, respectively); however, there were no differences in outcome when taxanes were used in combination with platinum.[30] As such, it is tempting to speculate that a PLD/platinum combination potentially may be a better option than a taxane/platinum combination at some stage of treatment for patients with BMOC. However, no prospective comparative data presently support this. The two randomized trials that compared their efficacy in the first-line (MITO-2 trial)[48] and recurrent (CALYPSO trial)[49] settings did not include subgroup analyses of patients with BMOC vs. patients who are non-BMOC. There is a good case, however, to retrieve samples in these trials for *BRCA1/2*-mutation testing.

HOW SHOULD PATIENTS WITH BMOC BE TREATED AT PRESENT?
First-Line Chemotherapy for Patients with BMOC

In recurrent disease, the retrospective data appear to suggest that PLD may be superior to paclitaxel as a single agent, but the situation for carboplatin-based combinations in first-line treatment may be quite different. Although some may consider the option of PLD/carboplatin as the first-line treatment of choice in newly diagnosed patients with BMOC, there are no randomized data to support this approach. Data from the JGOG3016 study demonstrating significantly superior PFS and OS outcomes when carboplatin is combined with dose-dense weekly paclitaxel instead of thrice weekly paclitaxel also should be taken into account (PFS, p = 0.0037; OS, p = 0.039).[50] Therefore, although the PLD/carboplatin combination represents a viable alternative to the current standard of paclitaxel/carboplatin in patients with BMOC who wish to reduce the risk of neuropathy, which is in line with the data from MITO-2,[48] there are currently no data to support dropping paclitaxel routinely from first-line chemotherapy for patients with BMOC.

The role of first-line intraperitoneal (IP) chemotherapy for patients with EOC remains controversial despite the positive data from the GOG-172 phase III randomized trial of intravenous paclitaxel and cisplatin compared with intravenous paclitaxel and IP cisplatin plus IP paclitaxel in patients with optimally resected stage III EOC.[51] However, a recent retrospective analysis of tumor samples taken from patients in the trial revealed a 36-month survival improvement in patients treated with IP chemotherapy who had decreased *BRCA1* expression (defined as ≤ 10% immunohistochemical staining) in their archival tumor compared to intravenous treatment.[52] Further analyses of the *BRCA1/2* mutation status of tumor samples from other ongoing IP trials, including GOG 252, OV-21/GCIG, and the iPocc study,[51] may help consolidate the data regarding its role in patients with BMOC.

Chemotherapy for Patients With Recurrent BMOC

For patients with recurrent EOC, the choice of chemotherapy should probably take *BRCA1/2* mutation status into account. First, as to platinum-resistant recurrent disease, it is unclear if the current clinical definition of platinum sensitivity and resistance in recurrent EOC, based on the 6-month platinum-free interval, accurately predicts the likelihood of response when patients with BMOC are rechallenged with platinum-based chemotherapy. In a small subgroup of the Australian series, Alsop et al reported that 80% (8 of 10) of patients with BMOC with recurrent disease who experienced relapse within 6 months of their last platinum chemotherapy treatment subsequently responded when rechallenged with platinum-based chemotherapy.[5] This provides a tantalizing signal that patients with BMOC may have increased ability to regain platinum sensitivity even after platinum resistance develops and we should perhaps be less conservative with the definition of platinum resistance in the context of BMOC. To some extent, this feature of BRCAness also may explain why responses to platinum-based chemotherapy can still be attained in a proportion of patients with EOC in the platinum-resistant/refractory setting.[53,54] Based on the data in the small subgroup described by Alsop, and leaving the role of PARPi aside for the moment, a possible option would be early rechallenge with platinum-based chemotherapy for patients with BMOC who are platinum-resistant. However, a more logical option, if available, probably would be to extend the platinum-free interval by first using a nonplatinum-based agent in the platinum-resistant setting before reintroducing platinum at disease progression. Options for prolonging the platinum-free interval include incorporating a course of single agent PLD (and it would be interesting to elucidate the benefit of PLD rechallenge for patients who previously were treated with PLD in combination with platinum)[23] or weekly paclitaxel with or without bevacizumab based on data from the AURELIA trial.[55] At any rate, serious consideration always should be given to patients with BMOC and platinum-resistant disease who have a 12-month or more platinum-free interval (perhaps through intervening PLD or weekly

taxol) to be retreated with carboplatin-based chemotherapy (or cisplatin, if needed because of hypersensitivity). Using this paradigm, patients with BMOC may benefit from multiple lines of platinum-based therapy. At the Royal Marsden, for example, a 55-year-old patient received 8 courses of platinum-based treatment over 10 years.

For platinum-sensitive recurrences, the choice of chemotherapy for patients with BMOC probably mirrors that of any patient with platinum-sensitive recurrent EOC. Nonetheless, the PLD/platinum or gemcitabine/platinum combination may be the preferred choices in view of the aforementioned data. Finally, Leunen et al reported a response rate of 100% and a median OS of 37 months in a small series of six patients with BMOC with recurrent platinum-sensitive EOC who were treated with dose-dense paclitaxel and carboplatin,[20] but more experience with the combination is necessary before any conclusions can be drawn.

WHAT EFFECT WILL THE RECENT REGULATORY APPROVAL OF PARP INHIBITORS HAVE ON THE CHOICE OF CHEMOTHERAPY FOR PATIENTS WITH BMOC WITH RELAPSED DISEASE?

The first PARPi, olaparib, is now approved for treating patients with BMOC by regulatory authorities in both the United States and Europe, but in two different clinical situations. In the United States, approval has been granted for patients with BMOC who have received at least three lines of prior chemotherapy (and may be platinum resistant). Given the level of efficacy seen, (response rate of 31% with median PFS of 7 months), it seems likely that olaparib will be increasingly used before any alternative chemotherapy in this situation.[56] Approval was not granted for maintenance treatment. Conversely in Europe, approval is granted only in the maintenance setting following the placebo-controlled trial in patients with platinum-sensitive relapse by Ledermann et al, in which patients in the BMOC subgroup had a 7-month prolongation in median PFS (HR < 0.0001).[57] Olaparib was given following, but not concurrently, with platinum-based chemotherapy.

This development leads to a major therapeutic dilemma for the clinician and the patient with platinum-sensitive relapsed BMOC, since two options are now available. The first would be the use of bevacizumab in line with the positive data in this context when used concurrently with gemcitabine/carboplatin, and as follow-on maintenance treatment, which demonstrated a PFS increase of 4 months (HR 0.48).[58] The second is the olaparib option described above. Both require carboplatin-based treatment. Presently, the bevacizumab option requires this to be gemcitabine-carboplatin, which has to be given at first platinum-sensitive relapse. For the olaparib maintenance therapy option, the carboplatin partner is not specified and the treatment could be used at any relapse, providing it fulfills the criteria for platinum sensitivity. It would, therefore, be tempting to suggest that bevacizumab should be used first; however, the next

relapse could conceivably be platinum-resistant. In Europe, but not in the United States, this would deprive the patient with BMOC of the opportunity to receive a PARPi. Thus, in Europe it might be tempting to recommend olaparib first because bevacizumab could be given later in the context of platinum resistance (where it is approved according to the AURELIA data[55]). However, if the next relapse in that situation was still platinum sensitive, bevacizumab could not be given. According to the current label, it only can be used for the first platinum-sensitive relapse. The dilemma in Europe is clear, and this common clinical scenario will require careful discussion with patients with BMOC when the choice of chemotherapy in the platinum-sensitive relapse situation occurs. One way forward is to consider carefully the platinum-free interval in these patients as a way of predicting whether the next relapse is likely to be platinum sensitive or platinum resistant. However, this is an inexact science. The situation will best be resolved when more data are available from further studies to permit a more uniform and flexible approach from the regulatory authorities in Europe and the United States.

WHAT EFFECT WILL THE USE OF A PARP INHIBITOR HAVE ON RESPONSE TO SUBSEQUENT CHEMOTHERAPY?

This is a particularly pertinent question in view of the previously discussed preclinical data suggesting that the development of PARPi resistance also may compromise benefit to subsequent chemotherapy, particularly platinum-based regimens, in patients with BMOC through the acquisition of reversion mutations in *BRCA1/2*.[15] A recently published study of chemotherapeutic response in patients with BMOC following progression on olaparib demonstrated a response rate of 36% (24 of 67 patients) by RECIST and 45% (35 of 78 patients) by RECIST and/or Gynaecologic Cancer Inter-Group (GCIG) CA125 criteria following postolaparib chemotherapy, with a median PFS and OS of 17 weeks and 34 weeks, respectively.[59] Response rates to platinum-based chemotherapy were 40% (19 of 48 patients) and 49% (26 of 53 patients), respectively, with a median PFS of 22 weeks and OS of 45 weeks. For patients who received single-agent paclitaxel, response rates were 40% (4 of 10 patients) by RECIST and 50% (5 of 10 patients) by RECIST and/or GCIG criteria. Patients who received postolaparib PLD had a 0% (0 of 5 patients) response by RECIST and 30% (3 of 10 patients) response by RECIST and/or GCIG criteria. Notably, no evidence of secondary *BRCA1/2* mutation was detected in tumor samples of six PARPi-resistant patients, suggesting that other yet to be determined mechanisms of resistance to PARPi may be involved. These data suggest that a proportion of BMOC tumors will retain chemosensitivity, particularly to platinum and paclitaxel despite progression on PARPi therapy. However, it is still not known completely how resistance to PARPi will affect the subsequent duration of chemotherapy response. To understand more fully the mechanistic interplay between PARPi and chemotherapy resistance, it will be important to systematically collect tumor samples and treatment outcome data to define the optimal chemotherapeutic options and relevant predictive biomarkers for patients with BMOC in the post-PARPi setting.

CONCLUSIONS: CHEMOTHERAPY FOR PATIENTS WITH *BRCA1/2* MUTATION AND OVARIAN CANCER: SAME, BUT DIFFERENT

The hallmarks of BMOC are a high response rate to platinum-based chemotherapy at first and subsequent relapses, long treatment-free intervals between relapses, and improved OS. These features describe the clinical signature of BRCAness in the context of EOC; however, so far they have been less well documented in other *BRCA1/2*-mutant carrier– related cancers including breast, pancreatic, and prostate cancer. This suggests that the context of the *BRCA1/2*-mutant genotype has a significant bearing on disease behavior and outcome. Nonetheless, very encouraging data on responses to PARPi in *BRCA1/2*-mutant carriers with prostate,[60] pancreatic,[56,61] and breast cancer[62] have been reported and are likely to be associated with platinum sensitivity.[63] It remains to be seen if an assay for HR-deficiency can be identified that will predict for platinum and PARPi sensitivity in a broad range of cancers. In the meantime, however, it is clear that establishing the germ-line and/or tumor *BRCA1/2* mutation status in patients with cancers known to be associated with *BRCA1/2* mutations is of paramount importance because of the potential therapeutic options.

Our recommendations for chemotherapy for patients with BMOC are generally based on retrospective analyses, with a primary emphasis on rechallenging these patients with platinum-based treatment and prolonging the platinum-free interval in the event of early relapse following platinum-based treatment. The welcome arrival of using PARPi to treat patients with BMOC also provides an additional initial factor to consider within the context of relapsed disease. Hence, although a majority of treatment options remain the same for both patients with BMOC and with non-BMOC, the timing and sequence of therapy, and the indications for rechallenging patients with platinum-based chemotherapy, and perhaps even routes or schedules of administration (IV vs. IP, weekly vs. thrice weekly) are likely to differ as more data emerges from post hoc analyses of the mutation status of *BRCA1/2* and other HR-related genes in tumor samples from previously completed studies. Moreover, stratification based on HR-deficiency phenotype/genotype may become the standard in upcoming prospective clinical trials involving patients with EOC and that will be highly informative in this respect. Further work to dissect the precise relationship between *BRCA1/2*-mutation genotype and clinical phenotype also will be crucial to delineate the best treatment options in the future for patients with BMOC.

Research Progress in Head and Neck Squamous Cell Carcinoma: Best Abstracts of ICHNO 2015

Panagiota Economopoulou, MD, PhD, Jean Bourhis, MD, PhD, and Amanda Psyrri, MD, PhD

OVERVIEW

Head and neck squamous cell carcinoma (HNSCC) is a highly heterogeneous group of tumors that develop via one of the two primary carcinogenic pathways: chemical carcinogenesis through exposure to tobacco and alcohol or virally induced tumorigenesis. HPV-negative (HPV−) and HPV-positive (HPV+) HNSCCs represent distinct disease entities, and the latter is associated with a substantially improved outcome. Differences in molecular pathogenesis account for these different outcomes; their staging classification and therapeutic regimens also are currently being re-evaluated, and re-evaluation would be significantly facilitated by robust biomarkers for patient stratification. Through the past years, with the advent of the omics era, a better understanding of the biology of HNSCC has been accompanied by the exploration of a large and rapidly expanding number of targeted agents, which might be incorporated into standard management in the future. In the era of personalized medicine, and with a view to improve the outcomes and quality of life of patients, current research efforts also are focused on the identification of specific biomarkers for treatment selection. Treatment of HNSCC is expected to change in the next decade if molecular biology continues to evolve. Herein, we highlight research progress in HNSCC presented at the fifth International Conference on Innovative Approaches in Head and Neck Oncology (ICHNO).

Squamous cell carcinoma of the head and neck represents a heterogeneous group of tumors, which encompasses a variety of tumors originating in the lip/oral cavity, hypopharynx, oropharynx, nasopharynx, or larynx. Locally advanced HNSCC includes stage III or IV A,B carcinomas that invade proximate structures or spread to cervical lymph nodes, whereas recurrent/metastatic (R/M) HNSCC involves tumors that present with locoregional recurrence or distant metastases.[1] HNSCC historically has been associated with tobacco and alcohol use; however, in the past decade, infection with high-risk HPV and especially with HPV type 16 (HPV16) has been implicated in the pathogenesis of a growing subset of HNSCCs, mainly those arising from the oropharynx.[2,3] HPV-related oropharyngeal carcinoma has emerged as a distinct entity in terms of etiology, biology, and clinical behavior; importantly, it has a more favorable prognosis and might require less intensive therapy. Despite advances and innovations in multimodality treatment and a better understanding of head and neck carcinogenesis, survival rates of locally advanced HNSCC have not substantially improved, and the prognosis for R/M disease remains very dismal.[4] The ultimate goal in the treatment of patients with HNSCC is to enhance efficacy while minimizing treatment-related toxic effects.

Current research in HNSCC focuses on the establishment of novel treatment approaches, such as immunotherapy and molecular targeted therapy; the identification of biomarkers for prognostic classification and treatment selection; optimization of surgical techniques; management of treatment-related side effects; and implementation of screening methods. This year, several interesting studies presented at the fifth ICHNO shared important information, with potential implications in the management of HNSCC. The results of a randomized phase III study comparing afatinib with methotrexate as a second-line therapy in patients with R/M disease after platinum therapy showed a significant but modest benefit of 0.9 months (p = 0.03) in terms of progression-free survival (PFS; the primary endpoint of the study) in favor of afatinib arm.[5] An individual-patient meta-analysis of chemotherapy in nonmetastatic nasopharyngeal carcinoma (MAC-NPC) that included 4,806 patients suggests that incorporating induction chemotherapy or adjuvant chemotherapy to chemoradiotherapy may further improve the outcome in terms of tumor control probability and survival compared with chemoradiotherapy alone.[6] A randomized phase III study randomly assigned patients with HNSCC who were treated with curative surgery and whose tumors had high-risk pathologic features (positive margins or extracapsular extension) to receive either standard postoperative radiotherapy (SPORT) or postoperative accelerated radiotherapy (POPART); the results suggest that a reduction in the overall treatment time in this setting does not improve the

outcome in terms of locoregional control, PFS, and overall survival (OS).[7] One study demonstrated that genomic analysis in R/M HNSCC enables an assessment of the molecular profile in 38% of patients and might guide targeted treatment selection.[8] Preclinical data support the combination of HPV vaccines with anti-programmed cell death protein 1 (anti-PD-1)– blocking antibodies to enhance the response to immunotherapy.[9] Finally, a large cohort study indicated that the current TNM (turmor, node metastasis) staging system is not suitable for HPV-associated HNSCC.[10]

HPV-ASSOCIATED OROPHARYNGEAL CANCERS
Therapeutic HPV Vaccine Increases Sensitivity of Poorly Immunogenic Tumor to Anti-PD-1 Monotherapy

The immune system plays an important role in cancer development, because tumor cells have the ability to evade immunosurveillance through a variety of different mechanisms, including reduced expression of tumor antigens, secretion of immunosuppressive cytokines such as transforming growth factor (TGF) beta, recruitment of immunosuppressive cells such as regulatory T cells (Tregs), and overexpression of certain ligands, such as programmed cell death ligand 1 (PD-L1).[11] PD-L1 binds to the PD-1 receptor and activates the PD-1 checkpoint pathway, which blocks the immune response by downregulating T-cell effector functions.[12] Several lines of evidence underscore the crucial role of an intact immune system in controlling HPV infection and its associated lesions. First, most healthy individuals infected with HPV are capable of clearing the infection, and they do not develop clinical manifestations.[13,14] Only a minority of infected individuals is not capable of clearing the virus and subsequently develops HPV-associated lesions. Second, immune cell infiltrates frequently are found in HPV-associated regressing lesions, whereas these cell types are absent in persistent lesions.[15] Finally, immunocompromised individuals, such as HIV-infected people, have documented higher rates of HPV infection and associated lesions.[16] Because the immune system plays a pivotal role in controlling HPV infection, therapeutic vaccine strategies have been developed. Therapeutic vaccines are aimed to treat HPV-infected cells, and this can be accomplished by inducing a cellular T-cell immune response that can recognize and eliminate these HPV-infected cells.[17]

HPV16 E6 and E7 proteins are ideal targets for cancer immunotherapy. HPV16 E6 and E7 are foreign viral proteins and are more immunogenic than a self-protein overexpressed in cancer cells. Furthermore, they are continuously expressed by all virus-infected cells.[18] Thus, DNA vaccines, viral vector vaccines, bacterial vector vaccines, peptide vaccines, and cell-based vaccines are attractive targets for investigation. DNA vaccines are promising candidates for therapeutic HPV vaccination in HPV-associated oropharyngeal carcinoma (OSCC).[19] Strategies to increase the activity of vaccines include using alternative administration routes, eliminating the immunosuppressive tumor microenviroment, and combining the vaccine with chemotherapy. In patients with HPV-associated oropharyngeal cancers, a high frequency of Tregs that inhibit cellular immune response often are found in tumor biopsies.[20] In addition, Lyford-Pike et al[21] demonstrated that the PD-1/PD-L1 pathway is involved in immune resistance of HPV-associated HNSCC.[21] PD-1 antibodies that inhibit the interaction between PD-1 and PD-L1 currently are being evaluated in clinical trials in a variety of cancers, leading to renewed enthusiasm for immunotherapy as a treatment modality. Pembrolizumab and nivolumab have been approved recently for the treatment of metastatic malignant melanoma.[22,23] The clinical response to anti-PD-1 antibodies has correlated with PD-L1 expression and with the presence of tumor-infiltrating lymphocytes in several tumors, including HNSCC.[24] Furthermore, novel anti-PD-L1 antibodies also are being evaluated in clinical trials in HNSCC. In this setting, Pai et al[9] suggested that a possible strategy to enhance responses to immune checkpoint blockade might be attenuation of immune responses to the host tumor by combining the HPV vaccine with a PD-1 antibody.[9] This strategy may facilitate PD-1 blockade–induced T-cell function restoration. The authors created a mouse model, with subcutaneous inoculation of tumor cells, that was poorly immunogenic and resistant to anti-PD-1 antibody; subsequently, they evaluated the impact of an HPV vaccine on improvement or response rates to anti-PD-1 blockade. The mice then were treated with either anti-PD-1–blocking antibody, CRT/E7 (detox) DNA vaccine, or a com-

KEY POINTS

- In vivo preclinical data suggest that HPV vaccination could act as an immune-stimulating agent resulting in improvement of response rates of HPV-positive oropharyngeal cancers to anti-PD-1 checkpoint inhibitor.
- A better-designed staging system of HPV-positive carcinoma that also encompasses prognostic factors such as age and tobacco use could alter treatment of these patients.
- A reduction in the overall treatment time of postoperative radiotherapy in patients with head and neck squamous cell carcinoma (HNSCC) with adverse factors for locoregional failure does not improve outcomes in terms of locoregional control, progression-free survival, and overall survival.
- LUX-Head and Neck 1 clinical trials comparing the efficacy of afatinib as monotherapy compared to single-agent methotrexate as second-line treatment in HNSCC met its primary endpoint showing an increase in progression-free survival of 0.9 months with afatinib compared to methotrexate, but in practical terms this modest effect is of unknown clinical importance.
- An individual patient data network meta-analysis of the treatment of nonmetastatic nasopharyngeal carcinoma suggests that incorporating induction chemotherapy or adjuvant chemotherapy to chemoradiotherapy may further improve the outcome in terms of tumor control probability and survival over chemoradiotherapy alone.

bination of anti-PD-1 and CRT/E7 (detox) DNA vaccine. It was found that the administration of an HPV vaccine led to augmentation of vaccine-induced CD8[+] T cells that express the PD-1 receptor. Concomitant upregulation of PD-L1 expression caused by the vaccine rendered tumor cells resistant to vaccine-induced cytotoxic T-cell killing, which was restored with anti-PD-1 treatment. Importantly, mice treated with combination of the two agents displayed better overall survival.[9] These in vivo preclinical data clearly suggest that HPV vaccination could act as an immune-stimulating agent, resulting in the improvement of response rates to an anti-PD-1 checkpoint inhibitor; this strategy deserves further study in a clinical trial setting.

Refining the UICC TNM Staging System Stage and Prognostic Groups for Nonmetastatic HPV-Related OSCC

As previously mentioned, OSCC includes two distinct entities: tobacco-alcohol associated OSCC, which is described as HPV– and HPV+ OSCC caused by persistent HPV infection. HPV+ OSCC is characterized by different clinical behavior; it commonly presents at an early T stage with extensive nodal involvement. On the basis of clinical presentation, distant metastasis could be a concern in HPV+ OSCC, as nodal infiltration at diagnosis is known to reduce 5-year survival by 50%. Nevertheless, HPV-related OSCC is associated with a better prognosis and might require different treatment.[2,25,26] Despite differences in clinical behavior between the two entities, the TNM staging system classification proposed by the American Joint Committee on Cancer (AJCC) is the most commonly used staging system in both HPV+ and HPV– HNSCC. Based on these observations, O'Sullivan et al[10] designed a large cohort study in an attempt to refine stage grouping for nonmetastatic OSCC and to develop several prognostic subgroups reflecting the different biology of the tumor that could be incorporated in the staging system.[10] In total, 537 patients with HPV+ OSCC and 237 patients with HPV– OSCC were included in the study. OS was compared among TNM stages for HPV+ and HPV– cases separately. Two different modeling methods were explored to derive a better stage schema for HPV+ disease: recursive partitioning analysis (RPA) derived new RPA stages objectively, and Cox regression was used to calculate an adjusted hazard ratio (AHR) to derive AHR stages. With a median follow-up time of 5.1 years, a lower 5-year OS with a higher TNM stage was observed in HPV– but not in HPV+ cases. In addition, RPA group, age, and smoking pack-years history derived four valid groups for survival: group I (T1 to T3N0 to N2c and 20 or fewer pack-years history), group IIa (T1 to T3N0 to N2c and more than 20 pack-years history), group IIb (T4 or N3, age 70 or younger), and group III (T4 or N3, older than age 70). The 5-year OS rates for the respective groups were 89%, 64%, 57%, and 40% (p < 0.001, Cox regression).[10] These results have potential implications in clinical practice, because a better-designed staging system of HPV+ disease that also encompasses prognostic factors, such as age and tobacco use, could alter management of the

HPV+ OSCC. However, these findings should be validated in large cohorts.

LOCALLY ADVANCED HEAD AND NECK SQUAMOUS CELL CARCINOMA
POPART versus Conventional Postoperative Radiotherapy (CPORT) in HNSCC

Final results of a multicenter prospective randomized study of the Dutch Head and Neck Cooperative Study Group results are reviewed.

In HNSCC, the overall treatment time (OTT) of radiation is significantly associated with locoregional control (LRC; p = 0.013), which is consistent with rapid repopulation of cancer clones during radiotherapy (RT).[27] However, the importance of the OTT in the postoperative setting is not well defined. Langendijk et al[7] conducted a phase III study to determine the value of reduction of the OTT of postoperative RT in high-risk patients primarily treated with curative surgery.[7] Patients with HNSCC treated with curative surgery who had high-risk factors for locoregional recurrence (i.e., positive surgical margins and/or extracapsular extension) were randomly assigned to receive either SPORT at 2 Gy/fraction/day on 5 days/week to 66 Gy/33 fractions/7 weeks or POPART with 2 Gy/fraction/day on 5 days/week to 20 Gy followed by 1.8 Gy/fraction/day and 1.3 Gy/fraction/day to a boost field as a second daily treatment to 66.5 Gy/40 fractions/5 weeks.[7] The primary endpoint was LRC. Secondary endpoints were OS, PFS, acute and late toxicity, and quality of life. From November 2004 to August 2009, 148 patients were enrolled in the study (SPORT, 74 patients; POPART, 74 patients). The median follow-up time was 6.2 years. The two study arms were well balanced with regard to the most important prognostic factors. No significant differences were noted with regard to acute and late toxicity, although there was a trend toward more use of pain medication among patients treated with POPART. At 3 years, the LRC rate was 76.5% (95% CI, 67.0% to 87.4%) after POPART compared with 74.2% (95% CI, 64.6% to 85.0%) with SPORT (hazard ratio [HR] 0.75; 95% CI, 0.40 to 1.43; p = 0.39). No difference was found with regard to PFS (HR 0.74; 95% CI, 0.49 to 1.13; p = 0.16). The median PFS times were 42.6 months (95% CI, 31 to 78.3 months) for SPORT and 60.5 months (95% CI, 34.6 months to not achieved [NA]) for POPART. The disease-free survival probability at 8 years was 43.8% for SPORT (95% CI, 33.8% to 57.0%) and 51% for POPART (95% CI, 40.7% to 63.8%). No statistical difference was noted in the long term between the two arms. The 8-year overall survival rate was 46.0% for POPART compared with 33.1% for SPORT (HR 0.82; 95% CI, 0.53 to 1.28; p = 0.39).[7] These results suggest that a reduction in the OTT of postoperative RT in patients with HNSCC who have adverse factors for locoregional failure does not improve outcome in terms of LRC, PFS, and OS.

RECURRENT/METASTATIC HEAD AND NECK SQUAMOUS CELL CARCINOMA

Afatinib versus Methotrexate as Second-Line Therapy in Recurrent/Metastatic HNSCC after Platinum Therapy: LUX Head and Neck 1

For patients with R/M HNSCC, the recommended first-line treatment is combination platinum/fluorouracil with or without cetuximab for fit patients.[1] Limited options are available for second-line therapy, and, unfortunately, a small proportion of patients are fit enough to be suitable candidates for second-line therapy. The epidermal growth factor receptor (EGFR), a transmembrane tyrosine kinase receptor belonging to the HER/ErbB family, is a longstanding, challenging target in HNSCC, which is overexpressed in up to 90% of cases; overexpression of EGFR also correlates with poor clinical outcomes.[28,29] Cetuximab, a chimeric immunoglobulin G1 human monoclonal antibody against the extracellular domain of EGFR, has emerged as a powerful tool in the treatment of R/M head and neck cancer, and it is the only targeted agent currently approved for HNSCC. In the EXTREME (erbitux in first-line treatment of recurrent or metastatic head and neck cancer) study, the addition of cetixumab to platinum-based chemotherapy with fluorouracil was shown to improve OS, PFS, and response rates.[30] However, cetuximab has demonstrated modest response rates when used as monotherapy.[31] Afatinib, an oral irreversible ErbB family blocker that inhibits all kinase-active members (EGFR, HER2, and HER4), and which is currently approved for the treatment of *EGFR*-mutated non–small cell lung cancer,[32] has shown similar clinical activity to cetuximab in R/M HNSCC in a recent phase II trial.[33] On the basis of these results, the phase III LUX Head and Neck 1 clinical trial presented at the 2014 European Society of Medical Oncology Congress assessed the efficacy of afatinib as monotherapy compared with single-agent methotrexate as second-line treatment in HNSCC.[5] Patients were stratified according to performance status (PS) and prior use of cetuximab. The study met its primary endpoint, showing an increase in PFS of 0.9 months with afatinib compared with methotrexate (2.6 vs. 1.7 months; HR, 0.8; p = 0.03). In addition, it showed improvement in tumor shrinkage and response rate in favor of afatinib, whereas no improvement in OS with afatinib versus methotrexate was noted. Grades 3 and 4 treatment-related adverse events were skin rash (9.7%) and diarrhea (9.4%) with afatinib and stomatitis (8.1%) and neutropenia (6.9%) with methotrexate. A significant delay in the deterioration of global health status, pain, and swallowing was noted with afatinib. In practical terms, the difference in PFS of 0.9 months is of unclear significance and is unlikely to lead to drug approval.[5] However, this study is important, because it is the second study since the EXTREME trial that showed a benefit of a novel agent in HNSCC and the first study to demonstrate an active oral, targeted agent in HNSCC. Of note, subgroup analysis showed a benefit primarily seen in cetuximab-naive patients, which suggested a degree of cross-resistance that was not seen in phase II studies. Ongoing studies evaluating adjuvant afatinib in locally advanced HNSCC after chemoradiotherapy (LUX Head and Neck 2) hopefully will clarify the role of afatinib in HNSCC; until then, an active search for predictive biomarkers might lead to the identification of specific groups of patients who derive benefit from afatinib.

Molecular Screening for Cancer Treatment Optimization in Head and Neck Cancer: MOSCATO 01

In the era of personalized medicine, there is a push toward utilizing next-generation sequencing to identify driver mutations in individual tumors. The identification of driver molecular alterations in individual tumors may allow personalization of cancer therapy. Targeted agents matched with tumor molecular alterations were associated with improved outcomes compared with nonmatched therapy in patients who had advanced cancers, in some studies.[34] Recently, four whole-exome sequencing studies conducted in 190 HNSCC specimens shed light onto the molecular pathogenesis of HNSCC, identifying key mutations of several tumor suppression genes, such as *TP53* (60%), *CDKN2A* (9% to 74%), *PI3KCA* (8% to 20%), *Notch* (9% to 19%) and *PTEN* (13.6%).[35-38] These studies revealed, for the first time, the presence of novel inactivating mutations in tumor suppressor genes that regulate cellular squamous differentiation within the normal stratified squamous epithelium, such as *NOTCH1*, *TP63*, and *FBXW7*, as driver genetic events of neoplastic transformation in the head and neck area. Elucidation of the mutational spectrum of HNSCC is anticipated to have a great impact on the treatment of the various subtypes of the disease according to the constellation of targetable driver genetic events. In a prospective study that included 78 heavily pretreated patients with HNSCC, biopsy specimens obtained from the primary or metastatic tumor sites were subjected to comparative genomic hybridization and next-generation sequencing for up to 74 target genes (10% tumor cells required).[8] A weekly molecular tumor board reviewed the results of the molecular analysis to identify actionable molecular alterations for which the most relevant targeted therapy may be available through early clinical trials or approved drugs. In 30 of 78 heavily pretreated patients included in the MOSCATO 01 trial, actionable molecular aberrations were encountered and were defined as aberrations with significant prognostic and therapeutic implications for specific drugs currently used in other cancers. One-third of those patients were treated with a targeted therapy according to the molecular profile. Among patients treated on the basis of the genomic profile, three attained partial response, three had stable disease, one developed disease progression, and two were not evaluable. In this study, actionable molecular aberrations were observed in the following pathways: fibroblast growth factors (FGFs) and their receptors (FGFRs; 35%), phosphoinositide 3-kinase (PI3K)/AKT/mammalian target of rapamycin (mTOR) (26%), *MYC* (24%), CDKs/Cyclins (13%), *EGFR* (9%), *HER2* (7%), *Notch* (4%), and *KIT* (2%).[8] This study shows early results of a personalized medicine strategy in R/M HNSCC, and further results will be awaited with great interest. It is important to emphasize, however, that implementing a personalized cancer medicine program requires adequate tumor tissue available for molecular characterization; a standardized, high-quality laboratory for molecular profiling to ensure the accuracy, reliability, and timeliness of

patient test results; identification of targetable molecular aberration; and the availability of a targeted drug known to inhibit the function of the molecular alteration.[39] High-throughput sequencing technology provides the means to conduct a comprehensive analysis of all somatic alterations in the cancer genomes. However, interpretation of the large amount of genomic data that emerge from these genome-scale investigations for the development of new therapeutic strategies requires the efficient validation of genomic data and the characterization of mutations. It is important to determine whether the identified mutations are responsible for disease pathogenesis (driver mutations) or have been generated as the consequence of genomic instability but without obvious advantage to the cancerous cells (benign mutations). To address the challenge of fragmentation of cancer research in Europe that generates difficulties in translating preclinical discoveries into benefits that improve patients' lives, the Eurocan Plus project aims for the establishment of a European platform for translational cancer research by linking comprehensive cancer centers and basic/preclinical research centers.[39] The Eurocan Platform project was approved by the European Commission in 2010 and aims to develop a consortium for translational cancer research by linking 23 cancer research centers and five European cancer organizations. One of the most important aims is to promote personalized cancer medicine that is based on the better understanding of the biology of the tumor and normal tissues so that personalized treatment can be applied at an early stage of the disease. Furthermore, prevention strategies should be established in cancer biology to identify and target high-risk individuals.

NASOPHARYNGEAL CANCER
What Is the Best Treatment in Nasopharyngeal Carcinoma? An Individual Patient Data Network Meta-Analysis

With the improvement in local control accomplished by more precise imaging and RT, the predominant pattern of failure for nasopharyngeal carcinoma (NPC) is distant metastases. Concurrent cisplatin and RT with or without adjuvant PF (cisplatin/

fluorouracil) chemotherapy is the standard treatment approach for stages IIB and above disease.[1] The role of induction chemotherapy is not well defined. MAC-NPC presented the results of network meta-analysis, which allows one to perform simultaneous inference regarding the treatments and select the best among them.[6] Nineteen trials of RT with or without chemotherapy in 4,806 patients with nonmetastatic NPC were identified, and updated individual patient data were obtained. Treatments were grouped in the following categories: RT alone (RT), induction chemotherapy (IC) followed by concomitant chemoradiotherapy (IC-CRT), concomitant chemoradiotherapy (CRT), or concomitant chemoradiotherapy followed by adjuvant chemotherapy (CRT-AC). For the entire network, CRT-AC ranked as the best treatment in terms of OS, with a probability of 94%.[6] The probability that either CRT-AC or IC-CRT was the best treatment was 97% for OS, 96% for PFS, 81% for locoregional failure-free survival, and 93% for distant metastasis-free survival. When the network was restricted to cisplatin-based trials, as a sensitivity analysis, CRT-AC and IC-CRT remained the best treatments regarding PFS and OS.[6] This network meta-analysis of the treatment of nonmetastatic NPC suggests that incorporating IC or AC to CRT may further improve the outcome in terms of tumor control probability and survival versus CRT alone. Of course, as the authors point out, these results should be validated by well-powered randomized trials.

CONCLUSION
HNSCC comprises a heterogeneous disease in terms of epidemiology, etiologic factors, and clinical and biologic behavior. HPV status is the most important biomarker in this disease. Research efforts concentrate on identification of prognostic and predictive biomarkers for the personalization of treatment, deintensification of treatment to reduce late toxicity in good-prognosis HPV+ subsets, and the discovery of new treatments in poor-prognosis HPV− HNSCC. Immunotherapy, such as checkpoint inhibitors, is being explored as treatment strategy in HNSCC in different settings. In Europe and the United States, research funding for new treatments in HNSCC is rather limited, and progress against this disease has been difficult. Intergroup efforts may allow the execution of large, randomized trials that will improve the outcome of this devastating disease.

Targeting the PI3K Pathway in Head and Neck Squamous Cell Carcinoma

Pedro Henrique Isaacsson Velho, MD, Gilberto Castro Jr, MD, PhD, and Christine H. Chung, MD

OVERVIEW

Head and neck squamous cell carcinoma (HNSCC) is a heterogeneous disease arising from the mucosal epithelia in the head and neck region. The most common risk factors are tobacco use, alcohol consumption, and HPV infection, particularly in the oropharynx. The HPV-positive HNSCC is biologically and clinically distinct from the HPV-negative HNSCC; however, deregulations within the phosphatidylinositol 3-kinase (PI3K) pathway are frequent in both HPV-positive and HPV-negative HNSCC as it is the most frequently altered oncogenic pathway with a gain-of-function in HNSCC. This article reviews the basic biology and clinical data from the trials involving anticancer agents targeting the PI3K pathway in HNSCC. It also discusses the difficulties of translating the preclinical data to tangible clinical efficacy of these agents in patients with HNSCC even when there is significant preclinical data suggesting the PI3K pathway is a promising therapeutic target in HNSCC. We conclude that additional studies to determine appropriate patient selection for the activation of PI3K pathway and to develop targeted agents either as a monotherapy or combination therapy with favorable toxicity profiles are required before a broader clinical application.

Head and neck squamous cell carcinoma is a heterogeneous disease originating from the mucosal epithelia in the head and neck region, most commonly the oral cavity, oropharynx, hypopharynx, and larynx. The risk factors are tobacco use, alcohol consumption, and HPV infection, particularly in the oropharynx.[1,2] The HPV-positive HNSCC is now established as a separate entity with distinct clinical characteristics, including younger age of onset, better performance status, less smoking history, and its association with high-risk sexual behaviors compared to the HPV-negative HNSCC.[3,4] In addition, the HPV-positive HNSCC has a distinct molecular profile compared to the HPV-negative HNSCC, including lack of *TP53* and *CDKN2A* mutations; however, mutations or copy number variations of genes within the PI3K pathway are frequent in both HPV-positive and HPV-negative HNSCC as it is the most frequently altered oncogenic pathway with a gain-of-function in HNSCC.[5] This article reviews the basic biology and clinical data from trials involving the PI3K pathway inhibitors in patients with HNSCC.

BASIC BIOLOGY OF THE PI3K PATHWAY

P13Ks are divided into three classes: class I, II, and III. The differences in these classes are comprehensively reviewed by Thorpe et al.[6] Class I is further divided into subclass IA and

IB in mammals. Class IA PI3Ks are heterodimeric kinases consisting of a p110 catalytic subunit (p110-alpha, p110-beta, and p110-delta encoded by *PIK3CA*, *PIK3CB*, and *PIK3CD*, respectively) and a p85 regulatory subunit (p85-alpha and its splice variants, p55-alpha and p50-alpha, encoded by *PIK3R1*; p85-beta encoded by *PIK3R2;* and p55-gamma encoded by *PIK3R3*). These three p110 catalytic subunit isoforms can form a heterodimer with any of the five p85 regulatory subunits. Class IB PI3Ks are heterodimeric kinases consisting of a p110-gamma catalytic subunit encoded by *PIK3CG* and a p101 or p87 regulatory subunit encoded by *PIK3R5* and *PIK3R6,* respectively. Unlike class I PI3Ks, class II PI3Ks are monomeric lipid kinases without a regulatory subunit. There are three class II isoforms, including PI3K-C2-alpha, PI3K-C2-beta, and PIK3-C2-gamma encoded by *PIK3C2A, PIK3C2B,* and *PIK3C2G*, respectively. VPS34 is the sole Class III PI3K encoded by *PIK3C3* and forms a heterodimer with VPS15 encoded by *PIK3R4.*

Activation of the PI3K signaling pathway is highly regulated. PI3K activation is initiated by activated receptor tyrosine kinases such as ErbB family receptors, fibroblast growth factor receptors, insulin-like growth factor 1 receptor and others, as well as G protein-coupled receptors.[6,7] On activation, class I PI3Ks translocate to the plasma membrane where inhibition by the p85 regulatory subunit is relieved, and the p110 catalytic subunit catalyzes the phosphorylation

FIGURE 1. The PI3K Network

Class I PI3Ks are heterodimeric kinases consisting of a p110 catalytic subunit (class 1A-p110-alpha, p110-beta, and p110-delta, and class 1B-p110-gamma proteins) and a p85 regulatory subunit. PI3Ks are activated by receptor tyrosine kinases and GPCRs. PI3Ks phosphorylate PIP_2 to PIP_3, which functions as a second messenger. PIP_3 acts by recruiting downstream protein kinases, such as PDK1 and AKT, to the cell membrane that results in their activation. Subsequently, further downstream signaling network is activated and influence important cellular functions, such as cell proliferation, cell cycle, metabolism, and cell survival.

Abbreviations: 4EBP1, 4E binding protein 1; BCL-2, B-cell lymphoma 2; EEF2K, eukaryotic elongation factor-2 kinase; EIF4B, eukaryotic translation initiation factor 4B; ERK, extracellular signal-regulated kinase; FASL, Fas ligand; GPCR, G-protein coupled receptor; IRS1, insulin receptor substrate 1; mTOR, mammalian target of rapamycin; PI3K, phosphatidylinositol 3-kinase; PIP_2, phosphatidylinositol-4,5-bisphosphate; PIP_3, phosphatidylinositol-3,4,5-trisphosphate; PTEN, phosphatase and tensin homolog; RICTOR, rapamycin-insensitive companion of mTOR; RPS6, ribosomal protein S6; SGK3, serine/threonine-protein kinase 3; TSC, tuberous sclerosis protein.

of phosphatidylinositol 4,5-bisphosphate (PIP_2) to phosphatidylinositol 3,4,5-trisphosphate (PIP_3). In turn, PIP_3 acts as a second messenger and triggers AKT-dependent and AKT-independent signaling pathways (Fig. 1).[6-8] Activated AKT further phosphorylates downstream targets, including mammalian target of rapamycin (mTOR),[9] a master regulator of cellular proliferation, metabolism, and protein translation. Activation of the PI3K pathway is negatively regulated by a lipid phosphatase, phosphatase and tensin homolog (PTEN), which catalyzes the dephosphorylation of PIP_3 to PIP_2 and governs numerous cellular processes.[10] Although class I PI3Ks are extensively studied, physiological roles of class II and class III PI3Ks are poorly understood; therefore, they will

not be discussed in this review because they are beyond the scope of this article.

THE PI3K PATHWAY DEREGULATION IN HEAD AND NECK SQUAMOUS CELL CARCINOMA

With advancements in sequencing technology, HNSCC have been extensively sequenced through whole-genome sequencing, whole-exome sequencing, and targeted sequencing of cancer-related genes.[5,11-14] Collective data estimate the mutations and/or copy number variations of *PIK3CA* are detected in 32% of HNSCC (130/480 [27%] of HPV-negative and 63/171 [37%] of HPV-positive HNSCC).[14] Furthermore, a loss of *PTEN*, the PI3K negative regulator, also is frequently seen in patients with HNSCC, resulting in unrestrained activation of the pathway. Earlier studies showed 14% to 40% of patients with HNSCC to have *PTEN* loss of function because of a loss of heterozygosity or mutation, whereas recent tumor DNA sequencing studies show mutations or copy number variations in approximately 11% of HPV-positive and 5% of HPV-negative HNSCC.[14-16] When the mitogenic pathways (MAPK, JAK/STAT, and PI3K) relevant to HNSCC were evaluated, genes in the PI3K pathway were most frequently altered (30.5%).[17] In addition to the detectable genomic alteration by tumor sequencing, sufficient data suggest that deregulation of the PI3K pathway plays an important role in the development and metastasis of HNSCC associating with poor prognosis.[17-20]

For patients with HPV-positive HNSCC, recent studies also have demonstrated that epidermal growth factor recep-

KEY POINTS

· Deregulations within the phosphatidylinositol 3-kinase (PI3K) pathway are frequent in both HPV-positive and HPV-negative HNSCC.
· *PIK3CA* is the most commonly mutated oncogene in HNSCC.
· There are numerous clinical trials involving PI3K and mammalian target of rapamycin (mTOR) inhibitors, but clinical benefits of these agents in unselected patients with HNSCC are unclear.
· Predictive biomarkers of PI3K and mTOR inhibitor response are still under development.
· Further studies are required to develop the PI3K pathway targeted agents with favorable toxicity profiles.

tor (EGFR) and PI3K signaling are required for the viral entry into the cells that may be pertinent in this HNSCC subtype.[21,22] Pretreatment of patients with keratinocytes or cervical cancer cells in vitro with an EGFR inhibitor (gefitinib) and two different PI3K inhibitors (PI-103 and wortmannin) is sufficient to inhibit HPV-16 endocytosis and capable of preventing viral entry. In addition, PI3K/mTOR activation and suppression of autophagy in the early stages of patients with HPV16 infection are crucial for viral entry and infection.[22] Following HPV infection, the PI3K pathway appears to play an important role in established HPV-positive HNSCC as well. Gene-expression profile analysis of HNSCC has determined that HPV-positive HNSCC upregulates genes within the 3q26–29 chromosomal region, which is the locus containing *PIK3CA*. Further analyses by RT-PCR and reverse phase protein arrays confirm that *PIK3CA* is upregulated in patients with HPV-positive HNSCC compared to HPV-negative HNSCC.[20,23]

CLINICAL DEVELOPMENT OF PI3K INHIBITORS IN HEAD AND NECK SQUAMOUS CELL CARCINOMA

As *PIK3CA*, which encodes the catalytic subunit of PI3K, is overall the most frequently altered oncogene in human cancers, numerous PI3K-targeted agents currently are in clinical development. In a preclinical study using HNSCC patient tumor-derived xenografts (PDXs), PDXs harboring *PIK3CA* mutations were shown to be more sensitive to the PI3K and mTOR dual inhibitor, NVP-BEZ235, as compared with those lacking *PIK3CA* mutations.[17] Encouraged by the efficacy data seen in preclinical models such as these PDX studies, a number of clinical trials in patients with HNSCC currently are underway to evaluate the efficacy of small molecules that inhibit key points of this pathway (Table 1).

PI3K inhibitors are under evaluation as a monotherapy or in combination with previously established radiation and/or chemotherapy regimens in patients with HNSCC. PI3K inhibitors, such as buparlisib, BYL-719, or PX-866, are being investigated in phase II trials in patients with HNSCC in combination with chemotherapy or cetuximab. PI3K and mTOR share similarities in their kinase domain. Some compounds are developed to inhibit Class I PI3K isoforms, as well as mTORC1 and mTORC2, and many of these multikinase inhibitors are in clinical development (e.g., NVP-BEZ235).[24] However, although the biologic rationale is strong for the use of PI3K inhibitors, the efficacy of these agents presently is unclear in unselected patients with HNSCC. In a randomized phase II trial in recurrent and/or metastatic patients with HNSCC, PX-866 was administered with cetuximab, and it showed no evidence of clinically meaningful benefits.[25] Eighty-three patients were randomly assigned 1:1 to receive cetuximab once a week with or without PX-866; there were no complete responses. The objective response rates were 10% in the combination therapy and 7% in the cetuximab monotherapy, without any differences in disease control rates (55% vs. 56%), median progression-free survival (80 days for both groups), and overall survival (211 days in the PX-866 and cetuximab arm vs. 256 days in the cetuximab alone arm).

In addition, although there was no clear benefit of adding PX-866 in these previously heavily treated patients with HNSCC, the toxicities were more pronounced in the combination arm compared to the cetuximab alone arm. These toxicities included worse nausea (53% vs. 23%), vomiting (45% vs. 15%), fatigue (43% vs. 23%), diarrhea (40% vs. 21%), rash (45% vs. 31%), hypokalemia (25% vs. 10%), and dysphagia (18% vs. 3%). The clinical development of NVP-BEZ235 has been halted because of intolerable toxicities. For the further development, additional studies with appropriate patient selection with the activation of PI3K pathway and improved toxicity profiles are required.

Furthermore, numerous mTOR inhibitors also are being evaluated in patients with HNSCC. These mTOR inhibitors include everolimus and temsirolimus through phase II studies in neoadjuvant (or induction) chemotherapy and recurrent and/or metastatic settings. Rapamycin analogs, such as temsirolimus and everolimus, specifically inhibit mTORC1 and already are approved by the U.S. Food and Drug Administration in renal cell carcinoma, subependymal giant cell astrocytoma, pancreatic neuroendocrine tumors, and hormone receptor–positive, HER2-negative breast cancer in combination with exemestane in the United States.[26-30] In a phase II trial, a combination of temsirolimus and low-dose weekly carboplatin and paclitaxel was well tolerated in patients with recurrent and/or metastatic HNSCC.[31] When 30 patients were treated with the combination regimen, the overall radiological response rate was 43% with one complete response and 12 partial responses; median overall survival was 12.9 months. Overall, this regimen was well tolerated. The most common (greater than three) adverse events were neutropenia, dysphagia, and anemia. However, other combination trials evaluating temsirolimus and erlotinib in a similar recurrent and/or metastatic population of patients with HNSCC revealed intolerable toxicities such as fatigue, diarrhea, and infection, which resulted in early closure of the study.[32]

There are additional drugs that target other proteins within the PI3K pathway beyond PI3Ks and mTORs. Novel Akt inhibitors, such as MK2206, AZD5363, and GSK690693, are in development through phase I and II clinical trials.[33] Although it is not a direct inhibitor of mTOR, metformin, which is commonly used in type II diabetes, also is being investigated as an anticancer agent in patients with HNSCC.[34] Metformin indirectly inhibits mTORC1 by increasing intracellular adenosine monophosphate (AMP) levels mediated by AMP-activated protein kinase (AMPK)– dependent and independent mechanisms, and may play a role in management of HNSCC.[35,36]

ACTIVATION OF THE PI3K PATHWAY AS A BIOMARKER OF TREATMENT RESPONSE

Development of PI3K pathway inhibitors has not been straightforward because of the demonstrated lack of efficacy in unselected patient populations and unexpected degrees of

Table 1. Active Clinical Trials Evaluating PI3K/AKT/mTOR Targeted Agents in Patients with Locally Advanced, Recurrent, and/or Metastatic HNSCC*

Targeted Agent	Additional Targeted Agent	Additional Therapy	Inclusion Criteria	Phase	Clinical Trial Identifier
PI3K Inhibitor					
PX-866	-	Docetaxel	Recurrent or metastatic HNSCC/NSCLC	I/II	NCT01204099
PX-866	Cetuximab	-	Recurrent or metastatic HNSCC/CRC	I/II	NCT01252628
BYL-719	-	-	Recurrent or metastatic HNSCC	II	NCT02145312
BYL-719	Cetuximab	-	Recurrent or metastatic HNSCC	I/II	NCT01602315
BYL-719		Paclitaxel	Recurrent or metastatic HNSCC/BRC	I	NCT02051751
Buparlisib	-	-	Recurrent or metastatic HNSCC	II	NCT01527877
Buparlisib	Cetuximab	-	Recurrent or metastatic HNSCC	I/II	NCT01816984
Buparlisib	-	Paclitaxel	Recurrent or metastatic HNSCC	II	NCT01852292
Buparlisib	-	IMRT, cisplatin	Locally advanced HNSCC	Ib	NCT02113878
PI3K/mTOR Inhibitor					
NVP-BEZ235	-	-	Recurrent or metastatic solid tumors	I	NCT01343498
NVP-BEZ235	NVP-BKM120	Paclitaxel	Recurrent or metastatic solid tumors	I	NCT01285466
NVP-BEZ235	MEK-162	-	Recurrent or metastatic solid tumors	I	NCT01337765
NVP-BEZ235	Everolimus	-	Recurrent or metastatic solid tumors	I/II	NCT01508104
mTOR Inhibitor					
Everolimus	-	-	Recurrent or metastatic HNSCC	II	NCT01111058
Everolimus	-	-	Recurrent or metastatic HNSCC	II	NCT01051791
Everolimus	Cetuximab	Carboplatin	Recurrent or metastatic HNSCC	I/II	NCT01283334
Everolimus	Erlotinib	-	Recurrent or metastatic HNSCC	II	NCT00942734
Everolimus	Vatalinib	-	Recurrent or metastatic solid tumors	I	NCT00655655
Everolimus	-	IMRT, cisplatin	Locally advanced HNSCC	I	NCT00858663
Everolimus	-	Docetaxel, cisplatin	Locally advanced HNSCC	I	NCT00935961
Everolimus	-	Carboplatin, paclitaxel	Locally advanced HNSCC	I/II	NCT01333085
Everolimus	Cetuximab	Cisplatin, paclitaxel	Locally advanced HNSCC	II	NCT01133678
Temsirolimus	-	-	Recurrent or metastatic HNSCC	II	NCT01172769
Temsirolimus	-	Carboplatin, paclitaxel	Recurrent or metastatic HNSCC	I/II	NCT01016769
Temsirolimus	Cetuximab	-	Recurrent or metastatic HNSCC	II	NCT01256385
Temsirolimus	Cetuximab	Cisplatin	Recurrent or metastatic HNSCC	I/II	NCT01015664
Temsirolimus	Erlotinib	-	Recurrent or metastatic HNSCC	II	NCT01009203
Sirolimus	-	-	Recurrent or metastatic HNSCC	I/II	NCT01195922
Sirolimus	-	Grapefruit juice	Recurrent or metastatic solid tumors	I	NCT00375245
Ridaforolimus	Cetuximab	-	Recurrent or metastatic HNSCC/NSCLC/CRC	I	NCT01212627
Metformin	-	Paclitaxel	Recurrent or metastatic HNSCC	II	NCT01333852

Abbreviations: HNSCC, head and neck squamous cell carcinoma; IMRT, intensity modulated radiation therapy; NSCLC, non-small cell lung cancer; CRC, colorectal cancer; BRC, breast cancer.

toxicity. Because of the ease of tumor DNA testing for *PIK3CA* mutations, many have proposed that the *PIK3CA* mutations are an integral biomarker for screening patient populations with PI3K pathway activation for future clinical trials.[37] Some studies suggest that patients with HPV-positive HNSCC would be more sensitive because of frequent *PIK3CA* mutations and enrich the trial.[17] However, in a recent study of cetuximab with or without PX-866, tumor HPV status was assessed by p16 immunohistochemistry.[25] Twenty-six patients (57%) of 46 with available tissue were HPV positive and 20 patients (43%) were HPV negative. There was no association between the tumor HPV status and

response. *PIK3CA* mutations were detected in 17% of patients, but no response was seen in these eight patients with the *PIK3CA* mutation-harboring tumors.

In addition, the PI3K pathway activation through compensatory receptor tyrosine kinase activation, such as MET and HER3, has been proposed as one of the resistance mechanisms of EGFR inhibitors in preclinical studies, suggesting PI3K/mTOR inhibitors may be developed in patients who are EGFR inhibitor–resistant in addition to patients with the *PIK3CA* mutations.[38,39] In a recent preclinical study, the combined activity of cetuximab and mTOR inhibitors in patients with HNSCC was evaluated. Cetuximab-sensitive

HNSCC cells were transduced to express *PIK3CA* and *RAS* oncogenes, and tumor xenografts were treated with control, cetuximab, or rapamycin. The in vivo study showed that patients with HNSCC tumor xenografts expressing mutant PI3K and Ras proteins relapsed a few weeks after the initial response to cetuximab treatments. However, the addition of rapamycin dramatically increased antitumor activity in these cetuximab-resistant tumors, supporting the rationale to evaluate a combination of cetuximab/mTOR inhibitors for treatment of patients with HNSCC.[39]

However, a vast majority of the model systems use the H1047R *PI3KCA* mutation that does not reflect the most commonly seen mutations.[5] For example, there are differences in the *PIK3CA* mutation hotspots between patients with HPV-positive and HPV-negative HNSCC. Greater than 90% of HPV-positive patients with HNSCC have mutations in the helical domain (i.e., E542K or E545K), whereas patients with HPV-negative HNSCC have mutations throughout the entire gene, although the hotspot mutations in the helical and kinase domains (i.e., H1047R) are relatively more frequent.[14] The site of the mutations and resulting amino acid substitutions might produce functionally different mutant proteins and further differ depending on the genetic background of patients with HPV-positive and HPV-negative HNSCC. These phenotypical differences may result in varied responses to the PI3K targeted agents and substantially affect the development of predictive biomarkers. This concern is validated in the PX-866 trial in which the *PIK3CA* mutations were not associated with response to cetuximab or cetuximab and PX-866 combination.[25] In addition, patients with HNSCC have *PTEN* loss and other functional gain or loss of genes/proteins within the pathway that may affect the pathway in the absence of the *PIK3CA* mutations.[14] The functional significance of these features must be adequately characterized before applying them to clinical trials.

CONCLUSION

Advancements in genomic and proteomic technology are providing a glimpse of the complexity of cancer biology and generating rich hypotheses for potential therapeutic targets. In addition, respective companion diagnostic biomarkers are being developed for clinical application. Currently, a large body of preclinical data indicate the PI3K pathway is important and a promising therapeutic target in patients with HNSCC. However, they have not always translated to clinically meaningful efficacy in clinical studies. Additional studies to determine an appropriate method of patient selection with the activation of PI3K pathway and to develop targeted agents with favorable toxicity profiles are required. Existing data on *PIK3CA* mutations as a predictive biomarker to PI3K/mTOR inhibitor response or the EGFR inhibitor resistance are not yet fully developed. Potential differences in the gene/protein function based on the location and amino acid changes resulting from the *PIK3CA* mutations in appropriate genetic context of other coexisting pathologic signaling network, must be delineated further before proceeding with a broader clinical application.

Comparative Effectiveness Research in Cancer with Observational Data

Sharon H. Giordano, MD, MPH

OVERVIEW

Observational studies are increasingly being used for comparative effectiveness research. These studies can have the greatest impact when randomized trials are not feasible or when randomized studies have not included the population or outcomes of interest. However, careful attention must be paid to study design to minimize the likelihood of selection biases. Analytic techniques, such as multivariable regression modeling, propensity score analysis, and instrumental variable analysis, also can also be used to help address confounding. Oncology has many existing large and clinically rich observational databases that can be used for comparative effectiveness research. With careful study design, observational studies can produce valid results to assess the benefits and harms of a treatment or intervention in representative real-world populations.

Comparative effectiveness research increasingly is being recognized as a priority area in cancer research. Although researchers have been conducting comparative effectiveness research for decades, this area of research achieved national prominence when, as part of the American Recovery and Reinvestment Act of 2009, $1.1 billion was allocated to comparative effectiveness research. Shortly thereafter, the Patient Protection and Affordable Care Act of 2010 established the Patient-Centered Outcomes Research Institute (PCORI). The mandate of PCORI is "to improve the quality and relevance of evidence available to help patients, caregivers, clinicians, employers, insurers, and policy makers make informed health decisions. Specifically, we fund comparative clinical effectiveness research, or CER, as well as support work that will improve the methods used to conduct such studies."[1] These initiatives have stimulated interest and provided new funding opportunities in comparative effectiveness research.

The Institute of Medicine has formulated a definition of comparative effectiveness research as follows: "CER is the generation and synthesis of evidence that compares the benefits and harms of alternative methods to prevent, diagnose, treat and monitor a clinical condition or to improve the delivery of care. The purpose of CER is to assist consumers, clinicians, purchasers, and policy makers to make informed decisions that will improve health care at both the individual and population levels."[2] Thus, comparative effectiveness research is meant to compare the risks and benefits of a given approach in a real-world heterogenous population with the ultimate goal of improving health care decisions and out-

comes. Comparative effectiveness research encompasses a broad array of study types, including randomized trials (pragmatic clinical trials, cluster-randomized trials, adaptive trials), research synthesis (systematic reviews, meta-analysis, decision analysis), and observational studies (cohort, case-control, cross-sectional designs).

Randomized trials have long been considered the gold standard when evaluating the efficacy of a particular intervention. These studies test the effect of an intervention under carefully controlled conditions and are the gold standard to evaluate the efficacy of a particular intervention. Although randomized trials have the best internal validity, the generalizability of results can be limited because of strict eligibility criteria. Clinical trial participants tend to be systematically different than patients in the general population, with younger ages and fewer concurrent medical conditions.[3] Pragmatic clinical trial designs address some of these issues, but randomized trials remain expensive and time consuming. Observational studies increasingly are being used to evaluate the effectiveness of treatments in real-world populations, because they can address the gaps in randomized studies and the benefits in patient populations who were not included in the clinical trials. In addition, observational studies can be conducted with a relatively low cost and often include large numbers of representative populations.

ROLE OF OBSERVATIONAL STUDIES

The Effective Health Care website has published a guide for methods in comparative effectiveness research.[4] This article

From the Department of Health Services Research, The University of Texas MD Anderson Cancer Center, Houston, TX.

Disclosures of potential conflicts of interest are found at the end of this article.

Corresponding author: Sharon H. Giordano, MD, MPH, Department of Health Services Research, The University of Texas MD Anderson Cancer Center, 1400 Pressler, Unit 1444, Houston, TX 77030; email: sgiordan@mdanderson.org.

provides a conceptual framework for the use of observational studies in comparative effectiveness research. The authors note that researchers should ask two key questions before undertaking an observational CER study: (1) Are there gaps in the evidence from randomized controlled trials? and (2) Will observational studies provide valid and useful information?[4]

When data are available from randomized clinical trials, observational studies may provide little additional information. However, at times, randomized clinical trials may not be possible. Studies of medications, particularly if they are off patent, may have no financial support. In some situations, random assignment may not be feasible or ethical. For instance, studies of a rare cancer may never be able to accrue a sufficient number of patients to obtain statistically valid results. Trials may be unethical to conduct in situations when there is not clinical equipoise between the two therapeutic options. Even in situations when clinical trials may be possible, existing clinical trials may not be relevant to the population of interest or may not include the outcomes of interest. This situation often arises when evaluating the benefit of a treatment for patients who are older or who have many comorbid conditions. Randomized trials often focus on short-term outcomes and may not have sufficient follow-up times to evaluate late outcomes of interest. For example, clinical trials for patients with breast cancer typically have not observed patients to assess the risks of long-term outcomes, such as congestive heart failure related to anthracyclines or myocardial infarction as a result of radiation therapy, both of which may occur decades after treatment. In these situations, when no randomized studies exist, the trials were not conducted in the population of interest, or the studies do not capture the endpoint of interest, observational studies can be used to fill in the gaps in data.

The second question to ask before undertaking an observational study is whether an observational study can provide valid information.[4] The major challenges in observational studies are assessing and addressing the risk of bias, particularly the risk of selection bias. Selection bias refers to systematic differences in the risk of the outcome between the two compared groups of patients. For instance, in a comparison of the effectiveness of chemotherapy, selection biases could work in several ways. First, patients who have high-risk disease features, such as higher-stage disease or high-grade tumors, would be more likely to be treated with chemotherapy.

This selection bias could cause the chemotherapy-treated group to appear to have a worse outcome, simply because they had higher-risk disease. Many of these high-risk features can be measured and adjusted for in analyses, but some high-risk features, such as positive margins or lymphovascular invasion, may not be routinely captured or reported in national databases. A second way in which selection biases can work is that patients who are older or who have poorer performance statuses and more comorbidities will be less likely to be treated. This selection bias would result in the untreated patients appearing to have worse outcomes, simply because of poorer health at diagnosis. Again, some of these predictors of treatment, like age, can be measured and adjusted for in statistical models. However, other important factors that clinicians use to decide treatment, like performance status or frailty, are not routinely captured in databases. These factors can act as unmeasured confounders, which are extraneous variables that are associated with both the independent variable and dependent variable. For instance, performance status is associated with both the likelihood of treatment and survival and could lead to biased estimates of the efficacy of treatment. Another illustration of selection biases can be seen in an example of evaluating the benefit of treatment for patients with prostate cancer.[5] In an analysis of older men with early-stage prostate cancer, the use of any active treatment (radiation or surgery) was associated with better survival after adjustment for all measured covariates.[5] When evaluated by cause of death, treatment was associated with improved overall survival and improved prostate cancer–specific survival. However, prostate cancer treatment also was associated with better cause-specific survival from cardiovascular disease, pneumonia, and diabetes. There are no plausible mechanisms by which treatment for prostate cancer could affect survival from diabetes, other than through confounding from underlying health. This example illustrates the challenges of identifying and accounting for selection biases. Selection biases also can result in confounding by indication. Confounding by indication can occur when the patients who are prescribed a particular treatment differ from those who are not prescribed a given treatment because of the medical indication for which the drug is prescribed. Many other biases can occur in observational studies, such as performance bias (e.g., difference in adherence), detection bias (e.g., differential assessment of outcomes), and outcome-reporting bias.[4] Before undertaking an observational analysis, careful consideration must be given to the possibility of bias and how potential biases could affect the results.

ANALYTIC TECHNIQUES

Several approaches can be taken to address bias in observational studies. Most studies will use multivariable regression analyses to adjust for confounders and to address issues related to nonrandom treatment assignment. This method can provide statistical adjustment for all measured variables but cannot adjust for unmeasured confounders. Propensity score analysis is another approach to improve the balance of un-

---

KEY POINTS

- Observational studies are particularly useful when randomized studies are not feasible or have not included the population or outcome of interest.
- Selection biases are the primary threat to validity of observational studies.
- Multivariable regression models, propensity score analyses, and instrumental variable analyses can be used to help address selection biases and confounding.

measured confounders between the two experimental groups. In propensity score analysis, multivariable regression is used to calculate the propensity of receiving the intervention of interest. This propensity score then can be entered as an explanatory variable in the regression models or can be used for matching. Some studies have suggested that propensity score stratification can remove more than 90% of the bias in observational studies.[6] Another approach is the use of instrumental variable analysis, which is a method used in econometrics. An instrumental variable is a variable that is strongly correlated with the treatment or intervention but without any independent effect on the outcome. An appropriate instrumental variable can help address unmeasured confounding. In oncology studies, distance to the treatment center and regional treatment rates have been used as instruments.[7-9] However, finding an appropriate instrumental variable can be challenging.

TYPES OF OBSERVATIONAL STUDIES

Several different study designs, such as cross-sectional, cohort, and case-control designs, can be used for observational research. A cross-sectional study is a study in which the prevalence of the exposure and outcome are measured at the same point in time. In this design, participants are identified independent of exposure and outcome. Cross-sectional studies can evaluate prevalence but cannot measure disease incidence. In a cohort study, participants are identified by their exposure and then observed over time for the outcome of interest. For instance, patients with breast cancer who were and were not treated with trastuzumab could be observed for the risk of congestive heart failure. A cohort study allows for the calculation of incidence in treatment groups. When they are prospectively designed, these studies may need an impractically large sample size if the outcome is not common. Large, retrospective, cohort studies using existing national databases get around this limitation with their large size and lengthy follow-up times. A third common study design is a case-control study. In this study design, cases and controls are identified by the outcome of interest, and then the prevalence of exposure is compared. In the example of trastu-

zumab cardiotoxicity above, patients with heart failure would be identified and then compared by exposure to trastuzumab. Other study designs, such as case cohorts or case crossovers, also may be used but are beyond the scope of this review.

SAMPLE DATA SOURCES IN ONCOLOGY

Oncology has a long track record of observational studies, in part because of the high-quality data provided by cancer registries. Incident cancer cases are reported to state cancer registries, which track cancer incidence, staging, first course of treatment, and outcomes. Cancer registries have provided data for numerous research studies and also have been linked with other databases. Commonly used observational data sets for cancer research are described below and are summarized in Table 1.

Surveillance, Epidemiology, and End Results

The Surveillance, Epidemiology, and End Results (SEER) program of the National Cancer Institute (NCI) collects and complies data from cancer registries to provide information on cancer incidence and survival in the United States. This program was started in 1973 and has expanded over the years to include data from 10 states (Connecticut, Hawaii, Iowa, New Jersey, New Mexico, California, Virginia, Kentucky, Louisiana, and Utah), six metropolitan areas defined by county borders (Atlanta, Detroit, Los Angeles, San Francisco/Oakland, San Jose/Monterey, and Seattle/Puget Sound), the supplemental SEER registries of[4]Alaska Natives, Arizona Native Americans, and Cherokee Nation, and 10 counties in rural Georgia.[10] These SEER registries cover approximately 28% of the U.S. population.[10] For each patient with an incident cancer, the following information is reported: (1) demographics: case number, age, sex, race/ethnicity, state and county of birth, state and county of residence, date and cause of death according to death certificate (of note, cancer recurrence is not captured); (2) cancer: type, month and year of diagnosis, diagnostic confirmation, and laterality; (3) extent of disease: American Joint Committee on Cancer (AJCC) stage, historic SEER stage, tumor size and extension, number

TABLE 1. Data Sources

Data Set	Type of Data	Years Available with Incident Cases	Population
SEER	Cancer registry	1973-2013	All incident cancer cases in SEER regions
100% Medicare	Health care claims	Through 2012	Age > 65, disabled, end stage renal disease
SEER-Medicare	Registry-linked claims	1973-2011	Age > 65, disabled, end stage renal disease
SEER-MHOS	Registry-linked to survey	1998-2011	Age > 65
SEER-NLMS	Registry-linked to survey	1979-2011	All ages
HCCI	Health care claims from United, Aetna, Humana, and Kaiser	2009-2013	All; employees, spouses, dependents
Marketscan	Health care claims from 45 large employers	2003-2013	All; employees, spouses, dependents
NCDB	Clinical database	Since 1985	All ages; patients treated at CoC accredited facilities

Abbreviations: SEER, Surveillance, Epidemiology, and End Results; MHOS, Medicare Health Outcomes Survey; NLMS, National Longitudinal Mortality Study; HCCI, Health Care Cost Institute; NCDB, National Cancer Database; CoC, Commission on Cancer.

of lymph nodes examined, number of positive lymph nodes, histologic grade, histologic type; and (4) treatment: type of surgery and radiotherapy for first course of treatment. These data provide a definitive source of information on cancer incidence, staging, and survival. The information on treatment is less complete. In general, the ascertainment of surgery by registries is the highest-quality treatment variable. The use of radiation therapy may be under-ascertained by registries. In the case of breast cancer, the under-ascertainment has been reported to be differential by age, income, and other treatment.[11,12] Complete information on chemotherapy administration is difficult to capture; thus, rates of chemotherapy use are not reported in the SEER database. The SEER database is de-identified, publically available, and free of charge.

Medicare

Medicare is the primary health insurer for 97% of the U.S. population age 65 and older. The Medicare Claims Data System collects information on all services provided to Medicare beneficiaries under its hospital (Part A), supplemental (Part B), and prescription drug (Part D) insurance plans. Part A covers inpatient hospitalizations and care in skilled nursing homes, whereas Part B covers physician services; hospital outpatient services; durable medical equipment; home health services; and other outpatient medical services, such as diagnostic x-rays and laboratory tests. Part D data includes information on prescription drug use and has been available since 2006. The unlinked Medicare data are comprised of enrollment files and health care claims. These data do not have information on the dates of diagnosis, stage, histology, or recurrence, and this lack of registry data has limited the use of the unlinked Medicare files for cancer research. For several cancer types, such as breast cancer, validated algorithms have been developed to identify incident cases.[13] The strength of these data is in studies of patterns of care, geographic variation, and costs of therapy. To obtain the data set with identifiers, an application should be submitted to the Research Data Assistance Center (ResDAC). The cost is dependent on the specific data request.

SEER-Medicare Linked Database

Under an agreement between the NCI and the Centers for Medicaid & Medicare Services (CMS), patients in the SEER database who are eligible for Medicare have been linked with their Medicare records. Of persons who are reported by SEER as diagnosed with cancer at age 65 or older, 93% were matched with their Medicare enrollment records.[14] At present, patients with cancer who were diagnosed through 2011 are linked, and their Medicare claims are available through 2012. For patients with cancer in the SEER database, Medicare enrollment and eligibility information and a subset of SEER data are in the Patient Entitlement and Diagnosis Summary File (PEDSF). The PEDSF also contains census-tract–level information, including ethnicity, education, income, percentage English-speaking residents, and population density. In addition to the registry data provided by SEER, these data include all billing claims for each patient. The claims can

supplement data from the SEER registry and provide information on diagnostic testing and additional treatment information, such as chemotherapy use and patterns of surveillance. In addition, the data can be linked to the Area Resource File and the American Medical Association's Physician Masterfile, which can provide additional information about health resources and physician characteristics, respectively. These data do have some substantial limitations. First and foremost, these data are administrative data generated for billing, so they lack the detail of clinical data. The claims are only complete for those patients in the fee-for-service plans (rather than in the HMO plans) and do not capture services provided by the U.S. Department of Veterans Affairs. Finally, as with the SEER data, cancer recurrences are not captured. To obtain these data, an application must be submitted to the NCI for review. Cost estimates can be found on the SEER-Medicare website.[15] All publications resulting from these data must be reviewed before publication to ensure that patient confidentiality is protected.

SEER-Medicare Health Outcomes Survey Linked Database

The SEER–Medicare Health Outcomes Survey (MHOS) data set is a linkage of two large population-based databases. The SEER database, described above, has been linked with the MHOS, which is a large survey of health-related and quality-of-life information among participants in the Medicare Advantage Organization. These data include information on 12 cohorts of baseline and follow-up surveys at 2 years, which were conducted between 1998 and 2011.[16] Collected data include patient demographics, marital status, income, smoking status, chronic conditions, and health-related quality of life. From 1998 to 2005, the MHOS used the 36-question short-form (SF-36) to collect data on health-related quality of life, but the MHOS switched to the Veterans RAND 12-item health survey (VR-12) in 2006. This data set provides additional patient-reported information to the SEER data. However, the survey was not limited to participants with cancer nor timed with a diagnosis of cancer, therefore the small sample sizes may limit potential analyses.

SEER-National Longitudinal Mortality Study Linked Database

The National Longitudinal Mortality Study (NLMS) is a data set that includes sociodemographic data collected by the Census Bureau by in-person and telephone interviews, and it includes cause of death information. The variables include race/ethnicity, education, income, employment, occupation, smoking, health status, and health insurance status. These data have been linked with SEER and with Medicare claims and can be used in studies evaluating socioeconomic determinants of cancer and cancer outcomes or outcomes related to income or employment, in addition to other uses.

Commercial Claims Databases

There is an increasing number of databases that can be licensed for research on the commercially insured population.

These databases are analogous to the unlinked Medicare data, in that they are health care claims without linkage to cancer registry data. They lack information on cancer incidence, stage, or survival, but they can provide detailed treatment information on younger, privately insured patients. One of the most commonly used data sets is Marketscan data, which consist of proprietary data sets licensed by Thomson Medstat Inc. The data undergo internal quality checks for reasonableness of data and validity before they are released, and they are HIPPA compliant. Marketscan is a large nationwide employment-based database that contains information on medical claims and outpatient prescription drug claims for employees and their spouses and dependents; the data represent claims from approximately 45 large employers, and Marketscan captures insurance claims data from over 100 payers. All files of claims data can be linked to the enrollment file via de-identified person identifiers. These data represent the medical experience of insured employees and their dependents for active employees, early retirees, COBRA continuees, and Medicare-eligible retirees. The specific demographic covariates available through Marketscan include patient age and sex, birth year, marital status, and three-digit zip codes. Information on race and ethnicity is not available.

The Health Care Cost Institute (HCCI) is another source of data on the commercially insured population. The HCCI is a nonprofit organization founded by academic economists to create a comprehensive source of information on health care activity and costs. Their research database covers about 40 million people, which represents approximately one-quarter of the population covered by employer-sponsored insurance. The data set contains claims from Aetna, Humana, Kaiser Permanente, and United Healthcare. The data capture complete payment information, including payments from both the benefit plan and patient. Pharmacy and mail-order prescriptions are included. Other proprietary claims data include IMS LifeLink data, Perspective, and Optum Insight. These data sets can provide comprehensive information on younger, privately insured patients. However, these data sets also have some limitations beyond the lack of linked registry data. The continuous coverage in these data sets tends to be short, so longitudinal studies can be challenging. In addition, no information on survival is available, and thus long-term outcomes cannot be assessed.

National Cancer Database

The National Cancer Database (NCDB) is a clinical oncology database jointly sponsored by the American College of Surgeons and the American Cancer Society. This database collects information from hospital registries that are Commission on Cancer (CoC)-accredited facilities. This includes more than 1,500 hospitals in the United States and Puerto Rico. The database is quite extensive and covers approximately 70% of newly diagnosed cancer cases in the United States.[17] The data include information on patient characteristics, pathology, stage, prognostic factors, treatment, and outcomes. The strength of these data is the collection of clinically rich information, but the generalizability is somewhat limited because the data are not population based.

CONCLUSION

In summary, observational data can be a powerful resource for comparative effectiveness studies in cancer research. Observational studies are particularly useful to fill in gaps in data from randomized studies or when randomized studies cannot be conducted. Researchers must be cognizant of the risk of selection biases and confounding in observational research and must design studies carefully to minimize the risk of bias. The Agency for Healthcare Research and Quality's Effective Health Care Program has provided a checklist for considerations in study design when observational comparative effectiveness studies are proposed.[4] Given careful and thoughtful study design, observational studies can provide important and clinically relevant comparative effectiveness information in real-world populations. Finally, with the increasing use of electronic medical records and the ability to access large national data sets, this area of research is likely to continue to grow in scope and impact.

Disclosures of Potential Conflicts of Interest

The author(s) indicated no potential conflicts of interest.

The Impact of Industry on Oncology Research and Practice

Beverly Moy, MD, MPH, Reshma Jagsi, MD, DPhil, Richard B. Gaynor, MD, and Mark J. Ratain, MD

OVERVIEW

Public scrutiny has increased over potential conflicts of interest among oncology researchers and providers. Given the increased prevalence and complexity of industry relationships, oncologists are increasingly faced with ethical challenges when navigating their financial relationships with industry. Oncologists are continually dealing with changing conflict of interest policies within academic centers and professional societies. With the recent passage of The Sunshine Act, oncologists are beginning to understand the repercussions of this new law. The consequences of the increasing use of direct-to-consumer advertising on patients with cancer are also unclear. Finally, industry's perspective on the evolution of these relationships is not clearly understood. This manuscript discusses issues related to industry's influence on oncology practice and research.

Financial relationships between industry and oncology physicians and researchers are common. These relationships consist of research support, consultative fees, honoraria, and gifts. Recently, public scrutiny has increased about potential conflicts of interest that could arise in the oncology community. Given the increased prevalence and complexity of industry relationships, oncologists are increasingly faced with ethical challenges when navigating their financial relationships with industry.

Recent attention has been focused on physician–industry relationships in the wake of the Sunshine Act. Oncology researchers are forced to keep up with continual revisions of conflict of interest policies within academic centers and professional societies. The effect of the rise in direct-to-consumer advertising (DTC) on patients with cancer is also unclear. DTC advertising results in multiple ethical challenges since physicians are unable to function as unbiased intermediaries between patients and industry.

Industry's effect on physicians and patients with cancer is multidimensional and becoming increasingly complex. Patient and public reaction to these developments necessitate education and clarification of these complex issues. We will explore some of the issues relating to the effect of industry on oncology research and practice in the modern era.

FINANCIAL CONFLICTS OF INTEREST

Financial relationships between the pharmaceutical industry and oncology are common and increasing over time.[1-3] A cross-sectional survey of cancer clinical trials and editorials conducted in 2005 revealed that 44% of clinical trials were entirely or partially funded by industry.[4] Another study reported that 23% of all abstracts and 60% of plenary session abstracts from 2004 to 2005 at the American Society of Clinical Oncology (ASCO) Annual Meeting reported at least one author with an financial conflict of interest (FCOI).[2] A more recent analysis of ASCO Annual Meeting abstracts from 2006 to 2011 reported that 36% of all abstracts had at least one FCOI and that abstracts with FCOIs were featured at more prominent sessions at the Meeting.[5] These data demonstrate the increased influence of industry in oncology research and practice.

In the past, arguably the most prominent cancer research was funded by the federal government in the form of cooperative group studies. However, in recent years, there has been a shift toward industry-funded trials leading to the development and approval of cancer therapeutics. Modern cancer research has increasingly relied on efficient conduct of clinical trials using the newest anticancer therapeutic agents. Therefore, cancer researchers have formed increasing ties to industry given their access to research infrastructures and novel therapeutic agents.

The increasing relationship between industry and oncologists leads to both positive and negative consequences.[6,7] On the positive side, close collaboration between biomedical researchers and industry has undeniably facilitated the development of many new medical therapies.[8] Developmental therapeutics is an area in which key interests of the oncology researcher, patient, and industry are aligned. The patient community seeks effective new therapies, biomedical researchers and oncologists wish to translate basic discoveries into treatments, and industry wishes to develop new products.[9] However, as oncology researchers work more closely with industry, questions arise whether financial compensa-

tion and academic advancement may lead to unethical behavior. The presence of financial interests might influence decision making and research conduct. These relationships have the potential to compromise research integrity, create scientific bias for researchers, and lead to public and patient mistrust. Profit motives by the manufacturer, shared with the clinical researcher through FCOI, could potentially lead to poor or inaccurate science and ultimately harm the public interest.[10]

To date, management of FCOI has been based on rules or policies mandating disclosure of industry relationships. These policies aim to increase transparency to engender public trust for the medical research community, and by acknowledging the presence of these relationships, they ideally lead to an open dialogue between the public and oncologists. As policies call for wider disclosure of potential FCOI, and at times prohibition of specific financial relationships, there is both a need and an opportunity to better understand the prevalence of investigator and research relationships with industry and the effect of these relationships on research and dissemination of results.[6,7] However, despite the widespread implementation of conflicts of interest policies in academic centers, federal agencies, and professional medical societies, little is known about how FCOI influences research conduct, outcomes, and dissemination.[11-13]

These conflict of interest policies also do not address nonfinancial conflicts of interest that address professional or ideologic issues, such as academic advancement, promotion, and publication. The desire for academic advancement could lead academic cancer researchers to seek out relationships with industry that has proprietary technology in an effort to participate in more important and influential research. These nonfinancial conflicts have not been as well studied. Greater examination of the benefits and risks of these relationships should be paid.

Currently, most FCOI policies rely on disclosure alone to address conflicts of interest. In part because of the difficulty of relying on disclosure alone to address the problematic con-

sequences of physician–industry ties and associated conflicts of interest, proposals have emerged for academic medical centers to ban all gifts, meals, payment for travel to or time at meetings, and payment for participation in online continuing medical education (CME) from industry to physicians.[14] These concerns have also led to the consideration of creative ways to introduce more distance into relationships between physicians and industry, including provision of vouchers rather than samples for low-income patients, elimination of direct funding of CME, and limitation of grants for general support of research to institutions rather than individual physician investigators. Unfortunately, some conflicts of interest may be particularly hard to eradicate, including situations where physicians have an ownership interest in medical equipment being advertised. Nevertheless, it is clear that at least for relationships with manufacturers of drugs, tests, and technologies used in the management of patients with cancer, approaches that minimize the direct relationship and try to maintain some distance between individual physicians and industry merit consideration.

Given the complexity of these relationships with industry that lead to positive and negative consequences for the oncology provider and researcher, the oncology community must rationally understand these issues. It may be within the public interest to foster, rather than discourage, some relationships. Instead, there may be a need for greater scrutiny on the degree to which FCOI are managed or prohibited and the effect of such policies over time.

SUNSHINE ACT

The direct goal of the Sunshine Act is to enhance transparency about relationships between health care providers and purveyors of health care products and services. When the original bill was first introduced in 2007 (S.2029), one of the cosponsors, Senator Claire McCaskill, stated, "I believe that by bringing light to these relationships, this legislation will go far in reducing big drug companies' influence on the business of medicine." Another cosponsor, Senator Charles Schumer, stated, "This bill will shine a much needed ray of sunlight on a situation that contributes to the exorbitant cost of health care. Patients have the right to know if drug and device makers are attempting to influence physician prescribing decisions with gifts, consultations, and travel." Thus, the Sunshine Act requires companies to submit information regarding their financial relationships with providers to the U.S. Department of Health and Human Services (HHS) and for such information to be publicly available. This led to the creation of a database, Open Payments, so that patients can theoretically identify providers whose professional judgment may be clouded by personal financial interests, enabling informed patients to question their physicians' prescribing decisions. Furthermore, particularly concerned patients could simply choose physicians who had no financial relationships, based on a search of the Open Payments database.

It is too soon to assess whether or not patients are utilizing the Open Payments database in the manner Congress in-

---

KEY POINTS

- Financial relationships between industry and oncology physicians are common.
- Conflict of interest policies historically have relied on disclosure to maintain transparency, but little is known about the effect and influence of these relationships on research conduct, outcomes, and dissemination.
- The goal of the Sunshine Act is to enhance transparency about these relationships, but its implementation has raised multiple concerns.
- Direct-to-consumer advertising has a substantial effect on medical practice and influences drug utilization.
- Partnerships between pharmaceutical companies and oncology researchers are essential for the development of new treatments and innovations.

tended. However, there are both direct and indirect negative consequences to physicians and teaching hospitals as a result of the Sunshine Act. Although the direct financial costs to physicians and teaching hospitals were estimated to be relatively modest ($250 and $3,500 for the first year, respectively), the potential for indirect costs from stigmatization of physicians and/or teaching hospitals cannot yet be assessed.

There is no question that some medical decisions are motivated by physicians' associations with manufacturers of pharmaceuticals and devices, but there are also many legitimate and beneficial relationships between physicians and industry, particularly in the context of research and development of investigational products. In fact, if Americans wish to have access to such investigational products, financial relationships between American physicians and industry are necessary. Notably, the implementation of the Sunshine Act does attempt to differentiate financial relationships associated with research from those associated with inducement of prescribing (e.g., speakers bureaus). However, the problematic implementation of the Open Payments database has led to significant concerns about the validity of the data. Furthermore, physicians must access the database to assess the validity of submitted data (and have the option to dispute specific entries)—potentially a substantial implementation cost. (As an example, one of the authors of this manuscript spent multiple hours working directly with the Open Payments database developers to gain access to his own data, as the record associated with his National Provider Identifier number had been inadvertently duplicated, thereby blocking access.)

The Open Payments website provides a guide for patients that distinguishes the different types of potential financial relationships of their physicians.[15] These include consulting fees, "compensation for services other than consulting, including serving as faculty or as a speaker at an event other than a continuing education program," honoraria, gifts, entertainment, food and beverage (exceeding $10 per year), travel and lodging, education (including reprints of journal articles and even if not requested by the physician), research, charitable contributions, "royalty or license," "current or prospective ownership or investment interest," "compensation for serving as faculty or as a speaker for an unaccredited and noncertified continuing education program," "compensation for serving as faculty or as a speaker for an accredited or certified continuing education program" (but only if the company recommends the speaker), grant (payments in support of a specific cause or activity), and "space rental or facility fees."

Of significant concern is the requirement for companies to report all indirect payments, specifically financial support to third parties (e.g., Conquer Cancer Foundation) who then utilize a peer review process to allocate funds to grantees. In this context, the Conquer Cancer Foundation website contains the following language as a warning to applicants: "This grant receives support that may result in a report to the Centers for Medicare & Medicaid Services (CMS) Open Payments website under the Physician Payments Sunshine Act. The supporting companies are required to report the amount

of the grant, the names of physicians who are awarded this grant, and the names of their institutions. This information may appear on the Open Payments website." Presumably, this would dissuade at least some qualified applicants from applying for grants, given concerns about the potential stigmatization associated with a successful application.

Another area of concern to researchers is companies' variable interpretation of the CMS Final Rule in regard to requirements to report potential "transfers of value" (TOVs) in the context of research publications (e.g., abstracts, presentations, original research articles). As clinical research is uncommonly conducted at single institutions, investigators must rely on companies for the organization and primary analysis of results. In addition, many companies utilize professional medical writers and graphic artists (either employees or contractors) to assist in the preparation of abstracts, presentations, and original research articles. Thus, many companies have interpreted the requirement to report publication support as a transfer of value to individual physicians, even though such publications may primarily benefit the company.[16,17]

Given the interests of Congress to both improve health and reduce health care costs, it is important to ask whether or not the Sunshine Act's implementation challenges outweigh the potential gains. In fact, patients may be less troubled by the financial relationships of their physicians than Congress. In one study of 102 patients with advanced cancer, the majority of patients were not concerned about financial relationships between their physicians and industry but were concerned about potential intrinsic nonfinancial interests.[18] Specifically, patients were concerned about their physician being promoted or becoming famous because of their participation in such research studies. So, if potential physician fame (rather than fortune) is of highest concern to patients, then the achievement of financial transparency may have little effect on direct interactions between patients and physicians in the context of prescribing decisions.

In contrast, Congress has never expressed concern about physician activities aimed at fame, although often fame begets fortune, particularly if the famous physician leaves the practice of medicine. Furthermore, a recent study showed that approximately one-half of the medical recommendations made by one set of famous physicians—those on medical talk shows— had either no evidence or were contradicted by the best available evidence, and they were rarely accompanied by any disclosure of financial interests.[19] It is unclear whether or not Congress has ever considered regulating medical recommendations made on talk shows. This may be of relatively little concern to HHS, since many of these recommendations relate to medical interventions not covered by Medicare or Medicaid.

Of greater concern is Congress's failure to strengthen the regulations and/or eliminate direct-to-consumer advertising of medications, since patients may seek inappropriate medications based on seeing (or hearing) such advertisements.[20] Although such advertisements are regulated in theory by the U.S. Food and Drug Administration (FDA), their enforcement

has been "lackadaisical."[21] Notably, the United States is one of only two countries in the world that permits such advertising. Furthermore, a recent paper from the other country that permits such advertising—New Zealand— calls for that country's policy to be reviewed, since such advertising "exposes patients to unnecessary adverse effects and iatrogenic harm, and increases costs for the health care sector through the prescription of expensive branded medication."[22]

Although direct-to-consumer advertising may be protected by a constitutional right to free speech in the United States,[23] the U.S. Constitution would presumably not prohibit requirements analogous to those included in the Sunshine Act and the Final Rule regarding transparency reports of relationships between companies and health care providers. For example, Congress could require public dissemination (e.g., in a database) of the costs of drugs marketed directly to consumers, as well as the overall costs of the marketing and advertising of such drugs. In addition, Congress could also require that all print ads aimed at a consumer audience include detailed information about drug costs, given the increasing importance of financial toxicity related to expensive drugs.[24] Similarly, television and radio ads could also be required to devote adequate time (e.g., 15 seconds) to discussing this increasingly important issue, with the goal of reducing demand for expensive drugs that may be only marginally better than much cheaper alternatives.

DIRECT-TO-CONSUMER ADVERTISING

Since 1962, the FDA has had regulatory authority over prescription drug advertising.[25] Although professionals have historically been the primary target of advertisements, DTC advertising began as early as the 1980s, primarily in print form. DTC advertising expanded dramatically after 1997, when the FDA issued draft guidance on broadcast advertisements[26] that was later finalized in 1999.[27] Industry spent approximately $150 million on DTC advertising in 1993, which rose to $1.1 billion by 1997, reached $3.2 billion by 2003, peaked at $4.9 billion in 2007 (also the peak of overall promotional spending for pharmaceutical products), and was $3.9 billion in 2011.[28,29]

DTC advertising has substantial influence on medical practice and affects drug utilization.[30-34] A public survey revealed that 30% of respondents had initiated conversations with their physicians about a medicine they saw advertised, and, of these, 44% reported actually receiving a prescription for the drug as the outcome of the conversation.[35] Many DTC advertisements target patients with cancer,[36] and a survey found that 86.2% of oncology patients reported awareness of such ads.[37] In another survey, 94% of oncology nurse practitioners reported having received medication requests prompted by DTC ads, and 40% indicated that they received one to five such requests per week.[38] DTC advertising relevant to oncology extends well beyond the marketing of prescription drugs, to include advertising for genetic testing and medical imaging—other industries with which physicians often have ties.[39-41]

The ethical implications of DTC advertising are complex.[42] On one hand, advertising may promote autonomy, well-being, and distributive justice by informing and empowering patients, improving quality of care, and promoting responsiveness to patients' needs and values.[43-45] This is most likely when the advertisement is not itself disguised in educational programming or celebrity interviews,[46] when the product being advertised has clear indications, and when a physician without industry relationships is available to advise the patient and correct any misunderstandings. On the other hand, advertising may also lead to confusion and even disruption of the physician–patient relationship.[47,48] The very statement, "Ask your doctor about X" implies that one's doctor requires a prompt to provide necessary information, potentially jeopardizing patients' trust in their physicians. As noted above, DTC advertising has direct costs, and it can also increase the costs of the health care encounter or cause harm by distracting from other, more appropriate subjects for discussion.

Although there is some evidence that DTC advertising may improve patient education and physician–patient communication necessary for truly shared decision making—and it might even help mitigate health disparities by encouraging patients of low socioeconomic status to seek care—the primary goal of advertising is to increase utilization.[49,50] One study found a 1% increase in prescription drug spending for every 10% increase in DTC advertising.[51] In some circumstances, this increased use may be appropriate, such as that observed in one study of the effect of aromatase inhibitor advertisements.[52] Nevertheless, to avoid the possibility that advertising might compromise health care quality by leading to overuse or misuse (rather than correction of underuse), the physician's role as an unbiased intermediary and counselor is critical.[53] Unfortunately, the proliferation of ties between physicians and industry discussed above can compromise physicians' ability to play this important role.[54] DTC advertising is particularly problematic when coupled with the absence of an unconflicted provider to help in its interpretation.

As detailed in other sections of this manuscript, industry relationships that can affect the ability of physicians to serve as unbiased intermediaries are broad in range and scope. Recent regulations to mandate disclosure have stemmed from the recognition that industry was increasingly offering physicians not only samples, gifts, dinners, and junkets, but also consulting fees, honoraria for speaking engagements and speakers' bureau membership, ghostwriting services, and substantial financial support for research.[55,56] Although the bias that results from this entanglement with industry may be unintentional and unconscious, and most physicians firmly believe that they themselves cannot be influenced in this way, considerable evidence suggests that such ties do indeed have an effect.[57] Thus, although ethical concerns about the potential effect of these relationships exist even outside the context of concerns related to DTC advertising, they take on heightened importance in this light.[58]

Unfortunately, disclosure such as that mandated in the Sunshine Act is far from a panacea in this context. Patients need physicians' guidance not only because they lack relevant expertise to process complex medical information but also because they are in an inherently vulnerable position when making decisions about their own health. Patients may also find their decision-making abilities compromised by the symptoms of a serious disease such as cancer. Scholars have questioned whether disclosure is a useful approach in general, and the challenges appear particularly acute when considering how best to manage conflicts of interest stemming from physician–industry relationships.[59] It is quite unclear whether patients can truly make appropriate sense of information on physicians' financial incentives or detailed disclosure statements to determine the weight to give their advice in various scenarios.[60-62] Similarly, although one could mandate disclosure of industry spending on DTC advertising and other promotional activities, it is unclear whether such disclosure could serve as a meaningful check on this activity in the way that unbiased physician participation might. Although there are many opportunities for synergy between industry and physicians, there are also many inherent challenges that disclosure alone may be insufficient to mitigate.

PERSPECTIVES FROM INDUSTRY

Collaboration and partnerships between pharmaceutical companies and health care professionals/health care organizations continue to be essential for the development of new and life-saving treatments and medical innovations. Without the engagement of medical researchers and practicing physicians, for example, clinical research on new medicines would be impossible. However, some of these partnerships have raised concerns regarding potential conflicts of interest where a physician's professional judgments or actions regarding a patient may be unduly influenced by relationships with industry. As a result, greater and more detailed transparency into these relationships has evolved over the past decade.

Developing new treatments is the cornerstone of the pharmaceutical industry. On average, nearly 20% of pharmaceutical companies' revenue is returned to conduct research and development that leads to new discoveries.[63] The costs of administrating complex clinical trials typically require high levels of funding that are paid by industry. Physicians are engaged not only to recruit, enroll, treat, and monitor patients but also to design research protocols to scientifically demonstrate effectiveness and/or superiority, promote well-being in patients, and provide clues to the cost-effectiveness of particular treatments and regimens.

Making the research space transparent is particularly challenging because the majority of the payments made or attributed to physicians and teaching hospitals are for reimbursement of out-of-pocket costs associated with treating clinical trial subjects and not for fees or compensation earned by the physician or institution for their own work. In addition, the Open Payments regulations require reporting of "indirect" payments, such that physicians who may not have a direct relationship with any particular pharmaceutical company are still being reported as having received something of value. These complexities, combined with the lack of context, can paint a false picture for the layperson.

Indirect Payments and the Knowledge Standard

Indirect payments are payments or TOVs that are provided to a third-party, noncovered recipient (i.e., not a physician or teaching hospital) and then passed through to a covered recipient. Examples of third-party arrangements that might involve a pass-through to a covered recipient include, but are not limited to, consulting firm services (e.g., McKinsey, BCG), and contract research organizations (CROs) arrangements (e.g., Quintiles, Parexel). When engagement of a third party for services by its nature or by virtue of the contractual terms contemplates or requires the use of a covered recipient to perform the work, the applicable manufacturer (AM; e.g., pharmaceutical, medical device company, or group purchasing organization) will likely need to track, attribute, and report some portion of those payments as indirect payments to a covered recipient. Because physician engagement is essential in many research activities, the indirect payment provision's effect on the research space is significant. As a result of this provision, many CROs have created transparency divisions with the sole purpose of providing data to AMs on the breakdown of the (indirect) payments provided for research.

Steak Eaters, Stakeholders, and Principal Investigators

CMS established $10/$100 (adjusted annually by the Center for Program Integrity) as a de minimis of value transfer to trigger reporting: small TOVs less than $10 do not need to be reported except when the total annual value provided to a covered recipient exceeds $100. The de minimis rule results in the attribution of hundreds of thousands of transactions to just as many physicians. The de minimis threshold is usually not relevant for research, as costs for conducting clinical trials and their corresponding payments are usually well above the limit.

For research, payments are often made to third-party organizations who then use the funds to conduct clinical trials. In an effort to maximize research spend, most research-based pharmaceutical companies look to third parties such as CROs to conduct research associated with their products. By working with multiple AMs, CROs achieve a level of efficiency that any one AM would not be able to on its own. Although it achieves efficiency, engaging a third party inherently results in indirect payments between manufacturers and the (covered) recipient of the funds. Furthermore, the payments made by manufacturers, although based on detailed line-item budgets, usually consist of reimbursements and costs other than salaries or other fees paid to or received

by (covered) recipient principal investigators. As such, amounts being attributed to principal investigators in connection with research can appear very high in total value transfer (especially across multiple companies) but be misleading about actual value received and provide no relevant information about influence. This disconnect is especially egregious in the oncology research space, where patient care, concomitant therapies, required diagnostic equipment, etc., is that much more costly.

Assumptions, Interpretations, and Lack of Context

Because AMs are left to make individual interpretations and assumptions about Open Payments reporting, the data being reported are not amenable to apples-to-apples comparisons. For example, some AMs may report payment activity at the level of the study principal investigator and stop there if no physician is in that position. Others may go further to attribute funds to site principal investigators, while others may go still further to attribute funds to all physicians (including sub-investigators) actually working with patients. Each approach provides a different view of the same payment data. However, without knowledge of the underlying assumptions made, third parties could reach different and sometimes incorrect conclusions. Context to the public about the potential differences in application and interpretation of Open Payments is still needed.

Effect on Clinical Oncology Practice

As our understanding of oncology deepens to reveal that what was once believed to be a single disease (or a collection of diseases differentiated on where a tumor primarily presents) is, in fact, more than 200 disparate diseases whose nature depends more on an individual patient's specific molecular constitution than where the primary tumor first presented in that patient clinically, we will need to design and implement smaller, smarter, more nimble clinical trials to develop the suite of tailored medicines (and combinations thereof) that have the greatest potential to treat an individual patient's unique disease. This democratization of clinical trial design is likely to require an even greater absolute number of these smarter, nimbler trials, requiring industry to have even more relationships, with attendant financial ties, to individual physician investigators who either design and sponsor the trials themselves or partner with industry to manage and implement this important clinical trial work.

At the same time, the parallel global trend of increased transparency threatens to cast a pall over this necessary work, as some—concerned by a recent history replete with highly publicized allegations of industry marketing abuses—question the legitimacy of industry's continued financial ties with physicians who stand in the position to prescribe their medicines. Certain physicians, or their institutions, might react (or already have) by curtailing their ties to industry-sponsored research and development work, just when the pursuit of good science requires more partnership. We, as a society, need policies and practices that foster better collaboration across industry, private practice, academia, and government to pursue this good science for society's benefit. Meanwhile, and for some time to come, the burden will likely be placed on industry and physicians to explain how these legitimate relationships foster the greater societal good in an effort to win back our skeptics' trust.

CONCLUSION

Oncology research and practice in the modern era require collaborations between academic physicians and industry. These collaborations provide challenges and opportunities that the entire oncology community must understand and address—especially the complexities that result from these relationships. These relationships which are necessary to continue advancing the field of oncology influence decisions from the level of the individual patient and provider, academic institutions, professional societies, and, most recently, national health policy. As we strive to provide the best and most promising therapies to our patients, we must acknowledge the issues surrounding relationships with industry and learn to navigate and overcome these challenges.

Disclosures of Potential Conflicts of Interest

Cancer Care Quality: Current State and Future Directions

Lawrence N. Shulman, MD

OVERVIEW

Delivery of high-quality medicine is essential in all fields, but it is particularly crucial in cancer medicine in which therapies can be toxic and life-threatening and appropriate treatment can lead to long-term remissions or cure, and when poor therapy compromises survival. Variability in postoperative mortality has been demonstrated for several complex cancer surgeries, depending on surgical expertise and volumes. Systemic therapy, including both cytotoxic and targeted therapies (which are the backbones of many curative regimens), can have severe toxicities. Small upward errors in dosing or schedule can result in unnecessary morbidity and mortality, and they can result in reduced efficacy and poor outcomes. Similarly, radiation therapy is a critical modality in the treatment of so many cancers, but clinically important morbidity and mortality can be associated with it. Methods to continually assess quality in ways that lead to interventions to improve care are essential in cancer medicine today, and they can be viewed as an obligation of our profession.

Quality of any medical care is important, but it is particularly important in cancer care. Quality can be viewed through different lenses, including safety of practice, adherence to treatment guidelines (process measures), and outcomes that include overall survival, cancer-related survival, and quality of life. It is important to consider each of these quality metrics.

SAFETY

In the 1990s, there was a great deal of focus on patient safety. An Institute of Medicine report, "To Err is Human: Building a Safer Health System," published in 1999, examined medical safety and vulnerabilities that can lead to patient harm.[1] A critical component of this process was the acknowledgment that humans, in this case even medical personnel with appropriate training such as physicians, nurses, and other key health care personnel, can make errors that could lead to patient harm or death.

Cancer care is complex and multidisciplinary. A patient with locally advanced rectal cancer may receive concurrent chemotherapy and radiation that might be followed by a surgical resection, the safety of which can be influenced by the toxicity from preoperative therapy. A medical oncologist would prescribe the chemotherapy, including agents, dosing (e.g., based on body-surface area calculations relying on accurate measurements of height and weight), and schedules; a pharmacist would prepare the therapies; and an oncology nurse would administer the drugs. At the same time, a radiation oncologist—together with physicists, dosimetrists, and others—would plan the radiation ports and daily and total doses. The large number of individuals involved and the complexities of the therapies and calculations needed for correct dosing present a significant challenge in assuring care is administered as planned. In addition, care is likely to bridge out-patient and in-patient settings and sometimes involve several institutions. One calculation or human error in this process could lead to higher dosing than planned and added toxicity or death. Likewise, an error resulting in lower than planned dosing could reduce the likelihood of tumor control and long-term remission or cure.

Many errors go unnoticed or are only discovered later when it becomes clear that the outcomes were suboptimal. Continual assessment of processes and the identification of errors that occur in some part of the process, but are identified before reaching the patient and are corrected (near misses), is essential for any program. It is only with continual vigilance that safety will be at its highest level. Assuming that systems are safe can only lead to increased errors over time. The American Society of Clinical Oncology (ASCO) and the Oncology Nursing Society (ONS) have published guidelines for safe oncology practice.[2] Adherence to these guidelines is a component of their Quality Oncology Practice Initiative (QOPI) certification process, which is described later in this article.[3]

Health information technology can be used to improve safety in oncology practices, particularly through the use of electronic health records (EHRs) and computerized chemotherapy order entry systems.[4] These systems do not eliminate the need for human intervention; therefore, there can continue to be human error, so continued vigilance is necessary.

A culture of safety is key to reducing errors to their lowest possible level, with the understanding that errors probably

From the Dana-Farber Cancer Institute, Boston, MA.

Disclosures of potential conflicts of interest are found at the end of this article.

Corresponding author: Lawrence N. Shulman, MD, Dana-Farber Cancer Institute, 450 Brookline Ave., Boston, MA 02215; email: lawrence_shulman@dfci.harvard.edu.

will never be eliminated altogether. All members of a team must be free and willing to speak up when something seems wrong, and each team member must respect and encourage this approach. Hierarchical systems in which some team members are viewed as subservient add considerably to system vulnerabilities. An organizational structure that continually assesses culture and processes, with clear leadership and accountability, is essential in any cancer practice.

However, as important as safety is, it does not consider quality of cancer care in regard to appropriateness of treatment that is designed to provide optimal patient outcomes. It is possible for a medical oncologist to order a regimen correctly, to have it prepared and administered as intended with optimal safety, but if it is not the ideal regimen for the patient's particular type of cancer, the patient outcome is likely to be less than it might be.

PROCESS QUALITY

Much of current cancer care quality measurement is focused on process measures. Based on a high level of evidence from randomized clinical trials, a patient with stage III colon cancer should receive adjuvant chemotherapy. Most quality programs, however, only determine if the patient received chemotherapy. They do not assess whether the patient received the right chemotherapy, whether it was given in appropriate doses and schedule, and they do not assess patient toxicity, quality of life, or survival. There is an implication that if the patient received chemotherapy in this circumstance, appropriate therapy was given, and, by inference, outcomes would be ideal. These are big assumptions. Additionally, much of what oncology providers deal with on a day-to-day basis involves decisions where no high-level evidence exists, which narrows the number of important clinical decisions that can be assessed for quality.

Process measures are used for many reasons. They can be defined, measured, and assessed on recently treated patients. There is an assumption that receiving the right therapy will result in optimal ultimate outcomes. This assumption, however, can be variably defined. Did the patient with stage III colon cancer receive chemotherapy? Do we know what chemotherapy he or she received? Do we know if dosing and schedule was appropriate? Do we know if toxicities were managed appropriately? Care processes can be evaluated on a small random sample of patients or on all patients meeting defined criteria. ASCO's QOPI assesses a random subset of patients with a particular diagnosis and stage for appropriate therapy. For example, patients who have stage III colon cancer should receive adjuvant chemotherapy.[3] The Commission on Cancer (CoC) uses the National Cancer Data Base (NCDB), which will be described in more detail later in this article, to assess all patients treated at a CoC-accredited hospital for this same metric.[5] Process measures are most useful for a practice or hospital when data from other practices and hospitals are available to compare performance. This is true for both the QOPI program and the CoC quality program. In neither case, though, are the specific chemotherapeutic agents assessed, nor are the appropriateness of dosing and schedule.

Process measures can assess the current state of practice for a particular physician group or hospital. They also can be used as a quality improvement tool if performance is suboptimal. The QOPI program examined chemotherapy given during the last 2 weeks of life as a quality metric for end-of-life care. A group in Michigan realized that its rates of utilization of chemotherapy during the last 2 weeks of life were much higher than other QOPI programs. The group then designed interventions to influence practice and their performance quickly improved substantially.[6]

Some process measures derived from very high-level evidence represent relatively low bars to which excel. Both QOPI and CoC examine hormone therapy rates for women with certain stage, hormone receptor–positive breast cancer. Most programs rate very high on this metric. As such, most programs have little room for improvement and the measure does not represent a good approach to comparing performance across programs.

OUTCOMES MEASURES

Patient outcomes, such as overall survival, which takes into account survival from the cancer as well as potential complications of therapy, might be the ultimate quality metric. Survival as a quality metric, however, presents many challenges.

Survival depends not only on the stage of disease, but also on a number of related and unrelated factors. Gender and age have profound effects on survival, and these data are always available in databases for stratification. Socioeconomic status, ethnicity, performance status at presentation, comorbidities, and distance from the patient's home to his or her treating center all affect survival rates, but not all of these factors may be

---

KEY POINTS

- Cancer care providers have an obligation to measure the quality of their treatment to be certain they understand its current state and can design interventions to continually improve performance and patient outcomes.
- Cancer care quality encompasses the safety of care delivered, process measures assessing whether appropriate treatments were administered, and outcome measures that include survival and quality of life.
- Cancer care is complex, provided by medical, radiation, and surgical oncologists, and oncology nurses, with key support from pathologists and radiologists, and spans in-patient and out-patient venues, which makes quality assessment and improvement challenging.
- The Commission on Cancer's Quality program using the National Cancer Data Base and the American Society of Clinical Oncology's Quality Oncology Practice Initiative are examples of broad-based national quality programs.
- The use of health information technology will play a key role in future measurement of cancer care quality.

available for analysis. Comorbidities, in particular, are often complex, hard to quantitate, and variably documented in records. In addition, biologic factors influence survival. A prime example is HPV status in patients with head and neck cancer, in which HPV status radically affects survival with the same therapies.[7] If survival is not stratified for these factors, data will be difficult to interpret or could be misleading.

For many cancers, such as early-stage breast or colon cancer, survival is best assessed at 5 or 10 years after diagnosis. This is because it takes that long for a substantial number of recurrences to occur and for those recurrences to lead to death. Therefore, because of the delay in data entry into registries, survival is reflective of treatment administered 6 or more years earlier. Quality of care from 6 years ago will not necessarily be indicative of more recent efforts to improve quality. In addition, it reflects treatments chosen 6 years before and it does not take into account improved treatments introduced in the interval. Physicians and other providers frequently complain about these factors, suggesting the data are no longer relevant.

In some circumstances, treatment influences survival very little. Most patients with pancreatic cancer present with advanced disease, and current therapies, although marginally better than previous therapies, have very little influence on survival. Therefore, differences in the quality of care may not translate into differences in survival.[8]

In other circumstances, treatment may be so standard and reasonably easily administered that differences in care at one institution vs. another may not be great and will not translate into differences in survival. Examples might include the administration of hormone therapy for patients with estrogen receptor–positive breast cancer, or the administration of chemotherapy for patients with stage III colon cancer.

Quality of life is another important outcome. Optimal management of complex therapies, including surgery, radiation, and systemic therapies, is essential to reduce short- and long-term toxicities. Radiation therapy delivered for the treatment of head and neck cancer is complex and carefully constructed intensity modulated radiation therapy can minimize short- and long-term complications. Less sophisticated approaches result in greater speech, swallowing, and mobility problems both short and long term.[9] Degrees of expertise in performing prostatectomy can influence rates of impotence and urinary incontinence.[10]

Historically, health care providers have recorded toxicities and quality of life inconsistently and data are not always available to truly answer quality-of-life questions. Patient-reported outcomes are becoming increasingly important in documenting quality of life, toxicity specifics, and other important clinical outcomes. Patient-reported outcomes can be electronically recorded by the patient and entered into databases, either clinical databases such as electronic health records, or research databases.

QUALITY MEASURE DEVELOPMENT

The development of quality measures is an important first step in quality assessment and improvement. Quality mea-

sures should explore aspects of care that are important for patient outcomes. They should be based on solid medical evidence and targeted toward aspects of practice in which there is room for improvement. Quality measures must be defined so that the necessary data elements can be extracted from available databases.

DATA SOURCES AND CANCER CARE QUALITY

Ideally, quality of cancer care can be assessed in ways that tax human capital as little as possible. Manual abstraction of patient charts or other documentation can demand considerable time from clinical staff that might be better spent on activities more directly related to clinical care. Electronic data abstraction from EHRs or other databases can measure many aspects of clinical care more efficiently, including those related to quality of care. Not only is this method less demanding on people's time, but it also allows a practice to assess all of its patients with a particular disease and stage, or those who are receiving a particular treatment, whereas manual chart abstraction often limits the number of patient charts that can be reviewed.

Electronic health records provide some advantages as data sources for quality work. Information is entered "live-time" during the provision of care and becomes available for assessment almost immediately. There are several disadvantages, however. Frequently, important data are contained in text notes, or as other nonstructured data, which cannot easily be extracted in usable ways. Although natural language processing can often extract information in a meaningful way, it may have variable accuracy and completeness. Certain information, such as cancer staging, can be entered into an EHR as structured data, but it requires providers to enter the data and to enter it correctly. Data may not be entered at all, and, if entered, it may be entered incorrectly. Accurate diagnostic and staging information in cancer care is critical for almost any other metric to be assessed. Electronic health records frequently contain complete laboratory data and treatment specifics (e.g., drugs, doses, and schedules). For a patient with stage II estrogen receptor–negative, HER2–negative breast cancer who is receiving four cycles of doxorubicin and cyclophosphamide as adjuvant therapy, an EHR should be able to provide the drugs, doses, and whether there were dose reductions, or changes in the schedule; and hematologic values to assess that aspect of tolerance. But knowing that this was the appropriate therapy depends on having accurate anatomic and nonanatomic staging data. If the stage, estrogen receptor, or HER2 status was not entered, or entered incorrectly, there is no way of knowing if this is the appropriate therapy. EHRs are refined continually for usability, decision support, and conversion of data from free text to structured data with these issues in mind.

Registry data also have advantages and disadvantages. Most often, certified tumor registrars trained in the abstraction of data and entry into registry systems enter the data. Registries usually have data on all patients with cancer who are receiving some of their treatment at the facility. Staging

data can be very accurate and other aspects of care and follow-up well delineated in structured data fields. Data often are entered with some lag time—sometimes 6 to 12 months after the event. Although anatomic staging may be complete and accurate, nonanatomic staging, particularly biomarkers, are not always recorded. Estrogen receptor and HER2 data are routinely collected for breast cancers, but newer markers such as *KRAS, BRAF,* or *EGFR* kinase mutations frequently are not. These factors are becoming increasingly important for their prognostic value and for determining correct therapy choices. In addition, entries may indicate that systemic therapy was administered, yet the specifics of that therapy often are not given. It may be known that the patient received chemotherapy but not which chemotherapy. Also, when systemic therapy or radiation therapy is administered at practices outside of the registry's hospital, data are not always available to enter into the registry. Comparing data in registries against claims data has demonstrated this point.[11]

Currently, databases such as registries and EHRs do not communicate well, requiring dual entry of data that is costly and increases risk of data entry errors. Efforts are underway to better link EHRs and registries to overcome some of these challenges, increasing both accuracy and reducing workload.

ASCO'S QUALITY ONCOLOGY PRACTICE INITIATIVE
A decade ago, ASCO undertook an experiment to define quality measures in oncology practices and invited practices to voluntarily participate.[3] Initially, there was little incentive to participate, but many practices chose to do so. In the following years, many quality measures were added to the QOPI slate and more practices chose to participate. Quality was assessed by manual chart abstraction on a subset of patients with a particular disease, stage, or situation. Practice compliance with the measure was assessed and compared to other QOPI practices. Later, a certification program was introduced that involved a site visit that not only assessed compliance with quality measures but also adherence to ASCO/ONS safety standards.

Practices voluntarily participated, largely because they thought it was the right thing to do. In some circumstances, however, additional benefit was established, as in the case of a partnership between Blue Cross Blue Shield (BCBS) of Michigan and the Michigan Oncology Quality Consortium.[12] Practices were able to show substantial improvement in quality metrics and financial rewards for participating were established between the practices and Blue Cross Blue Shield.

The major disadvantage of the QOPI program is its reliance on manual chart abstraction of a small sample of patients. Work is underway to transition QOPI to an electronic abstraction process (eQOPI), which would be a major advance and benefit.

THE COMMISSION ON CANCER QUALITY PROGRAM
The CoC is an arm of the American College of Surgeons that accredits hospital cancer programs.[13] Currently, more than

1,500 hospitals in the United States are accredited. Accredited hospitals transfer their registry data into a de-identified database, the NCDB, which is cosupported by CoC and the American Cancer Society. Accredited hospitals can enter a portal to view their performance against many quality measures and compare them with other CoC-accredited hospitals. In addition, an annual report is produced for each accredited hospital—The Cancer Quality Improvement Program (CQIP). The CQIP contains the hospital's performance for 12 quality measures (in the 2014 report), 30- and 90-day postoperative mortality for six complex cancer surgeries (thoracotomy, esophagectomy, cystectomy, gastrectomy, rectal cancer resection, and pancreatectomy), and survival data for several more common cancers.

A major advantage of the NCDB quality program is that manual chart abstraction is not necessary. Quality data are derived electronically from the database for all patients who have cancer with a particular diagnosis and stage. It should be noted, however, that the NCDB is registry-derived data and registry data are manually entered by registrars. An individual hospital's data can be compared against all other CoC-accredited hospitals, or just hospitals in their region, or hospitals of similar type (e.g., community vs. academic cancer center). Disadvantages include registry data that are often 1 to 2 years old before completely entered into the database. Furthermore, not all desired data are housed in the NCDB. Programs such as the CoC's Rapid Quality Reporting System are driving more timely entry of registry data to affect quality of ongoing care."[13] Specifically, there is little granular data on specific systemic therapies administered and disease-free survival and cancer-related mortality data often are not there. Measures must be designed around what data are available in the NCDB.

COST OF DOING CANCER CARE QUALITY
A hospital or practice that addresses quality measures seriously has a team of individuals undertaking this work. This group often includes physicians, nurses, and individuals who manage the databases, data extraction, and analyses. Participation in the quality programs described above also carry a cost. The exact costs of doing cancer-quality work likely vary greatly among institutions and practices depending on size, databases available to be queried, and other factors. Currently, with few exceptions, practices and hospitals do not gain financially by participating in quality programs in a degree sufficient to offset these costs. In the future, reimbursement for clinical services hopefully will be more closely linked to performance and quality.

FUTURE DIRECTIONS
Our profession has an obligation to measure the quality of our work and to continually strive to improve our practice. This will become even more important as new biomarkers and therapies become available in cancer care and treatment

becomes increasingly multidisciplinary and complex. This can only be achieved when structured quality programs are in place. Funding those programs is not trivial, particularly in the current health care financial climate. Hopefully, in the future, reimbursement will be tied to quality of practice and outcomes for patients.

Disclosures of Potential Conflicts of Interest

The author(s) indicated no potential conflicts of interest.

The Challenges of Managing Older Patients with Acute Lymphoblastic Leukemia

David I. Marks, MB, BS, PhD, FRACP, FRCPath

OVERVIEW

Acute lymphoblastic leukemia (ALL), predominantly a disease of children, has a second incidence peak in older adults. Patients older than age 50 but younger than age 65 may be included in trials of intensive treatment with curative intent, but their outcome is poor with high nonrelapse mortality (NRM), high relapse rates, and low overall survival. Using limited published data from the United Kingdom ALL XII and HOVON trials, this manuscript explores the reasons for the high transplant-related mortality (TRM) and presents early data from the United Kingdom ALL 60+ and United Kingdom ALL XIV studies. Factors affecting therapeutic decisions for older patients are discussed. A case study illustrates some of the issues involved in managing these patients and the need to individualize therapy and consider all options. There may be a role for reduced intensity allografting in selected, fitter patients older than age 50; this article presents preliminary transplant data from United Kingdom ALL XIV that prospectively assesses this therapeutic modality. Detailed discussion of tyrosine kinase inhibitors and the potential place of novel targeted antibodies and immune T-cell therapies will be not discussed in detail. Finally, there is a description of the major outstanding issues and the trials that are needed to inform decision making and improve outcome in this challenging group of patients.

This article will focus on patients with ALL older than age 50 who are known to have a poor outcome in terms of complete remission (CR) rates and long-term survival (Tables 1 and 2, Fig. 1).[1] However, different investigators have used various age limits in defining older patients with ALL. Outcome worsens markedly when patients are older than age 40 and is considerably worse in patients older than age 60. Furthermore, Surveillance, Epidemiology, and End Results (SEER) Program data from the United States show that, unlike every other age group, there has been no significant improvement in outcomes during the last 25 years. In 1984, 8.4 ($\pm$ 3.4%) of patients older than 60 survived compared with 12.7 ($\pm$ 2.9%) from 2000 to 2004, a nonsignificant increase of 4.3%.[2]

In adults, the median age at diagnosis is older than age 60, making effective therapy of the older patient an important area of unmet need.[3-6] The age-specific annual incidence in individuals older than age 60 is 0.9 to 1.6 per 100,000 compared with 0.4 to 0.6 per 100,000 in the 25-year to 50-year age group. The number of cases of ALL occurring in older patients will increase as the general population ages.

DIFFERENT BIOLOGY OF DISEASE AND DIFFERENT PATIENT BIOLOGY
Disease Biology

Compared with younger patients with ALL, older patients have a reduced male to female ratio, their disease is more likely of B-cell origin, and there is greater coexpression of myeloid antigens; these factors portend a worse prognosis, although more recent studies suggest myeloid antigen expression may have minimal prognostic value. Cytogenetic findings such as Philadelphia chromosome positivity, t(4;11), complex cytogenetic abnormalities (more than five chromosomal changes), and low hypodiploidy/near triploidy result in inferior survival rates.[7] These changes are all more common in older adults. Good prognosis lesions, such as high hyperdiploidy, t(12;21), and a normal karyotype, are less common in older patients. The incidence of Philadelphia positivity was felt to progressively increase with age, but this has been challenged by Moorman's population-based study,[8] which indicates a plateau past the age of 50.

THERAPEUTIC DIFFERENCES

Available agents for remission induction therapy include steroids, vincristine, doxorubicin, and various formulations of asparaginase. Choosing the right agents for each patient should take into account reduced renal function, a tendency to more mucositis, and a higher probability of confusion with steroids, infection, and metabolic derangement. Steroids are also more likely to result in symptomatic myopathy and, undoubtedly, contribute to infection. Drug interactions are also more likely in this age group. Concomitant medications

TABLE 1. Prospective Studies of Acute Lymphoblastic Leukemia in Patients Older Than Age 54

should be stopped, if possible. Nutrition is a major issue; all older patients should be seen by a dietitian and their diets proactively managed.

One of the key treatment decisions in this age group is whether an older patient can safely receive conventional doses of anthracycline. A baseline echocardiogram with estimation of ejection fraction is essential. However, many patients will have had a past history of ischemic heart disease or abnormal echocardiograms. Cardiac arrhythmias are common pretreatment (and during induction) and may require cardiac consultation and a change in therapeutic strategy. Li-

---

KEY POINTS

- Older patients with ALL require an individualized assessment of comorbidities and therapy adapted to their performance status, disease response, and personal treatment goals. Newer targeted therapies are likely to play a larger role.
- Optimal postremission therapies in older patients are unknown as are their effects on quality of life and in maintaining complete remission (CR). Reduced intensity conditioning (RIC) allografting in fit patients who have responded well to therapy and have high-quality donors deserves further exploration.
- Arguably, older patients with Philadelphia-positive (Ph-pos) ALL have better outcomes than older patients with Ph-negative disease. This patient group can reliably achieve CR with vincristine, steroids, and a tyrosine kinase inhibitor (TKI) with minimal toxicity. Medium-term survival can be achieved in many older patients with gentle maintenance therapy and a TKI. Using a different agent at relapse may prolong survival.
- Internationally, ALL investigators need to target this neglected group of patients by opening clinical trials that ask questions aimed at improving survival and the quality of that survival. Physicians who manage these patients are urged to enter patients into these clinical trials so that we can learn which therapy can be tolerated and is most efficacious. These basic studies would provide the background data that will enable study of newer targeted therapies that have less marrow and extramedullary toxicity.

---

posomal daunorubicin deserves further testing and liposomal vincristine may result in less autonomic neuropathy.

GOALS OF THERAPY AND PHILOSOPHY OF TREATMENT

Progress in ALL in older patients has been inhibited by a lack of systematic prospective trials and a lack of consensus about the goals of therapy. Only a small percentage of older patients are enrolled in trials,[5] and these patients may not represent the entire group. Prospective studies of older patients show CR rates that range from 30% to greater than 70%, but median survivals generally less than a year. Some studies using a less aggressive treatment intent showed similar survival. Their data may be informing us that one treatment does not fit all: that some are suitable for treatment with curative intent but many are not.

Intensive, prolonged inpatient chemotherapy, with high toxicity and a substantial NRM, can only be justified in this age group within the context of a clinical trial or if there is a significant chance of at least medium term survival.

HOVON

The fairly small-scale data by the HOVON group highlights the uncertainties of how to manage this disease.[9] In 24 patients age 61 to 70 (who were undoubtedly highly selected), 79% achieved CR, and overall survival at 3 years was a remarkable 50%. However, the price for these results was 21% induction mortality. Patients and physicians might accept this NRM as it was accompanied by a realistic chance of medium-term survival. Three of the 24 patients underwent an allogeneic transplant.

POTENTIAL ROLE OF MINIMUM RESIDUAL DISEASE

Eligibility for the United Kingdom ALL XIV trial is for people age 65 or younger, although patients older than age 60 who are less fit may be entered onto the United Kingdom elderly patient trial (ALL 60+). There are few prospective minimum residual disease (MRD) data in the age 60 or older group.

Of the 19 patients older than age 60 analyzed so far, only three were MRD negative after phase I, but five of 16 were negative after phase II (Zakout, unpublished data) with some additional patients being very low-level positive. This shows that intensively treated older patients can be rendered MRD negative. How to use this very limited information is uncertain. MRD-positive patients, depending on their clinical well-being, could be informed of the result and given the choice of therapy to attempt to render them MRD negative or to receive more gentle palliative treatment.

Patients who are MRD-negative, on the other hand, would be candidates for RIC allografts, further intensive chemotherapy, or possibly even an autograft. We need further MRD

TABLE 2. Outcome Data Concerning Older Patients with Acute Lymphoblastic Leukemia

Group/Study	Age	No. of Patients	CR Rate (%)	OS (at 3 to 8 Yrs)	Author

Abbreviations: CR, complete remission; OS, overall survival; Yrs, years.

data in patients who are less intensively treated. It is likely that some of those patients will also be MRD negative; this gives the option of escalating or de-escalating therapy. Most available MRD data uses molecular techniques; MRD data using flow cytometric techniques require further standardization and prospective evaluation. This latter technology is more frequently used in the United States.

UNITED KINGDOM DATA
Issues with the Data

Fewer patients in this age group are enrolled in trials, and they are clearly a selected group and are probably unrepresentative of newly diagnosed older patients with ALL. The chance of early death is high as is refractoriness to chemotherapy.

SIVE ET AL

The United Kingdom Medical Research Council (MRC)/ Eastern Cooperative Oncology Group (ECOG) collaborative group reported outcomes of therapy in 100 patients older than age 55 out of a total of 1,914 recruited to United Kingdom ALL XII/ECOG2993 (median age 56, range 55 to 65).[10] Patients were treated with the full protocol as detailed in Goldstone et al,[7] with no planned dose reductions. Com-

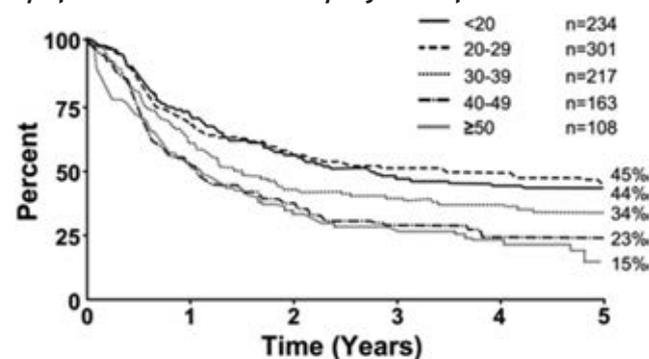
pared with younger patients on study (younger than age 55), more were female, Ph-pos (28% vs. 17%, p = 0.02) and slightly more were in a high-risk cytogenetic group (46% vs. 35%, p = 0.07). The chance of CR was reduced by 20% (73% vs. 93%, p < 0.001).

Strikingly, 5-year overall survival was 21% in the older group compared with 41% in the younger group (Fig. 2). Induction mortality was higher (18% vs. 4%) and infections were more frequent (81% vs. 70%, p = 0.05). A reported infection was associated with higher mortality, particularly if it occurred in both phases of induction. Bacterial infections also occurred at a 50% greater frequency in the older age group. Forty-six percent of older patients had dose reductions compared with 28% in the younger group (p = 0.0009). The most common reason for dose attenuations was hepatic derangement and asparaginase was the drug most often omitted. Reductions in chemotherapy dose were not significantly associated with worse outcomes but numbers were small.

Importantly, Sive et al concluded that the induction protocol used in this study was too intensive for many older patients with ALL. They further stated that stratifying patients based on their disease risk and fitness for therapy might be a way of individualizing therapy; those who are less fit should be treated less aggressively. Although unproven, using MRD to guide decision making may also be valuable.

ALL 60+

Recognizing the lack of prospective data to inform decision making, the United Kingdom National Cancer Research Institute ALL group initiated a prospective study in patients with ALL older than age 60 with the goal of informing how physicians and patients use information about comorbidities and performance status at diagnosis to determine therapy. Comorbidity information is being collected using a variety of tools that have been validated in other groups of infirm patients including many with cancer. There is also a noninterventional registration arm (of patients not wishing to participate) that will enable the estimation of the proportion of older patients with ALL willing to enter prospective trials.

FIGURE 1. Survival of Adults with Acute Lymphoblastic Leukemia by Age Group


Adapted from Rowe JM et al. *Blood.* 2005;106:3760-3767.

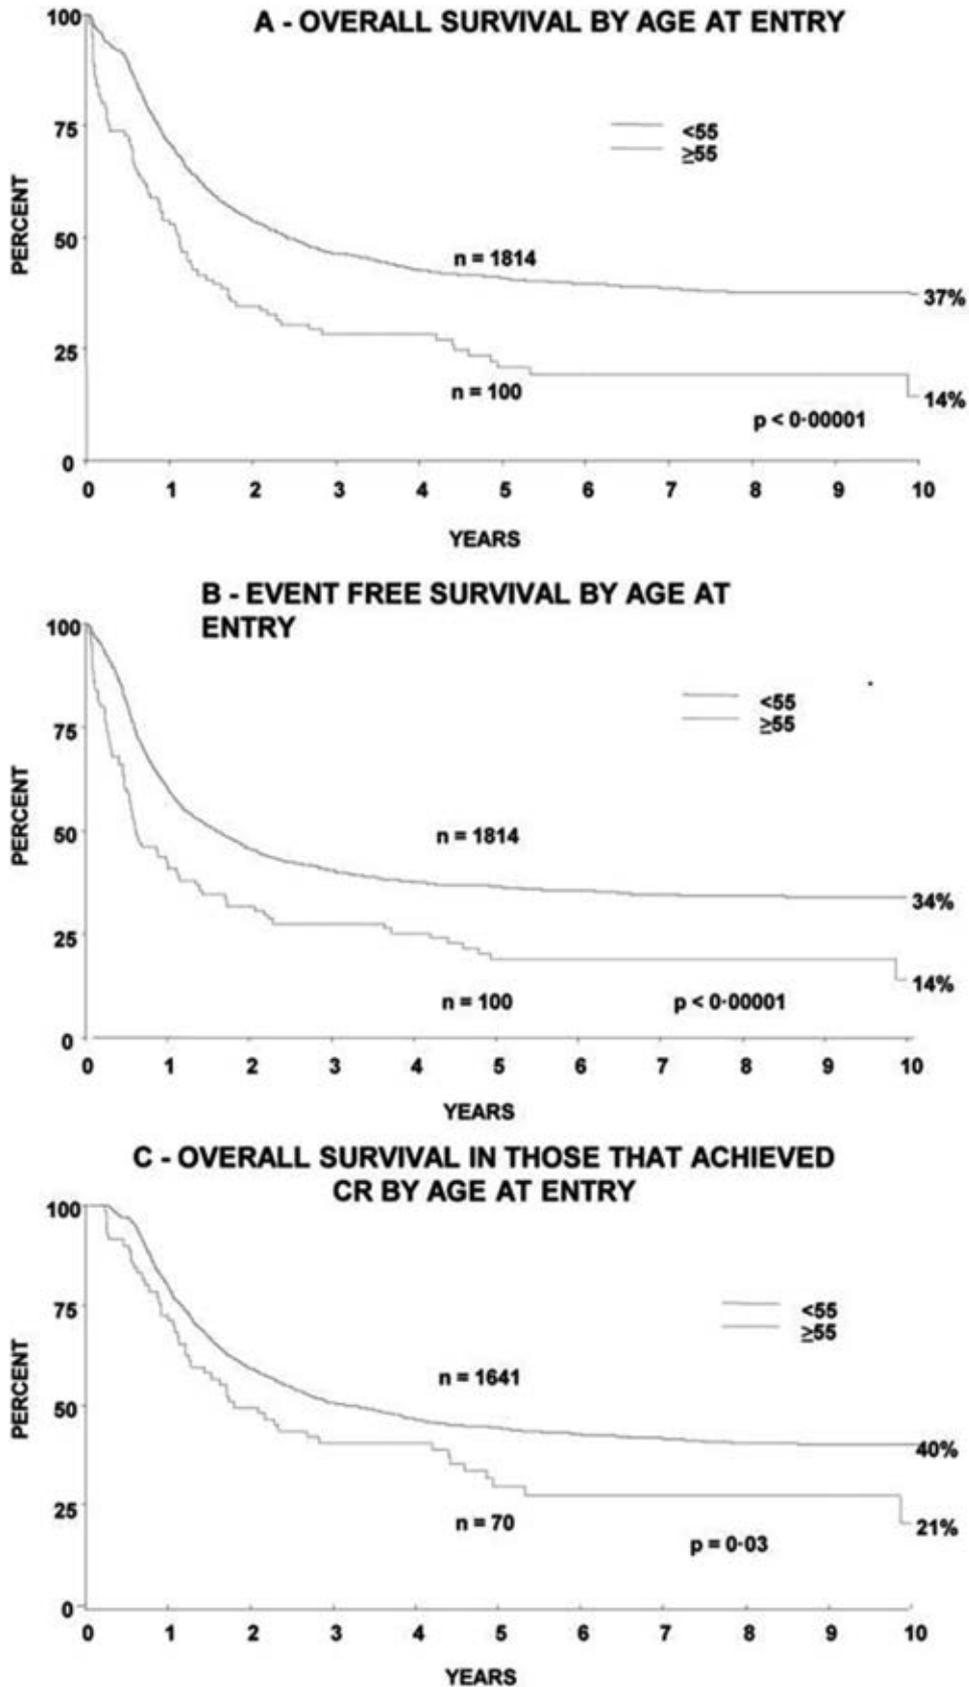
FIGURE 2. Survival of Patients by Age at Entry to Study Showing (A) Overall Survival and (B) Event-Free Survival in All Patients and (C) Overall Survival in Just Those Who Received Chemotherapy


FIGURE 3. Treatment Schema for United Kingdom ALL 60+ Trial Showing Four Treatment Arms and One Registration Arm
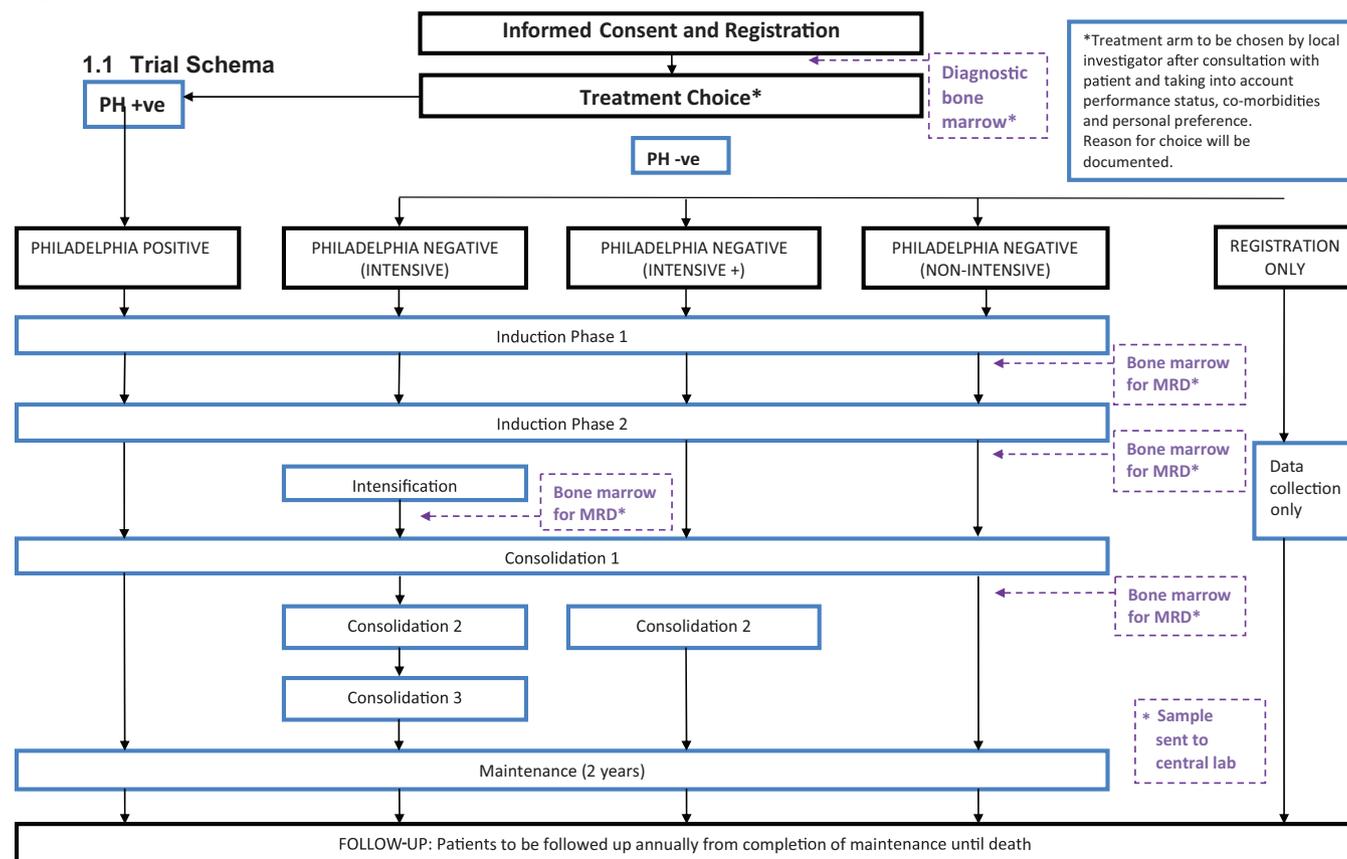

Four treatment arms ranging from very low to high intensity are available to patients enrolled in the study (United Kingdom CRN ID 12988; Fig. 3). The primary endpoints of the study are CR rate after two cycles, event-free survival at 1 year, and treatment-related mortality. Further aims include assessing quality of life (QOL), inpatient stays, and the prognostic value of MRD at three time points. We will further assess tolerability of treatment by assessing certain adverse events.

The trial is accruing slowly, but to date we have preliminary data about 39 patients from 21 centers. The median age of patients is 67 and seven patients are Ph-pos. Twenty one have been assigned to the intensive or very intensive arms. Only 18 patients are currently evaluable for response after phase II. There has been no NRM, and 13 have achieved CR. Two patients have died of ALL. These data will be updated just before the 2015 ASCO Annual Meeting. HOVON and New Zealand are planning to join the study.

During the next 3 years, we will collect data about postremission therapy and its effect on QOL and need for hospitalization. Having analyzed these data, in the next study we will add in some novel agents aiming to improve efficacy without worsening toxicity.

UNITED KINGDOM ALL XIV TRIAL

To date, 394 of 720 planned patients have been recruited to the United Kingdom ALL XIV multicenter study of adults with ALL age 25 to 65. This randomized controlled trial is evaluating up-front rituximab and nelarabine in B-cell and T-cell disease respectively, as well as testing reduced intensity allografting in high-risk patients older than age 40. The protocol was amended after the first 92 patients because of excessive NRM, mostly in older patients. The anthracycline dose was halved (from 60 mg/m^2 to 30 mg/m^2) and doses of PEG-asparaginase reduced from two to one or eliminated in patients with Ph-pos disease.

One-hundred fifty-two patients older than age 50 were entered (139 patients with B-cell disease and 13 patients with T-cell disease, median age 56.5). Philadelphia positivity was seen in 38% of evaluable patients. CR was achieved in 26 of 39 evaluable pre-amendment patients, nine patients died with evidence of leukemia, and four died of NRM (10%). NRM will be analyzed in the patients older than 50 who were enrolled in the study after the protocol amendment. To date, 17 of 137 evaluable patients have relapsed. Forty-four patients older than 50 have proceeded to a RIC allograft (15 sibling donors and 29 unrelated donors). The outcome of all patients

who received RIC allografts will be discussed later in the manuscript.

GERIATRIC ASSESSMENT, RECOMMENDATIONS FOR ADJUSTED THERAPY, USE OF NEW AGENTS

A thorough pretreatment assessment of comorbidities is important. Diabetes and prior malignancy are commonly seen.[5] These objective geriatric assessments have become more formalized recently.[11] On the basis of simple, easy-to-apply criteria (e.g., activities of daily living, performance status, assessment of cognition, and physical function), patients can be divided into three categories: fit, vulnerable, and frail.

Some very simple individualized adjustments to treatment can make treatment effective and tolerable. Shortening the period of neutropenia with granulocyte-colony stimulating factor (G-CSF) is sensible, and one study showed that this resulted in improved survival.[12] Some older patients are unable to tolerate the combination of prolonged neutropenia in the presence of steroids and require omission or dose reductions in myelotoxic drugs. If these drugs are omitted, physicians should consider using rituximab in patients with CD20-positive B-cell disease. Two randomized trials are currently evaluating rituximab's efficacy, but historic control data are encouraging.[13]

Asparaginase is more likely to cause severe hepatic dysfunction especially in the presence of hepatotoxic drugs such as omeprazole, cotrimoxazole, and imatinib. Asparaginase should be used sparingly, if at all, in patients older than 60 and with very careful monitoring.

Patients with significant smoking histories and concomitant cardiac and pulmonary dysfunction tolerate sepsis poorly. Although its use remains controversial, use of quinolone prophylaxis, G-CSF, and very early treatment of possible sepsis is recommended.

The use of agents such as blinatumomab may be an effective means of eliminating MRD with less immune suppression, but large scale efficacy data are lacking in older patients as are tolerability data, especially with regard to central nervous system toxicity.[14] Nelarabine may be an important adjunct up-front in T-cell disease;[15] United Kingdom ALL XIV is examining this issue. Inotuzumab has been examined in a phase III comparison with standard of care therapy in relapsed disease; this trial should yield important safety and efficacy data in patients older than age 50.[16-17]

PH-POS ALL

Ph-pos ALL will be only discussed briefly as it will be dealt with in detail in a subsequent manuscript. One-quarter of all adults are Ph-pos, and the incidence is approximately 50% in patients older than age 50. Until the results of recent studies in older patients became available, most patients with Ph-pos ALL were managed with intensive chemotherapy and a tyrosine kinase inhibitor. Imatinib has improved the CR rate in a number of trials to greater than 90% and makes more patients eligible for transplant.[18] Imatinib resistance mutations are increasingly reported, and these should be sought in patients with relapsed and refractory disease.

Nearly all older patients with Ph-pos disease should be treated with a TKI, vincristine, steroid, and possibly reduced-dose anthracycline. If they achieve CR, subsequent therapy should be individually tailored depending on toxicity, comorbidities, and, possibly, MRD status. B-cell antibodies are also worth considering in this age group; rituximab is well tolerated. This de-escalation of therapy is well tolerated and highly effective in the short term, but data are lacking regarding medium- to long-term survival. An alternative and very effective strategy in older patients is to use dasatinib alone or with steroids.[19]

ISSUES OF SUPPORTIVE CARE
Infection

Unless the patient has a contraindication to quinolones, such as past *Clostridium difficile* infection, they should be used in this patient group as bacterial infection is a common cause of death in induction. Similarly, G-CSF should be routinely used to mitigate neutropenia. There is randomized controlled evidence to support this practice, albeit from an older study. Antifungal prophylaxis should be considered during induction chemotherapy, but azoles need to be used carefully to avoid excess vincristine toxicity.

HEPATOTOXICITY

Some patients older than age 50 will be treated with asparaginase; this is the major cause of induction-associated liver dysfunction. There is an association between induction-associated liver dysfunction and anthracycline use and possibly with imatinib. Patients are generally given asparaginase in the third week from the start of chemotherapy. Liver function tests should be carefully monitored, and asparaginase should not be given to patients with significantly abnormal liver function tests. Hepatotoxic drugs such as cotrimoxazole, omeprazole, and many antifungals should be stopped.

RENAL DYSFUNCTION

Many older patients have abnormal baseline renal function. Careful attention should be paid to hydration and the avoidance of nephrotoxic drugs unless there is no alternative. Allowing patients to become fluid overloaded can necessitate the later use of furosemide, which depletes intravascular fluid with downstream effects on the kidneys.

A ROLE FOR REDUCED-INTENSITY ALLOGENEIC TRANSPLANTATION?

It may seem illogical to be contemplating reduced-intensity allogeneic transplantation in a group of patients who tolerate chemotherapy poorly; however, RIC allografting, if studies

show it to be an effective way of eradicating disease, uses moderate doses of chemotherapy and involves a short period of neutropenia, mild mucositis, and is generally not very debilitating. A transplant may be seen as providing a more rapid recovery than consolidation, intensification, and longer than 2 years of maintenance chemotherapy. It is important to avoid severe graft versus host disease (GVHD) in this older age group, but RIC allografts do rely on a graft-versus-leukemia effect. The main evidence for a graft-versus-leukemia effect is that relapse is less common in patients with grade 2 to grade 4 acute GVHD and/or chronic GVHD. However, this effect is most operative in patients with low levels of disease. Full intensity conditioning causes excessive TRM in this age group and is seldom indicated. It should be noted that RIC allografts are mainstream therapy in older patients with AML with many studies showing acceptable TRM in selected patients.

Two registry-based comparisons with full intensity conditioning show adjusted survival and event-free survival to be similar to full-intensity conditioning (Fig. 4).[20,21] Unsurprisingly, relapse rates are increased and TRM only marginally decreased. The optimum conditioning regimen and GVHD prophylaxis strategy are yet to be defined.

The United Kingdom ALL XIV trial is prospectively examining the role of RIC sibling and unrelated donor allografting. All patients older than age 40 are considered high risk and are eligible for allografts if they are fit, in CR, and have a matched sibling or 8/8 molecularly matched unrelated donor. (Patients with high-risk cytogenetics or persistent MRD are permitted to have a 7/8 match). Sixty-two percent of the first 374 patients are eligible, and we have data on the first 60 allografts. Survival with a median follow-up of 12 months exceeds 80%, and the current TRM of 9% shows that the procedure can be performed safely on a multicenter basis. The rates of acute and chronic GVHD are modest (Table 3). Mixed chimerism is a common outcome of fludarabine, melphalan, and alemtuzamab allografts; 10 patients received do-

TABLE 3. Major Demographic Characteristics and Outcomes for 60 RIC Allografts

Registered for RIC transplant	91
Transplant data available	60
Median age	49
Sibling donor	36 (60%)
ECOG PS 1-2	24 (40%)
WBC >30 × 10e9/L	12 (20%)
High-risk cytogenetics	27/51*
Median time to transplant from diagnosis	5.4 months (4-9)
Acute GVHD grade 2-4	29%
Chronic GVHD	14 (23%)
Donor lymphocyte infusions	16/41**
Relapse	4 (2 survive)
Transplant-related mortality	6
Total deaths	8

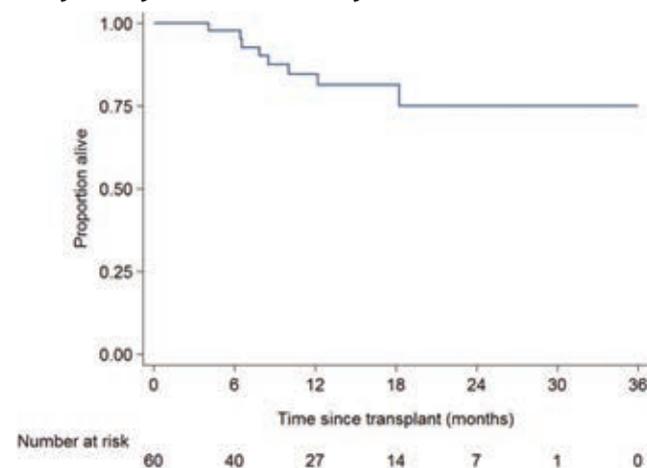
*Nine patients did not have evaluable cytogenetics.
**Data only available on 41 patients currently (10 for mixed chimerism and six for persistent or rising minimum residual disease).

nor lymphocyte infusions for this and six additional patients received donor lymphocyte infusions for persistent or progressive MRD. Fifteen of these 16 patients currently survive, but follow-up is short.

FUTURE DEVELOPMENTS

The newer agents, blinatumomab and inotuzumab,[14,16] have not been tested specifically in this age group, but there will be some data from the ongoing phase III studies (Inovate and Tower). Both drugs have been tested mainly in the relapsed/refractory setting, but blinatumomab is very impressive at converting persistent MRD positivity (after 3 months of chemotherapy) to negativity (78% of 116 patients in the phase II study).[22,23] As most older patients have dose reductions that may result in higher incidences of persistent MRD positivity, it is attractive to add in a 28-day course of blinatumomab to deepen remission states before further consolidative or maintenance chemotherapy. However, first we need data comparing this agent with conventional chemotherapy and to know if older patients tolerate the cytokine release syndrome and neurotoxicity. Similarly, the efficacy and safety of inotuzumab will need to be compared with conventional salvage therapy before we can assess the place of this drug in older patients.

In the United Kingdom, we are working to establish a backbone of chemotherapy that older patients can tolerate, with reasonable CR rates and 1-year survival. We then plan to add in novel agents to improve those outcomes without increasing toxicity and NRM. The collection of diagnostic specimens in these patients and correlation with clinical data may improve our understanding of the biologic differences that exist in older patients with ALL.

FIGURE 4. Preliminary Results of Reduced Intensity Allografting from United Kingdom ALL XIV


Overall survival post-transplant.

Chimeric antigen receptor T cells directed against CD19 have shown remarkable efficacy in a relatively small number of children but are likely to be tested in younger adults before any trials in the older-patient population.[24] A proportion of patients experience severe cytokine release syndrome requiring ICU admission; this could be a limiting factor in the older age group.

CONCLUSION

Effective management of older patients with ALL is a major unmet need. The different biology of the disease and the patient is recognized, and we now need the systematic trials that have improved the outcome of ALL in children and adults to be applied to the older age group. Many fit patients between age 50 and 65 will be able to tolerate conventional aggressive chemotherapy with reasonable outcomes and acceptable NRM. However, older and less-fit patients require less-aggressive chemotherapy, and strategies are needed to improve CR rates in this group. It is essential that we better understand the comorbidities that affect tolerance to chemotherapy so that we can rationally adjust therapy and not rely on end-of-the-bed impressions. Trials such as the United Kingdom ALL 60+ study that assess comorbidities and include objective and subjective QOL endpoints will hopefully advance the field. Leukemia physicians are urged to enter older patients into trials in order that we may improve the outcome of this difficult clinical management problem.

Treatment of Philadelphia Chromosome–Positive Acute Lymphoblastic Leukemia in Adults: A Broader Range of Options, Improved Outcomes, and More Therapeutic Dilemmas

Adele K. Fielding, MB, MS, PhD, FRCP, FRCPath

OVERVIEW

The article addresses selected key areas of flux in the management of Philadelphia chromosome–positive acute lymphoblastic leukemia. There is no doubt that tyrosine kinase inhibitors (TKIs) have made a major contribution to higher rates of complete remission and that more patients are now surviving long term. Many patients tolerate TKIs well, and remission can be achieved with minimal toxicity. Because remissions can include a proportion of patients who become *BCR-ABL1* transcript negative, the question of whether allogeneic hematopoietic stem cell transplantation can be avoided requires discussion. Despite the major progress that has been made and the relative profusion of therapeutic choice compared with 10 years ago, evidence is still lacking for many of the major possible interventions, and how to combine them is unclear. Because of the rarity of the condition and the enticing possibility of increasing traction to therapy, clinical trials and international cooperation remain paramount.

Acute lymphoblastic leukemia (ALL) in which the Philadelphia (Ph) chromosome t(9;22) is detected (i.e., Ph+ ALL) is a genetically, biologically, and clinically distinct subtype of B-precursor ALL, and it comprises approximately 20% of the total ALL incidence. The incidence of Ph+ ALL increases with age, from less than 5% in younger children to 20% to 25% in older adults,[1,2] although population-based studies indicate that the incidence does not continue to increase beyond the fourth decade.[3] Standard ALL chemotherapy treatment alone results in a complete remission (CR) rate of at least 10% lower than in Ph-negative ALL,[4,5] with a median survival of around 8 months.[2] However, in recent years, the addition of TKIs to remission induction treatment—combined with earlier and more frequent allogeneic donor identification, facilitating allogeneic hematopoietic stem cell transplantation (alloHSCT)—has made a considerable change to the outcome. However, the relatively rapid expansion of the range of realistic therapeutic possibilities in an uncommon disease has generated some genuine therapeutic dilemmas in an arena where testing all of the possibilities in well-designed trials has not yet occurred. Furthermore, there is international variability and even local variability in the availability of some of the therapeutic options and of what may be considered standard-of-care choices in some geographic locations is not relevant to others. In this summary, I will focus on key decision points in the treatment of Ph+ ALL, posing the relevant therapeutic questions and evaluating evidence that supports common approaches. I will highlight areas in which there is no clear best practice, providing my personal opinion only when no prevailing consensus exists.

WHAT ARE THE KEY POINTS IN THE PRETREATMENT WORK-UP?

This is a rare disease. As many patients as possible should be offered the opportunity for referral to a major treatment center as soon as possible when ALL is suspected. Even so, diagnostic adequate work-up for Ph+ ALL is straightforward and within the reach of most centers. All patients with ALL should be evaluated urgently for the presence of the Ph chromosome by conventional cytogenetics, fluorescent in situ hybridization, and reverse transcriptase polymerase chain reaction (RT-PCR) for *BCR-ABL* p190 and p210 transcripts. The absolute number of *BCR-ABL* transcripts should be quantified relative to a housekeeping gene, usually *GUS* or *ABL*, using real-time quantitative PCR. p210 quantification is standardized internationally because of its routine use in chronic myeloid leukemia (CML) monitoring, whereas p190 quantification is not standardized, and interlaboratory variation in methods and results can occur.[6] ABL kinase domain mutations at diagnosis that are likely to render resistance to TKIs have been identified by deep sequencing,[7,8] but they typically are not detected by current conventional ap-

proaches. Because their clinical significance is undetermined, they currently cannot be used to direct initial therapy.

HOW TO INDUCE COMPLETE REMISSION IN PH+ ALL

Traditional chemotherapy regimens result in a low CR rate and poor outcome, but, despite the lack of randomized studies over the past 10 years, overwhelming evidence of a higher rate of CR and a long-term survival benefit with the addition of TKIs to chemotherapy regimens has emerged. Most of these studies have been conducted with imatinib at doses between 400 mg and 800 mg daily. The German Multicenter Acute Lymphoblastic Leukemia (GMALL) study evaluated imatinib alternating with or concurrent to induction chemotherapy in 92 patients who had de novo Ph+ ALL. CR was achieved in 95% of patients, and the 2-year overall survival (OS) rate was 36%.[9] The University of Texas MD Anderson Cancer Center (MDACC) used a hyperCVAD regimen in combination with imatinib in patients with de novo or minimally treated Ph+ ALL, resulting in 3-year OS rate of 54%.[10] Yanada et al[11] reported CR rates of 96% in 80 patients (70% achieved *BCR-ABL1* transcript negativity) compared with 51% in historic controls.[11] The 1-year event-free survival (EFS) and OS rates were 60% and 76%, respectively. The Northern Italian Leukemia Group (NILG) reported a CR rate of 92% in 59 patients with newly diagnosed Ph+ ALL using short pulses of an imatinib/chemotherapy combination; 5-year OS and disease-free survival (DFS) rates were 38% and 39%, respectively, compared with 23% and 25%, respectively, in historic controls.[12] The U.K. ALL12/E2993 study[13] was the most recent to report and was the largest of its type (175 patients treated with imatinib added to standard therapy and compared with a large historic cohort of 266 patients treated on the same trial in the preimatinib era). The study showed a considerable survival advantage for an imatinib-containing regimen. The earlier addition of imatinib during therapy resulted in the best outcome.[5] The data are discussed in more detail later in this chapter. There is no rationale now for treating Ph+ ALL without a TKI.

WHICH TKI IS OPTIMAL FOR FRONT-LINE THERAPY?

Studies reporting the use of a TKI other than imatinib as front-line therapy are in the minority,[14,15] but some studies are ongoing (e.g., the European Working Group on ALL study of dasatinib and chemotherapy induction in older persons[16]). There are theoretical differences between the TKIs in *BCR-ABL1* kinase domain binding, potency of *BCR-ABL1* kinase inhibition (e.g., nilotinib and dasatinib are more potent than imatinib), and activity against non–tyrosine kinases (e.g., dasatinib is active against *SRC* kinases). Ponatinib has potential activity against polymutant *BCR-ABL1* alleles, which occur (at least in CML) after the progressive exhaustion of the pool of unmutated *BCR-ABL1* alleles over the course of sequential TKI therapy.[17] Researchers at the MDACC have evaluated and published data from sequential trials with imatinib,[10] dasatinib,[14] and ponatinib, a potent pan–*BCR-ABL1* TKI,[18] each in combination with hyperCVAD, with no clearly elucidated difference between them to date. No direct comparison has been evaluated, and—to my knowledge—no ongoing clinical study is addressing the question of which is the best initial TKI. I would like to direct the readers to well-researched and carefully concluded evidence-based guidelines for TKI use in ALL, which have recently delineated the Canadian perspective on this matter and which provide more detail than can be given here.[19]

CAN PH+ ALL BE TREATED WITHOUT CHEMOTHERAPY?

Induction chemotherapy for ALL is not without toxicity; a number of patients, regrettably, succumb to complications. Sepsis during the neutropenic period of induction therapy is a common precursor to serious morbidity and mortality. Mortality varies with age but is rarely less than 5%[20,21] and can be as high as 15% to 20% in older people.[21,22] Vignetti et al[23] were the first to report data on chemotherapy-free induction therapy for Ph+ ALL.[23] The LAL0201-B trial from the Gruppo Italiano Malattie Ematologiche dell'Adulto (GIMEMA) study included only patients older than age 60, with a median age of 69. Imatinib (800 mg/day) was given with prednisolone. The CR rate was 100%, with minimal toxicity, and the median survival was 20 months, with a 12-month OS of 74%. Postremission therapy and long-term outcomes were not reported. A further study from the same group, GIMEMA LAL1205, showed a similarly high CR rate with no mortality when dasatinib was combined with a corticosteroid alone as induction.[15] Interpretation of those studies will be

---

KEY POINTS

- The outcome of treatment of Philadelphia chromosome-positive (Ph+) acute lymphoblastic leukemia (ALL) has changed considerably for the better over the last 10 years, with up to 60% 5-year overall survival rates with tyrosine kinase inhibitor (TKI) induction followed by allogeneic hematopoietic stem cell transplantation (alloHSCT).
- Complete remission can now be achieved with minimal toxicity TKIs with little or no chemotherapy, but the long-term outcome of chemotherapy-free induction regimens is not known.
- The optimal TKI for induction of remission is not known.
- *BCR-ABL1* transcript monitoring demonstrates that complete molecular remission can be achieved in some patients. Whether this may indicate that future treatment intensification with alloHSCT can be omitted or reserved for disease progression is a totally open question.
- Presently, alloHSCT retains an important role in the management of Ph+ ALL; nonmyeloablative conditioning regimens are now widely used, but results of prospective evaluations of this strategy are still unknown.

confounded by the heterogeneous therapy given subsequently. An ongoing trial, GIMEMA LAL 1509, used a similar chemotherapy-free induction with dasatinib and corticosteroid induction treatment, but added chemotherapy and/or alloHSCT for patients who did not reach a sustained complete molecular response (CMR; i.e., no detectable *BCR-ABL1* transcripts). This approach has been reported so far only in abstract form,[24] but the results are very interesting. The CR rate was 97%, with no induction-related deaths, which included CMR in 18%. Interestingly, *BCR-ABL1* p210 (45% of cases in the report) had a worse prognosis, with lower initial susceptibility to TKIs and a 58% incidence of relapse. The report provocatively suggests that the subset of patients who had deep molecular remissions may be spared further intensive treatment. The long-term follow-up of this study will be of major importance to the field. A recently completed, but also not yet published, study (GRAAPH-2005) from the French Group for Research on Adult Acute Lymphocytic Leukemia Study (GRAALL) also highlights the value of a lower intensity of chemotherapy during induction. Chalandon et al[25] randomly assigned 265 previously untreated patients with Ph+ ALL to receive induction with imatinib/hyperCVAD or imatinib with dexamethasone/vincristine (DIV). Very high CR rates were noted in both arms (DIV, 98%; hyperCVAD, 91%); the lower CR rate in the hyperCVAD arm was a result of higher induction mortality.[26] DIV induction was noninferior to hyperCVAD, with no difference in 3-year EFS (46% vs. 38%; p = 0.25) and OS (53% vs. 49%; p = 0.61).

Although the long-term outlook of treating patients without chemotherapy is unknown, this is a reasonable treatment approach in older patients and should be considered. A detailed discussion of the treatment of older people with ALL in general is given in the chapter by Dr. David Marks.

WHAT IS THE MOST APPROPRIATE CNS-DIRECTED THERAPY IN PH+ ALL?

A small proportion of patients with ALL will present with central nervous system (CNS) disease,[27] but all will need prophylaxis. Recent data using sensitive detection of ALL cells in the cerebrospinal fluid (CSF) suggest that higher-than-expected proportion of patients (18%) present with occult ALL cells in the CSF.[28] This did not emerge as a clinically relevant problem in the series studies, which suggests that therapy directed at preventing the emergence of CNS disease has been and will remain a very important component of the treatment of ALL. Traditionally, a combination of intrathecal therapy, high-dose systemic therapy that crosses the blood-brain barrier, and irradiation has been used and has resulted in a very low level of CNS relapse. However, CNS relapse, when it does occur, portends a very poor prognosis.[29] Typically, patients with Ph+ ALL have been referred for myeloablative HSCT wherever possible and have benefitted from total-body irradiation. However, as we consider chemotherapy-free treatment approaches and reduced-intensity conditioning (RIC) regimens for alloHSCT, the opportunities for CNS-directed prophylaxis to be built-in to the typical protocol are not always obvious. Treating physicians and trialists alike need to consider this issue carefully in an area of practice that does not have a strong evidence base. Imatinib and nilotinib do not cross the blood-brain barrier; dasatinib does and is reportedly part of an effective therapy,[30] and ponatinib has been reported to cross the blood-brain barrier in a murine model.[26] However, there are no trial data to support using TKIs as CNS-directed prophylaxis. CNS irradiation now—and rightly—is little used because of toxicity, but it remains unclear whether systemic methotrexate can be dispensed with, even if the approach is a chemotherapy-free one. The clear benefit of high-dose methotrexate on prevention of CNS relapse has never been demonstrated; there is considerable variability in the dose and number of courses used, so there is little firm evidence on which to select this therapeutic component. It may be safest to be assiduous with intrathecal therapy. The total number of intrathecal treatments needed to constitute an appropriate course of therapy is also unclear. However, if patients quickly move from induction to nonmyeloablative alloHSCT, its unlikely they will have had sufficient intrathecal therapy, so resumption after HSCT may be wise.

WHAT IS THE OPTIMAL POSTREMISSION THERAPY? Myeloablative AlloHSCT: Is It Still the Cornerstone of Definitive Therapy for Ph+ ALL?

The cornerstone of postremission therapy for Ph+ ALL traditionally has been myeloablative alloHSCT (reviewed in Fielding[31]). The strongest support for the overall benefit of sibling alloHSCT in unselected patients with Ph+ ALL comes from the two largest studies conducted in this disease. The LALA-94 trial[4] showed that, among 103 patients eligible for HSCT, the availability of a sibling allogeneic donor was independently predictive of remission duration. An analysis of treatment received in the U.K. ALL12/E2993 trial[5] in 267 patients showed that patients with Ph+ ALL who received sibling or unrelated donor myeloablative alloHSCT had a much better outcome than those receiving chemotherapy alone. Fewer than 30% of the study population were able to receive allogeneic HSCT, mostly because of older age or failure of existing therapy to generate a CR.

Although any data on the outcome of alloHSCT must be interpreted with caution, because of the problems of selection bias and immortal time bias, the weight of evidence in the pre-TKI era has been interpreted in favor of myeloablative HSCT using either a sibling or unrelated donor in adults with Ph+ ALL who have experienced first complete response (CR1).

CAN WE TREAT PH+ ALL WITHOUT TRANSPLANTATION?

With the advent of the genetically targeted treatment that can generate, at least in a proportion of patients, a negative *BCR-ABL1* transcript response, the possibility of dispensing with

alloHSCT, which would be a major advance, must be considered. Evidence in support of this has so far been gathered in patients in whom alloHSCT has not been possible; these patients are never a comparable group to those in whom alloHSCT could be and was performed. Nonrecipients are typically older, have more comorbidities, and are more likely to have experienced relapse by the median time to alloHSCT.[5,13]

Studies in which alloHSCT was not the primary focus may nonetheless contribute to our understanding of its role. As always, though, the circumstances under which patients did not receive alloHSCT must be taken into account. One of the first studies to suggest omission of alloHSCT as a realistic possibility in the TKI era was a Children's Oncology Group study in which patients up to age 21 were treated with imatinib added to chemotherapy.[32] Postremission treatment with sibling alloHSCT was included in the protocol, but the trial did not allow for matched unrelated donor (MUD) alloHSCT on the basis of a previous, international study in children[33] that showed a 43% treatment-related mortality (TRM) for MUD alloHSCT. Hence, this study left a small cohort of children who received an imatinib/chemotherapy combination without alloHSCT. There was relatively high rate of off-protocol MUD alloHSCT that confounded data interpretation. However, at 3 years, the outcomes for those treated with imatinib/chemotherapy (25 patients) compared favorably with those treated with alloHSCT (21 patients); the 3-year DFS without alloHSCT was 85%. Although the study was neither designed nor powered to answer the question of whether imatinib/chemotherapy could replace sibling alloHSCT for children with Ph+, the data introduced the hypothesis that children with Ph+ ALL can be treated successfully without alloHSCT. In combination with emerging data of improved overall outcomes for adults with Ph+ ALL, this study has reasonably sparked consideration of the omission of alloHSCT from treatment. A multivariate analysis of patients treated at the MDACC with hyperCVAD and TKI regimens,[34] which excluded those who had received alloHSCT, revealed that achievement of major molecular response (MMR), namely a BCR-BCR-ABL ratio of < 0.1, was associated with better survival outcomes. However, the selection of the MMR as a cutoff remains somewhat arbitrary, although it is explained in the paper, and the numbers of patients on whom this analysis is based are limited. The authors reasonably take the data to support the role of minimal residual disease (MRD) monitoring but wisely do not suggest that these data currently support the omission of alloHSCT.

In my opinion, the most robust evidence to date on the present need to continue considering alloHSCT as a core therapy comes from trials groups that have reported on the outcome of patients who received chemotherapy and a TKI alone and have been able to compare that group with those who received alloHSCT. Among the few published studies to report on the outcome of a substantial group of patients of transplantable age who did not undergo transplantation was the ALL202 trial from the Japanese Adult Leukemia Study Group,[11] in which the combination of imatinib and chemotherapy was evaluated in 80 adult patients, 31 of whom did not undergo alloHSCT. When compared with historic controls in whom there were no event-free survivors at 24 months, the 2-year estimated EFS was significantly better for those patients receiving imatinib as part of their therapy. In the largest such study internationally, the Ph+ arm of the U.K. ALL12/E2993 trial examined the outcome of treatment in 266 patients enrolled on the preimatinib era and was compared with the outcome in 175 patients receiving the same chemotherapy treatment and alloHSCT approach but with the addition of imatinib.[13] There was a large and statistically significant outcome benefit with imatinib cohort; at 4 years, the OS of all patients in the imatinib cohort was 38%, versus 22% in the preimatinib cohort. However, the rate of alloHSCT was 46% in the imatinib cohort and was 31% in the preimatinib cohort.[13] This raises the question of what proportion of the benefit accrued was a direct result of imatinib alone, rather than the contribution made by imatinib to a significantly better initial therapeutic response facilitating more frequent alloHSCT. A Cox multivariate analysis, which took alloHSCT into account, showed only a modest additional benefit with the addition of imatinib (hazard ratio for EFS, 0.64; 95% CI, 0.44 to 0.93; p = 0.02). Importantly, there was significant benefit for OS and RFS. The investigating team, of whom I was a member, concluded that the addition of imatinib to standard therapy considerably improved the CR rate and long-term OS for adults with ALL. However, our data showed that a proportion of the OS benefit derived from imatinib facilitation of alloHSCT. Studies in which the long-term outcome of patients who have been selected by good risk criteria to postpone alloHSCT will eventually inform a more strategic deployment of alloHSCT in this disease. Additionally, non-alloHSCT immunotherapies, such as the bispecific antibody against CD19 and CD3, blinatumomab,[35] and chimeric antigen receptor T cells (discussed in the companion article by Sadelain et al), may find a role in postremission therapy of high-risk ALL as a potential alternative to alloHSCT.

UNDER WHAT CIRCUMSTANCES SHOULD WE USE NONMYELOABLATIVE (REDUCED-INTENSITY CONDITIONED) ALLOHSCT?

As an alternative to no transplantation for patients who are beyond the upper age limit for myeloablative alloHSCT or who have comorbidities that rule it out, nonmyeloablative (RIC) alloHSCT is used increasingly widely. Retrospective reports constitute the only evidence base to date, although the United Kingdom National Cancer Research Institute Adult ALL subgroup U.K. ALL14 trial includes a prospective evaluation of RIC alloHSCT. Most published series of RIC include patients beyond CR1, and none confine themselves to Ph+ ALL.

A few key, positive messages regarding RIC alloHSCT in Ph+ ALL emerge from the studies reported to date.[37-43] First, RIC can be used, with an acceptable early TRM in patients who are older than those suitable for a myeloablative approach. The median ages reported range from 38 to 50 years, and treatment-related mortality in more recent studies,

which include more patients in CR1, is consistently between 20% and 30%. Currently, no particular conditioning regimen can be considered optimal. Chronic graft-versus-host disease (cGVHD) rates are high, and there is insufficient evidence to determine whether the high rate of GVHD is positively associated with a better disease-related outcome. There likely is scope for approaches in which conditioning regimens that have lower risks of cGVHD are investigated. In summary, nonmyeloablative allogeneic HSCT approaches appear promising and offer DFS rates in Ph+ ALL that, when overtly specified, appear higher than those obtained with chemotherapy and imatinib alone and are in line with what has been achieved by using myeloablative approaches. Two large studies from the IBMTR and EBMT registries reported the comparative outcomes of myeloablative versus RIC alloHSCT in patients with ALL. Ph+ disease was excluded from the IBMTR analysis. The EBMT analysis[44] included 145 patients with Ph+ ALL; among that subgroup, OS was 47% ($\pm$ 5%) for myeloablative conditioning versus 40% ($\pm$ 9) for RIC. In the multivariate analysis of the whole population, the nonrelapse mortality was lower in RIC recipients (hazard ratio, 1.98; p = 0.0001), whereas relapse risk was higher. Multivariate analysis showed that the type of conditioning regimen was not significantly associated with leukemia-free survival. In the IBMTR study,[45] which only included patients with Ph-negative ALL, no independent effect of conditioning intensity was seen. Importantly, all reports of RIC alloHSCT in ALL show poor outcomes when used beyond CR1.

HOW SHOULD TKI BE USED FOLLOWING ALLOHSCT?

The necessity for TKIs after alloHSCT and the duration, if used, is unknown. When studies have specifically reported, TKIs are described as hard to tolerate immediately after alloHSCT. Only one study has addressed this question directly. The German Multicenter Adult ALL Group carried out a prospective, randomized, multicenter trial that compared the tolerability and efficacy of post-transplantation imatinib administered either prophylactically (26 patients) or only after detection of BCR-ABL1 transcripts (29 patients).[46] The study did not find any difference in outcome between the two arms, but it was noted that, when given prophylactically starting at 3 months after alloHSCT, it was hard to tolerate, and not all patients were able to continue. Early or high-level reappearance of BCR-ABL1 transcripts after alloHSCT identified a small subset of patients who did not benefit from the addition of imatinib. Regular monitoring of BCR-ABL1 transcripts is arguably the most important component of the therapy. Although bone marrow provides a higher sensitivity of detection than blood, it is feasible to monitor blood more regularly. In my personal practice, I do not routinely administer a TKI after alloHSCT in the absence of detectable BCR-ABL transcripts, but I monitor BCR-ABL1 transcripts monthly in peripheral blood and immediately carry out a bone marrow assessment if transcripts are detected.

IS THERE ANY ROLE FOR AUTOLOGOUS STEM CELL TRANSPLANTATION?

In the largest study of adult ALL ever, U.K. ALL12/E2993, autologous stem cell transplantation (autograft) was compared with chemotherapy in a randomized manner. Chemotherapy was statistically significantly superior.[47] Nonetheless, the concept of high-dose therapy and return of autologous cells continues to be realized under certain circumstances,[48] and studies have reported good outcomes under particular circumstances in which patients are MRD negative[49] at the time of treatment and, usually, continue to receive a TKI. To what extent the autograft contributed to the good outcomes is not clear, because other studies report long-term outcomes in selected patients who are MRD negative and continue to receive TKIs who did not have autografts.

ADDITIONAL PROGNOSTIC INFORMATION

Additional genetic information can provide prognostic refinement in Ph+ ALL. High-resolution single nucleotide polymorphism (SNP) arrays identified alterations in the transcription factor gene IKZF1 (IKAROS) essential for lymphoid proliferation and differentiation. IKZF1 deletions, identified in greater than 60% of patients with Ph+ ALL, partly explained the aggressive nature of the disease.[50] At present, these are not actionable genetic lesions. For physicians whose patients are not enrolled in trials and who are struggling with individual alloHSCT decisions, these may be relevant factors in decision making.

WHAT SHOULD BE MONITORED AND HOW CAN IT BE INTERPRETED?

Monitoring of Ph+ ALL by quantification of BCR-ABL1 transcripts offers a sensitive and specific way of detecting and monitoring disease. The concepts of CMR or MMR, as used in the assessment of patients with CML, often are cited. The clear relevance in CML relates to the internationally standardized therapy, so responses can be compared among patients and among centers. This is far from the case in Ph+ ALL; hence, the level of response and its predictive value are only relevant to the therapeutic scenario in which they have been reported. I urge caution in extrapolating data described in terms of these definitions beyond the original reporting conditions.

WHAT CAN BE DONE FOR PATIENTS WITH RELAPSED PH+ ALL?

The outcome of relapsed ALL in adults is poor.[29,51,52] Most large studies of relapsed ALL show that factors at diagnosis, such as cytogenetics, do not strongly influence the outcome once relapse has occurred. Time since diagnosis and age are the two strongest predictors of relapse outcome when considering chemotherapy and alloHSCT as therapies. A shorter duration of first remission and older individual age lower the

chance of a good outcome. However, in the TKI era, the mechanisms of resistance are reasonably well studied. At relapse of Ph+ ALL, it is possible now for patients to progress through newer generations of targeted agents in a systematic fashion according to the results of mutational analysis of *BCR-ABL1* transcripts. Patients in whom imatinib ceases to produce a response may respond to nilotinib[53] or dasatinib,[54] and there is even an option, ponatinib, for patients with the T315I mutation.[55] Although TKIs are not without adverse effects, and ponatinib in particular carries a risk of cardiovascular events, they are nonetheless a vastly superior option to rounds of myelosuppressive chemotherapy in preserving performance status and being available to and tolerated by patients in the older age range. There is no evidence of long-term survival mediated by TKIs after relapse. Nonetheless, the difference between EFS and OS in relapsed Ph+ ALL is moving apart. Studies should continue to carefully record both, and readers should pay attention. In addition, results with allografts are being reported. Although allografts have uncertain long-term benefits, there are case reports of good outcomes. Immunotherapy without alloHSCT also is an option for the treatment of relapsed ALL. An international,

phase II trial of blinatumomab in patients with Ph+ ALL who have experienced relapse after treatment that included a minimum of two lines of TKI therapy has recently been completed, and analysis is underway. Patients with Ph+ ALL can respond to CD19 CART cell therapy.

PH-LIKE ALL

In the so-called Ph-like ALL, t(9;22) is absent, but the leukemia is characterized by a range of genomic alterations that activate a limited number of signaling pathways similar to those activated in Ph+ ALL,[56] some of which may be amenable to inhibition with approved TKIs. The precise definition of these targetable, kinase-activating lesions in clinical practice using standard techniques is not yet clear, but suggested algorithms have emerged that provide practical advice on when and how to consider this subtype of ALL.[57] TKIs have yet to be formally evaluated, except in case reports.[58] Nonetheless, there will be patients in whom physicians wish to consider a TKI as an option, and requests for insurers or health systems to reimburse these agents will have to be taken into account soon.

Disclosures of Potential Conflicts of Interest

CD19 CAR Therapy for Acute Lymphoblastic Leukemia

Michel Sadelain, MD, PhD, Renier Brentjens, MD, PhD, Isabelle Rivière, PhD, and Jae Park, MD

OVERVIEW

Chimeric antigen receptor (CAR) therapy is an emerging immunotherapy that shows great promise for cancer, in particular acute lymphoblastic leukemia (ALL). CARs are recombinant receptors for antigen, which, in a single molecule, redirect the specificity and function of T lymphocytes. Following their genetic transfer to patient T cells, the latter acquire the ability to recognize leukemia cells and destroy them. Several years ago, we identified CD19 as an attractive target for CAR therapy for most B cell malignancies, including ALL. We and others have reported remarkable clinical outcomes in adults and children with ALL, achieving a high complete remission rate irrespective of age, prior treatments, or other prognostic markers. Severe cytokine release may develop in patients with high tumor burdens. Several interventions are available to curb the cytokine release syndrome when it occurs. Based on the impressive results obtained with CD19 CAR therapy for ALL, it is realistic to expect that CD19 CARs will become part of the armamentarium for B cell-ALL and other B cell malignancies.

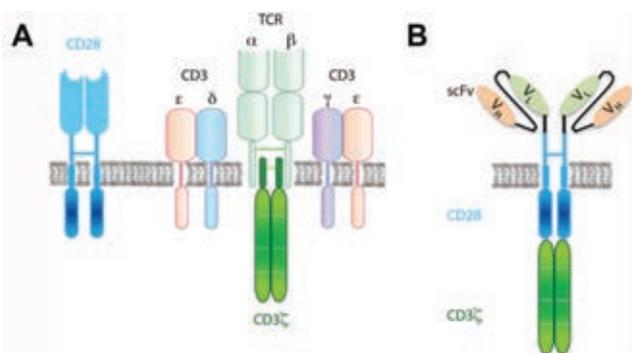
Chimeric antigen receptors (CARs) are recombinant receptors for antigens, which in a single molecule, redirect the specificity and function of T lymphocytes. A general premise for their use in cancer immunotherapy is to rapidly generate tumor-targeted T cells, bypassing the barriers to and incremental kinetics of active immunization.[1] Second generation CARs not only redirect cytotoxicity, but also reprogram T cell function and longevity, thus conferring supraphysiological properties on T cells, which then become "living drugs" that exert both immediate and sustained therapeutic effects.[2]

T cells normally recognize their target antigen through the T cell receptor (TCR), which binds to human leukocyte antigen (HLA)-peptide complexes displayed on the surface of target cells. The TCR does not itself signal, but it does determine, based on its affinity for the HLA-peptide complex, the strength of the activation signals the T cell generates on contacting the tumor. The strength of these signals is further modified by costimulatory receptors, which may be either activating (such as CD28 and 4–1BB) or inhibitory (such as CTLA-4 and PD-1).[3] The ligands for these receptors are not ubiquitously expressed, and therefore place costimulation under the control of the target cell engaged by the T cell. Thus, professional antigen presenting cells, such as B cells and dendritic cells, may express powerful ligands for CD28 and 4–1BB, but tumors typically do not, as is the case for ALL. The concept underlying second generation CARs is to provide costimulatory support to T cells irrespective of the presence of a ligand on tumor cells (Fig. 1). In this context, T cells that engage the tumor through the CAR are given a costimulatory signal within the tumor microenvironment itself, resulting in a pharmacologic boost that we thought would radically alter the functional profile of T cells.[4] The CARs that have recently shown impressive clinical outcomes in patients with B cell malignancies, especially ALL, are indeed second generation CARs.

CAR TARGETS AND THE CD19 PARADIGM

Unlike the physiological TCR, which engages HLA-peptide complexes, CARs are able to engage native cell surface molecules and do not require any processing or HLA expression to be recognized. CARs therefore can recognize target antigens on any HLA background, in contrast to TCRs, which need to be matched to the patient's HLA haplotype. Furthermore, CARs can target tumor cells that have downregulated HLA expression or proteasomal antigen processing, two mechanisms that contribute to tumor escape from TCR-mediated immunity.[5] Another attractive feature of CAR-mediated T cell responses is that they are not limited to proteins and may target carbohydrate and glycolipid structures. The target must, however, be found on the tumor cell surface.

Identifying appropriate CAR targets is important to achieving complete tumor eradication, as is avoiding damage to normal tissues that express the same target antigen ("on-target, off-tumor effect"). Two decades ago, we selected CD19 as the prime target for developing our CAR technology. CD19 is a cell-surface antigen found on most B lineage lymphomas and leukemias.[6] We chose CD19 not only because it is highly expressed in these tumors, but also for its highly restricted expression in normal tissues. CD19 is indeed known to be only expressed among normal tissues in

FIGURE 1. TCR and CAR Structure


A: Physiological T cell activation is mediated by the heterodimeric T cell receptor (TCR) in association with the CD3 complex (which comprises the gamma, delta, epsilon, and zeta chains) and modulated by a multitude of costimulatory receptors, such as CD28. B: In contrast, CARs possess, in a single molecule, the ability to trigger antigen specific T cell functions through three critical domains: a single-chain variable fragment (scFv) (at the top), which mediates antigen recognition; the CD3 zeta chain (green), which initiates T cell activation; and a costimulatory domain (here CD28, in blue), which is lacking in first generation CARs and is a hallmark of second generation CARs.

TABLE 1. Outcomes of Patients with ALL Treated with CD19 CAR Therapy

Publication/Meeting Date	Number/Age of Subjects	Complete Remission Rate
Brentjens, *Sci Transl Med*[17] March 21, 2013	5 (adults)	100%
Grupp, *N Engl J Med*[18] April 18, 2013	2 (children)	100%
Davila, *Sci Transl Med*[19] February 19, 2014	16 adults	88%
Lee, *Lancet*[20] October 13, 2014	21 (children)	67%
Maude, *N Engl J Med*[21] October 16, 2014	30 (25 children, 5 adults)	90%
Park, ASCO-2015 May 30, 2015	33 adults	91%

the B cell lineage. Thus, a successful therapy would be expected to induce a B cell aplasia, which was indeed observed in murine models[7,8] and later in patients treated with CD19 CAR therapy. Furthermore, we thought that the role of CD19 in B cell development may extend to a role in tumor survival, which would ensure that CD19 is expressed on most malignant cells and uncommonly lost.[6,9] We provided the first proof of principle that CAR-modified human peripheral blood T cells targeted to CD19 could eradicate a broad range of B cell malignancies, including ALL, using immunodeficient mice bearing medullary and systemic disease. In these mice, a single intravenous infusion of CD19 CAR–targeted T cells could eradicate a tumor and induce long-term remissions.[10] Successful B cell tumor eradication was eventually obtained with a range of different CD19 CARs,[11-15] paving the way for several ongoing clinical trials.

KEY POINTS

- CAR therapy is an emerging immunotherapy based on engineering of T cells.
- Second generation CARs, which provide costimulatory support to engineered T cells, have transformed the prospects of adoptive cell therapy.
- CD19 CARs have induced dramatic complete responses in patients with relapsed, chemorefractory ALL.
- The two toxicities of CD19 CAR therapy are B cell aplasia (destruction of normal cells that express CD19) and sCRS (which occurs in some patients following in vivo activation of the infused CAR T cells).
- It is reasonable to anticipate that CD19 CAR T cells will become part of the armamentarium for B-cell ALL and other B cell malignancies.

CD19 CAR THERAPY FOR ALL

We reported the first clinical results obtained with CAR therapy for patients with ALL more than 2 years ago by utilizing 19–28z, a second generation CAR that we transduced in autologous peripheral blood T cells collected by apheresis.[16] After enrolling adult patients with relapsed chemorefractory disease, we treated them with an infusion of 3 million CAR T cells per kg following a single infusion of cyclophosphamide (3 g/m^2) as chemotherapy conditioning. Four out of four patients with measurable disease went into molecular remission within 4 weeks.[17] We and two other groups (from the Children's Hospital of the Philadelphia and National Cancer Institute [NCI]) subsequently published follow-up studies in adult and pediatric publications, summarized in Table 1.[18-21] Results obtained at the three different centers all reported a highly remarkable complete remission rate–a rare occurrence for phase I studies in oncology, especially considering the dire prognosis of patients with relapsed ALL, particularly in adults. Although these studies follow the same overall procedure (apheresis, CAR transduction, T cell infusion following chemotherapy conditioning), they differ in several regards, including the CAR design (CD28/CD3-zeta dual-signaling domain utilized at NCI and Memorial Sloan Kettering Cancer Center [MSKCC], 4–1BB/CD3 zeta utilized at the University of Pennsylvania), T cell manufacturing, conditioning chemotherapy, patient age, tumor burden, tumor chemotherapy sensitivity, and T cell dosage.[22] Despite these variances, the comparable outcomes speak to the extraordinary robustness of CD19 CAR therapy in ALL.

At the 2015 ASCO Annual Meeting (May 29–31, 2015), Dr. Jae Park will report on 33 adult patients treated at MSKCC, of which 32 patients are evaluable for response. The median age was 54 (range, 22 to 74). Twelve patients (36%) had Philadelphia-positive ALL, 11 patients (33%) had prior allogeneic stem cell transplant (alloSCT), and 14 patients (42%) had at least three prior lines of therapy. At the time of the

CAR T cell infusion, 16 patients had morphologic disease (> 5% blasts in brain marrow) and the remaining 16 patients had minimal residual disease (MRD). Thirteen out of sixteen patients with morphologic disease (81%) and 16/16 patients with MRD (100%) were in complete remission (CR) after the 19–28z CAR T cell infusion, yielding an overall CR rate of 91% (29/32 patients). Of the 28 evaluable patients with MRD, the MRD negative CR rate was 82%. Eleven patients underwent alloSCT following the CAR T cells infusion. As of January 25, 2015, the median follow up was 5.1 months (range, 1.0 to 37.6 or longer), with 14 patients having at least 6 months of follow-up. The 6-month overall survival (OS) rate of all patients was 58% (95% CI, 36 to 74). Among the patients who achieved CR, OS at 6 months for patients who had alloSCT versus no alloSCT following CAR T cell infusion was 70% (95% CI, 33 to 89) and 61% (95% CI, 29 to 82; p = 0.30), respectively. Two patients relapsed with CD19-negative disease (6%).

The two main safety concerns associated with the use of CARs are the targeted destruction of normal tissues and strong cytokine responses occurring in a subset of patients, now referred to as severe cytokine release syndrome (sCRS).[19] The immune-mediated rejection of normal tissues that express the targeted antigen (referred to as an on-target, off-tumor response) results in B cell aplasia in the case of CD19 CAR therapy. B cell aplasia can be effectively managed by administering intravenous immunoglobulin. Furthermore, B cell aplasia is reversible following the disappearance of CAR T cells and after bone marrow transplantation. It remains an issue in those few patients who show very long-term persistence of the CAR T cells.

The second major concern is that of sCRS, which is associated with intense antitumor responses mediated by large numbers of activated T cells. These typically cause high fever (>38°C for >3 days), hypotension, respiratory distress, and/or neurological symptoms (in particular confusion, aphasia, or global encephalopathy). Management of these symptoms may require steroids, interleukin-6 receptor blockade (tocilizumab), vasopressors, and/or supportive therapy delivered in the intensive care unit. Importantly, we observed in our first five patients[17] and later confirmed in the first 16 patients[19] that the likelihood of developing sCRS is tightly correlated with tumor burden, thus providing a simple means to anticipate patients who are at risk of developing sCRS. This has proven true in pediatric patients.[18,20,21,23] In a study of 33 adult patients who all had high tumor burden, sCRS requiring vasopressors or mechanical ventilation for hypoxia occurred in 7 patients and was effectively managed with IL-6R inhibitor and/or corticosteroid therapy. Other approaches to treat or prevent sCRS are reviewed elsewhere.[23-25]

PERSPECTIVE

The past 2 decades have seen the creation of a new toolbox of recombinant receptors for cancer immunotherapy. Second generation CARs have transformed the adoptive T-cell therapy field. CD19 has become the poster child for CAR therapies. The most remarkable results have been reported to date in ALL, in both adults and children. Remarkably, the CR rate remains high irrespective of patients' age or prior treatments. sCRS may occur in patients with high tumor burden, but means to control it are available. CD19-negative relapse may occur (possibly more commonly in children), for which CD22 CAR therapy may provide an effective recourse.[26] CD19 CARs, which received breakthrough designation by the U.S. Food and Drug Administration at CHOP and at MSKCC in 2014, will soon become part of the armamentarium for B cell-ALL and other B cell malignancies.

New Targeted Therapies for Indolent B-Cell Malignancies in Older Patients

Maxwell M. Krem, MD, PhD, and Ajay K. Gopal, MD

OVERVIEW

Molecularly targeted agents have become an established component of the treatment of indolent B-cell malignancies (iNHL). iNHL disproportionately affects older adults, so treatments that have excellent tolerability and efficacy across multiple lines of therapy are in demand. The numbers and classes of targeted therapies for iNHL have proliferated rapidly in recent years; classes of agents that show promise for older patients with iNHL include anti-CD20 antibodies, phosphatidyl-3-kinase (PI3K)/Akt/mammalian target of rapamycin (mTOR) signaling pathway inhibitors, immunomodulators, proteasome inhibitors, epigenetic modulators, and immunotherapies. Here, we review the proposed mechanisms of action, efficacy, and tolerability of novel agents for iNHL, with an emphasis on their applicability to older patients.

For slightly more than a decade, targeted therapies have established a track record of improving outcomes for older patients with lymphoma. Rituximab was the first widely utilized targeted therapy for B-cell lymphomas and resulted in survival improvement when combined with standard chemotherapy for older patients with diffuse large B-cell lymphoma,[1] chronic lymphocytic leukemia (CLL),[2] and follicular lymphoma (FL).[3-6] The addition of rituximab to traditional chemotherapy ushered in a new standard of care for fit patients with both aggressive and indolent B-cell non-Hodgkin lymphomas, termed chemoimmunotherapy, that led to new benchmarks for response rate (RR) and overall survival. In recent years, targeted therapy options have multiplied rapidly, which may once again lead to new standards of care and treatment expectations for B-cell malignancies, in particular indolent lymphomas.[7,8]

Based on 2008 World Health Organization classifications, iNHL comprises the following histologic subtypes: FL; small lymphocytic lymphoma (SLL)/CLL; lymphoplasmacytic lymphoma (LPL), which is defined as Waldenström macroglobulinemia (WM) when associated with a monoclonal immunoglobulin M component and bone marrow involvement; and marginal-zone lymphoma (MZL), which includes marginal-zone lymphoma of mucosa-associated lymphoid tissue.[9] iNHL disproportionately affects older populations (Table 1) and may require multiple treatment courses over decades,[10-12] so there is a need for effective targeted agents as either supplements to or replacements for traditional regimens. An observational study of 1,495 patients with CLL demonstrated that older age was associated with worse performance status, a higher comorbidity score, and more advanced disease at treatment initiation,[13] highlighting the need for agents that have efficacy and tolerability in older patients. Furthermore, age-related host factors reduce treatment tolerability and increase the risk of grade 3 to 5 toxicities,[14] making adverse effects key considerations.

Both the classes and numbers of targeted therapies have rapidly proliferated, resulting in an evolving and more complex treatment landscape. Available classes that have spawned second-generation agents include monoclonal antibodies, cell-signaling pathway inhibitors, immunomodulators, and proteasome inhibitors. Several new classes of agents are in clinical trials and show promise (Table 2). We will discuss these classes of agents, their proposed mechanisms of action, and the clinical data regarding their efficacy and tolerability in older patients. Our emphasis will be on those that are currently marketed, have been studied in older populations, and have later-phase clinical data.

ANTI-CD20 ANTIBODIES

CD20 is a glycosylated phosphoprotein antigen found on the surface of B lymphocytes at most stages of B-cell development, starting at the pro-B-cell phase but ending before differentiation into plasma cells. Its function is believed to be optimization of antibody responses, but it has no known natural ligand.[15,16] Monoclonal antibodies directed against CD20 neutralize both benign and malignant B cells; anti-CD20 antibody cytotoxicity mechanisms include antibody-dependent cell-mediated cytotoxicity (ADCC), complement-

Disease	Median Age (Years)	Reference(s)
CLL/SLL	72	12
LPL	60-64	10, 11
MZL	72	12
FL	65	12

Abbreviations: iNHL, indolent B-cell malignancies; CLL, chronic lymphocytic leukemia; SLL, small lymphocytic lymphoma; LPL, lymphoplasmacytic lymphoma; MZL, marginal-zone lymphoma; FL, follicular lymphoma.

dependent cytotoxicity, and apoptosis.[17,18] With the advent of rituximab, anti-CD20 monoclonal antibody therapy assumed an essential role in the therapy of the majority of B-cell malignancies. Novel anti-CD20 agents have been developed in an effort to build on the progress made in the rituximab era. There are two recognized classes of anti-CD20 antibodies: type 1 (ibritumomab, rituximab, and ofatumumab) and type 2 (obinutuzumab). Type 1 antibodies organize CD20 molecules into "rafts" and exert their effects primarily by ADCC and complement-dependent cytotoxicity, and less so by apoptosis. Type 2 antibodies utilize apoptosis to a greater degree and also exert more potent ADCC as well.[19,20]

The radioimmunoconjugate [90]yttrium-ibritumomab-tiuxetan (YIT) fuses a murine anti-CD20 antibody to a chelator (tiuxetan) that holds the beta-emitter isotope 90Y. YIT received initial approval in 2002 for relapsed or refractory low-grade lymphoma, but recent data show that it has considerable single-agent efficacy as initial therapy[21,22] or consolidation therapy[23] for patients with FL or MZL. The percentage of patients age 60 or older ranged from 28% to 50% in those stud-

KEY POINTS

- Older patients are more prone to comorbidities, reduced performance status, and grade 3 or higher toxicities, making safety and tolerability key considerations in the choice of treatment for indolent B-cell malignancies.
- New anti-CD20 monoclonal antibodies, administered in combination with chlorambucil, have demonstrated efficacy in patients with chronic lymphocytic leukemia who are older or have comorbidities.
- The phosphatidyl-3-kinase inhibitor idelalisib and the Bruton's tyrosine kinase inhibitor ibrutinib have demonstrated good efficacy and tolerability in patients with chronic lymphocytic leukemia, including patients with high-risk cytogenetics.
- mTOR inhibitors, immunomodulatory drugs, and proteasome inhibitors have efficacy across several indolent B-cell malignancy histologies but have not resulted in high tolerability in all patient subtypes.
- Immunotherapies such as programmed cell death 1 blockade show promise of efficacy with excellent tolerability.

ies, with minimal or no grade 3 to 4 nonhematologic adverse events. In the randomized consolidation FIT trial, 8% of patients in the YIT arm experienced grade 3 to 4 infections versus 2% of patients in the control arm. Thus, radioimmunoconjugate therapy offers potent single-agent efficacy coupled with excellent tolerability, a favorable combination in older patients.

Ofatumumab was approved by the U.S. Food and Drug Administration (FDA) in October 2009 as a single agent for relapsed CLL after a single-arm, phase II study with 59 patients of median age 64 with relapsed or refractory disease after fludarabine and alemtuzumab therapy demonstrated a 58% overall response rate (ORR). In the trial, 27 patients were age 65 or older and 10 patients were age 70 or older. Response rates were similar for younger and older patients. Grade 3 to 4 infections developed in 12% of patients, 10% of patients experienced fatal infections, and 64% of patients experienced infusion reactions.[24]

A subsequent open-label trial in the first-line setting, COMPLEMENT-1, randomly assigned 447 patients who were not candidates for fludarabine-based therapy to receive ofatumumab and chlorambucil (217 patients) versus chlorambucil alone (227 patients). The median age was 69, with 69% of patients age 65 or older, and 72% of patients had at least two comorbidities including chronic kidney disease; thus, the trial had excellent applicability to patients with advanced age. Efficacy and safety results are summarized in Table 3. Briefly, first-line ofatumumab and chlorambucil achieved a higher RR and improved progression-free survival (PFS) compared with chlorambucil alone.[25] It should be noted that the comparator arm, chlorambucil monotherapy, is commonly reserved for patients who are candidates for minimally aggressive therapy, yet still produced substantial rates of adverse events and severe infections. A Canadian cost-effectiveness analysis of the COMPLEMENT-1 trial demonstrated an incremental cost-effectiveness ratio of CAD $68,672 per quality-adjusted life-year (QALY) gained.[26] On April 17, 2014, the results from COMPLEMENT-1 led to the FDA approval of ofatumumab in combination with chlorambucil for the front-line treatment of patients with CLL.

Obinutuzumab received FDA approval on November 1, 2013, for the first-line treatment of patients with CLL in combination with chlorambucil, based on results of the open-label, phase III CLL11 trial of 781 patients comparing obinutuzumab and chlorambucil, rituximab and chlorambucil, and chlorambucil alone. All patients had coexisting morbidities and a median age of 73. Results are summarized in Table 3. The obinutuzumab-chlorambucil arm demonstrated superior PFS, and overall survival favored obinutuzumab/chlorambucil over chlorambucil alone (RR 0.41; p = 0.002), but did not reach statistical significance for obinutuzumab/chlorambucil compared with rituximab/chlorambucil. In the aggregate, hematologic toxicity was higher in the obinutuzumab/chlorambucil arm versus rituximab/chlorambucil, emphasizing that the improved PFS was somewhat counterbalanced by increased toxicity. Of note, 109 of 240 patients in the obinutuzumab plus chlorambucil

TABLE 2. Selected Molecular Pathways and Marketed Novel iNHL Therapies That Target Them

Pathway	Molecular Target	Agent	Dosing	Disease(s)	FDA Indication(s)	Phase(s) of Clinical Trial Data
CD20	CD20	Ofatumumab	300 mg IV day 1 and 1,000 mg IV day 8 (cycle 1) and 1,000 mg IV day 1 (cycles 2-12) of 21-day cycles	CLL, FL	CLL (first-line, relapsed)	II, III
		Obinutuzumab	100 mg IV on day 1, 900 mg IV on day 2, and 1,000 mg IV on days 8 and 15 (cycle 1) and 1,000 mg on day 1 (cycles 2-6) of 21-day cycles	CLL	CLL (first-line)	III
		Ibritumomab tiuxetan	14.8 MBq/kg IV once, maximum 32 mCi	FL, MZL	iNHL or FL (relapsed); FL (first-line consolidation)	II, III
PI3K/Akt/mTOR	PI3K	Idelalisib	150 mg PO BID	CLL, FL, LPL, MZL	CLL/SLL, FL (relapsed)	II, III
	mTOR complex 1	Everolimus	10 mg PO QD	CLL, MZL, WM	Renal cell carcinoma, breast cancer	II
		Temsirolimus	25 mg IV every week	CLL, FL, WM	Renal cell carcinoma	II
	BTK	Ibrutinib	420 mg PO QD	CLL/SLL	MCL (relapsed), CLL (relapsed and del[17p]), WM	II, III
			560 mg PO QD	FL		
			420 mg PO QD	WM		
Immunomodulation	Cereblon	Lenalidomide	25 mg PO QD, days 1-21 of 28-day cycles	FL, MZL, SLL, WM	Multiple myeloma, MCL, MDS	II
Proteasome	20S subunit chymotryptic site	Bortezomib	1.6 mg/m^2 IV on days 1, 8, 15, and 22 of 35-day cycles	CLL, SLL, FL, MZL, WM	Multiple myeloma, MCL (relapsed)	I, II, III
		Carfilzomib	20 mg/m^2 IV on days 1, 2, 8, and 9 (cycle 1), 36 mg/m^2 IV (cycle 2-6), 20 mg/m^2 on days 1 and 2 (maintenance) of 21-day cycles	CLL/SLL, FL, WM	Multiple myeloma (relapsed)	I, II
Epigenetics	Histone deacetylase	Vorinostat	200 mg PO BID days 1-14 of 21-day cycles	FL, MZL	Cutaneous T cell lymphoma	I, II
	DNA methyltransferase	5-azacitidine	75 mg/m^2 SC on days 1-7 every 3 to 8 weeks	CLL	MDS	II
		Decitabine	15 mg/m^2 IV on days 1-5 of a 28-day cycle	CLL	MDS	I
Immunotherapy	PD-1	Nivolumab	3 mg/kg IV day 1 of 14-day cycles	FL	melanoma	I, II

Abbreviations: IV, intravenous; CLL, chronic lymphocytic leukemia; FL, follicular lymphoma; PO, by mouth; SC, subcutaneous; Bq, becquerels; QD, once daily; BID, twice daily; MZL, marginal-zone lymphoma; LPL, lymphoplasmacytic lymphoma; WM, Waldenström macroglobulinemia; SLL, small lymphocytic lymphoma; MCL, mantle cell lymphoma; MDS, myelodysplastic syndrome.

arm were older than age 75. Of those patients, 45% experienced serious adverse events, and 5% of patients experienced adverse events that led to death; similar rates were seen in the comparator arms.[27] It is interesting to note that the CLL11 and COMPLEMENT-1 trials used different chlorambucil regimens. A 65-kg person with body-surface area 1.8 m^2 would have received a substantially higher dose of chlorambucil per cycle (126 vs. 65 mg) if enrolled in the COMPLEMENT-1 trial, possibly accounting for the lower response rate and PFS observed for the chlorambucil arm of the CLL11 trial.

A cost-effectiveness study of obinutuzumab versus rituximab in combination with chlorambucil found that obinutuzumab increased QALYs by 0.56 compared with rituximab, with an 89% probability that obinutuzumab was cost-effective at the $100,000 threshold.[28] The study was based on Medicare reimbursements and wholesale acquisition costs and was sponsored by Genentech, which markets obinutuzumab. In contrast, the United Kingdom's National Institute for Health and Clinical Excellence (NICE) found that obinutuzumab/chlorambucil versus rituximab/chlorambucil added $45,000 per QALY in costs and $77,130 versus bendamustine/rituximab in costs. NICE initially decided not to fund obinutuzumab, finding it inadequately cost effective.[29,30] NICE revised its decision, funding obinutuzumab for the first-line treatment of patients with CLL after a nondisclosed discounted price was offered by the company.[31]

Ofatumumab and obinutuzumab demonstrated substantial activity in untreated older individuals, except for patients with a 17p deletion (del[17p]). The caveats from these studies

TABLE 3. Selected Randomized Controlled Trial Data for Chemoimmunotherapy in Untreated CLL with Novel Anti-CD20 Monoclonal Antibodies

Study, Reference	Regimen	Median Age (Years)	ORR (%)	PFS (Months)	Grade 3 or Higher Toxicity (%)	Infusion Reaction (Grade 3 or Higher, %)	Infection (Grade 3 or Higher, %)	Death (%)
COMPLEMENT-1, Hillmen et al 2013[25]	Ofatumumab and chlorambucil	69	82	22.4	50	10	15	2
	Chlorambucil	70	69	13.1	43	n/a	14	2

are that infusion reactions and infections are encountered frequently. In older patients, managing infusion reactions, as a result of effects of premedications, may be more challenging. Severe infections may also be more difficult for older populations because of reduced organ reserves but are likely to be encountered regardless of the regimen chosen.

PI3K/AKT/MTOR PATHWAY ANTAGONISTS

The PI3K/Akt/mTOR signaling pathway governs a wide range of cellular housekeeping and growth functions. The multiple classes and isoforms of PI3K enzymes transduce signals from receptor tyrosine kinases at the cell membrane, notably including the B-cell receptor (BCR), and activate the serine-threonine kinase Akt, which functions as an oncogenic effector. Akt in turn indirectly activates mTOR kinase complexes 1 and 2. Bruton's tyrosine kinase (BTK) is also a downstream target of PI3K signaling, an activator of Akt, and a crucial factor in BCR signaling and B-cell development.[32-34]

Preexisting and new therapeutic agents that target various steps of the PI3K/Akt/mTOR pathway have demonstrated efficacy in B-cell lymphomas and have obtained FDA approvals for the treatment of patients with iNHL. The oral PI3K-delta inhibitor idelalisib, which interferes with BCR signaling and microenvironmental support signals in both healthy and malignant B cells, received FDA approval in July 2014, based on clinical trial data that demonstrated single-agent efficacy in relapsed iNHL and, in combination with rituximab, activity in relapsed CLL. In a phase II study of 125 heavily pretreated patients of median age 64 with iNHL whose disease was refractory to both rituximab and alkylating agents (FL, 72 patients; SLL, 28 patients; MZL, 15 patients; and LPL, 10 patients), treatment with idelalisib resulted in a 57% RR, with PFS of 11 months. Hematologic serious adverse events included neutropenia (27%), anemia (2%), and thrombocytopenia (6%); nonhematologic serious adverse events included transaminase elevations (13%), diarrhea (13%), and pneumonia (7%). In total, 54% of patients experienced serious adverse events, and 20% of patients discontinued therapy because of adverse events.[35]

In a double-blinded, placebo-controlled, phase III study, 220 pretreated patients of median age 71 with CLL were randomly assigned to receive idelalisib and rituximab or placebo and rituximab. Treatment with idelalisib significantly im-

proved PFS, the primary endpoint (hazard ratio [HR], 0.15; $p < 0.0001$). ORR improved from 13% to 81%, and the 12-month OS was 92% in the idelalisib/rituximab arm compared with 80% in the placebo/rituximab arm (HR, 0.28; $p = 0.02$). Notably, 42% of patients in the idelalisib arm had a del(17p); idelalisib showed efficacy across all prognostic subgroups. Severe adverse events occurred in 40% of the patients in the idelalisib arm compared with 35% of the patients in the placebo arm. Grade 3 or higher hematologic adverse events were similar between the two arms. Discontinuation of the study drug occurred in 8% of patients taking idelalisib and in 10% of patients in the placebo group.[36] Idelalisib appears to have excellent efficacy in pretreated patients with iNHL with manageable toxicity. The placebo-controlled, randomized CLL trial adds perspective to the tolerability data seen in the single-arm trial; the relatively high discontinuation rate may be more attributable to the age and pretreatment status of the patient populations enrolled, as evidenced by the 10% placebo group discontinuation rate in the randomized study.

Next-generation PI3K inhibitors are also in development, including duvelisib (IPI-145), a PI3K-delta and PI3K-gamma inhibitor. Duvelisib has demonstrated efficacy in early phase studies of patients with FL, MZL, LPL,[37] and CLL.[38] It was well tolerated and did not have a decrease in efficacy in adverse-risk CLL.

The rapamycin (sirolimus) analogs temsirolimus and everolimus inhibit mTOR complex 1, with the effects of stimulating apoptosis and inhibiting cell growth and proliferation.[33,39] Those second generation "rapalogs" have demonstrated efficacy in both aggressive and iNHL, as explored in several phase II trials.[33,40-43] Trial results are summarized in Table 4. The limited available clinical data for those agents suggest that they may be less tolerated than other agents indicated for iNHL, which may limit their use in older patients. Temsirolimus and everolimus have not yet been FDA-approved for the treatment of patients with iNHL. Interestingly, mTOR inhibition may help overcome resistance by a mobilizing effect.[43] Inhibition also seems to overcome fludarabine resistance by suppressing mTOR complex 1–mediated metabolic reprogramming, manifested by higher rates of glycolysis and oxidative phosphorylation, in CLL cells.[44]

Ibrutinib, a covalent, irreversible, oral inhibitor of BTK, received FDA approval in February 2014 for the treatment of patients with CLL. In July 2014, the label was extended to

TABLE 4. Selected Phase II Trial Data for mTOR Inhibition in iNHL

Regimen	Disease Subtype(s)	Median Age (Years)	Overall Response Rate (%)	Progression-Free Survival (Months)	Grade 3 or Higher Toxicity (%)	Treatment-Related Deaths (%)	Toxic Discontinuation (%)	Reference

Abbreviations: MZL, marginal-zone lymphoma; WM, Waldenström macroglobulinemia; CLL, chronic lymphocytic leukemia; FL, follicular lymphoma.

patients with the del(17p) cytogenetic abnormality. A phase Ib/II, multicenter trial of ibrutinib was conducted in 85 patients with relapsed CLL; the median age was 66, and 35% of patients were age 70 or older. Patients had received a median of four prior therapies, and 33% of patients harbored the del(17p). In the study, 71% of patients responded to therapy and 18% of patients had a partial response (PR) with lymphocytosis. Patients with a del(17p) experienced a 68% ORR. The discontinuation rate was 4% in the 420-mg cohort and 12% in the 840-mg cohort. The most common severe adverse events were pneumonia (12%) and dehydration (6%). Serious bleeding occurred in 5% of patients and death occurred in 8% of patients. Considering the age and prognostic features of the study population, ibrutinib was well tolerated with no decrease in efficacy for patients with a del(17p).[45]

Ibrutinib was also studied as first-line therapy in a phase Ib/II trial of 31 patients with CLL/SLL age 65 or older; the median age was 71. The ORR was 71%, with a 13% complete response (CR) rate. Toxicity was mainly grade 1 to 2 in severity, with serious adverse events including diarrhea (13%), fatigue (3%), and infection (10%). Neither grade 4 nor grade 5 infections were reported.[46] Thus, in the first-line setting among older patients, ibrutinib is an efficacious, well-tolerated option.

Ibrutinib has also been studied versus ofatumumab in relapsed or refractory CLL/SLL in a multicenter, open-label, phase III trial that enrolled 391 patients; the median age was 67, and 32% of patients had a del(17p). The primary endpoint was PFS. Compared with ofatumumab, ibrutinib had superior PFS (HR, for progression 0.22; p < 0.001), OS (HR, 0.43; p = 0.005), and ORR (63% versus 4%; p < 0.001). Ibrutinib also demonstrated superior efficacy for patients with del(17p). Severe adverse events occurred in 57% of patients who received ibrutinib and 47% of patients who received ofatumumab. Bleeding events occurred more in the ibrutinib group (44%) compared with the ofatumumab group (12%). Grade 3 or higher infections occurred in 24% of patients in the ibrutinib arm and in 22% of patients in the ofatumumab arm. Discontinuation because of adverse events occurred in 4% of patients in each group. Fatal adverse events occurred in 4% and 5% of patients in the ibrutinib and ofatumumab arms, respectively. The relatively low rate of response to ofatumumab compared with the study that resulted in the initial FDA approval may have been attributable to more rigorous re-

quirements for serial CT scanning to assess response.[47] The efficacy of ibrutinib (versus placebo) is also being studied in combination with bendamustine and rituximab in refractory and relapsed CLL; the phase III HELIOS trial is currently ongoing.[48]

Ibrutinib has also shown efficacy in relapsed or refractory WM. In a phase II study of 63 patients of median age 63 who had received a median of two prior therapies, ibrutinib induced PRs in 57% of patients and minor responses in 24% of patients. Treatment was discontinued by 6% of patients. Common grade 2 or higher toxicities included thrombocytopenia (14%) and neutropenia (19%).[49] On January 29, 2015, the FDA approved ibrutinib for treatment of WM. In FL, a phase II study of ibrutinib in 38 evaluable patients of median age 64, demonstrated a more modest 30% ORR in the ibrutinib arm, but 65% of patients had tumor size reduction. Grade 3 to 4 events occurred in 30% of patients, and 5% of patients discontinued treatment because of adverse events. There was one death due to gastric hemorrhage.[50]

Ibrutinib has developed a track record as an efficacious and well-tolerated agent in CLL, especially in older patients. The potential for bleeding in patients treated with ibrutinib and the exclusion of patients on warfarin from most clinical trials suggest that ibrutinib should be avoided in anticoagulated patients or those patients with a history of serious bleeding (such as intracranial hemorrhage). Importantly, it also offers efficacy for patients without regard to cytogenetic risk. Ibrutinib has shown efficacy in mantle cell and diffuse large cell histologies as well. Later-generation BTK inhibitors are also in development.[51,52]

IMMUNOMODULATORY AGENTS

The immunomodulatory drugs (IMiDs) are thalidomide analogs that have the capacity to alter immune microenvironments, have antiangiogenic effects, promote T-cell costimulation, and activate NK cells.[53] Lenalidomide has been shown to stimulate T-cell– and NK-cell–mediated cytotoxicity in indolent lymphomas.[54] Molecularly, IMiDs interfere with the function of the ubiquitin ligase cereblon (CRBN), which may be the key mediator for their microenvironmental and immunomodulatory effects. CRBN has been shown to interact with potassium and chloride channels, AMP-

activated protein kinase, and Cullin 4 to function as part of an E3 ubiquitin ligase complex.[55] CRBN is required for the therapeutic effect of IMiDs. Its downstream signaling targets include interferon regulatory factor 4 and tumor necrosis factor-alpha.[56] Lenalidomide-bound cereblon, in its ubiquitin ligase function, also targets the Ikaros family zinc finger proteins 1 and 3, which are B-cell–specific transcription factors, for degradation.[57]

Lenalidomide has shown efficacy in the treatment of relapsed or refractory iNHL. In a study of 43 patients of median age 63 (21% older than 75) with FL, SLL, or MZL, 25 mg lenalidomide monotherapy administered 3 out of 4 weeks for up to 52 weeks induced a 23% ORR with a median duration of response of 16.5 months or greater.[58] Common adverse events (any grade) included neutropenia (58%), fatigue (51%), thrombocytopenia (42%), anemia (37%), and diarrhea (33%). Common grade 3 to 4 toxicities included neutropenia (46%), thrombocytopenia (19%), anemia (9%), asthenia (5%), and pneumonia (5%); 67% of patients required dose reductions or interruptions. Treatment discontinuation because of adverse events occurred in 19% of patients; there was one treatment-related death. Lenalidomide showed efficacy in a relatively heavily pretreated population (median of three prior treatments) with moderate tolerability, with a study population that included older patients.

Later-line efficacy of lenalidomide led to a first-line, phase II trial of lenalidomide and rituximab in 110 patients with iNHL. Histologic subtypes included FL (50 patients), SLL (30 patients), and MZL (30 patients), with median ages of 56, 59, and 59, respectively. Treatment with lenalidomide plus rituximab resulted in an ORR of 90%, a 65% CR rate, and a median PFS of 54 months. Response rates were similar across subtypes but highest in patients with FL. The most common grade 3 to 4 AEs included neutropenia (35%), pain or myalgia (9%), rash (7%), fatigue (5%), thrombosis (5%), and pulmonary symptoms (5%); 28% of patients required dose reductions. No treatment-related deaths occurred.[59] Thus, the combination of lenalidomide and rituximab was well tolerated with good efficacy, though the median patient ages were younger than those typically seen for the histologic subtypes treated. Toxicity and dose-reduction or discontinuation rates may be higher in older patient populations. This approach is under investigation in a phase III trial that recently completed accrual to evaluate rituximab and lenalidomide versus rituximab and chemotherapy in untreated patients with FL.

IMiDs have also demonstrated efficacy in WM.[60] The combination of rituximab and lenalidomide induced a 50% ORR in a trial of 16 patients; 12 had been previously untreated and four patients had received prior therapy. The median age was 65. However, 13 out of 16 patients experienced a hematocrit decrease, resulting in early termination of enrollment; 88% of patients required treatment discontinuation. The most common grade 3 to 4 toxicity was neutropenia (31%).[61] Given the concern for thalidomide and neuropathy in WM patients, and the unique, idiosyncratic association of lenalidomide with anemia

in WM, IMiD therapy will require further development before being ready for "prime time" in WM, especially in older patients who may be more affected by adverse events.

PROTEASOME INHIBITORS

Proteasome inhibitors such as bortezomib and carfilzomib inhibit the chymotrypsin-like sites of the proteasome's 20S subunit. That inhibition disrupts protein homeostasis and protein folding quality control, resulting in proteotoxic stress and activation of the unfolded protein response, leading to cell death; cancer cells experience higher toxicity as they are more susceptible to proteotoxic stress.[62] Bortezomib has been in use for the treatment of multiple myeloma for more than a decade, and its use in mantle cell NHL dates back several years, having received approval for relapsed or refractory disease in 2006 and approval for first-line therapy in October 2014. Bortezomib is still being studied for use in indolent lymphoma.

Three phase II studies have established efficacy of bortezomib in relapsed or refractory iNHL.[63-65] Results varied, with response rates ranging from 13% to 53%; the study with the lowest ORR was notable for a 64% stable disease rate.[64] None of the studies reported grade 3 neuropathy higher than 10%. Notably, Di Bella et al enrolled a cohort of median age 70,[64] with grade 3 or 4 adverse events including thrombocytopenia (20%), fatigue (10%), neutropenia (8.5%), neuropathy (6.8%), and diarrhea (6.8%).[64] Thus, bortezomib may be a reasonably well-tolerated option with modest efficacy in an older population. de Vos et al compared biweekly (1.3 mg/m^2 on days 1, 4, 8, and 11 of 21-day cycles) with weekly (1.6 mg/m^2 on days 1, 8, 15, and 22 of 35-day cycles) bortezomib in combination with rituximab and found the weekly regimen to be better tolerated, with fewer grade 3 or higher adverse events, including neuropathy (10% biweekly versus 5% weekly).[65]

These initial favorable results led to a randomized, phase III trial of bortezomib plus rituximab versus rituximab alone for patients with relapsed or refractory FL. In the study, 1.6 mg/m^2 of bortezomib was administered intravenously on days 1, 8, 15, and 22 of 35-day cycles. A total of 676 patients were enrolled with a median age of 57; 28% of patients were older than age 65. The addition of bortezomib resulted in a modest increase of PFS from 11 to 13 months. Grade 3 or higher adverse events were higher in the combination arm, 46% compared with 21%. Grade 3 or higher infection (11% vs. 4%), neutropenia (11% vs. 4%), diarrhea (7% vs. 0%), and neuropathy (3% vs. 1%) favored rituximab alone. The combination arm experienced 1% possible treatment-related deaths.[66] Given the higher toxicity of the combination regimen, the modest 2-month improvement in PFS was disappointing.

However, recent data in high-tumor burden iNHL suggest that combination therapy with bortezomib and rituximab may still be desirable. A front-line phase II trial with 42 patients of median age 61 with primarily FL received 1.6 mg/m^2 of bortezomib intravenously on days 1, 8, 15, and 22 of 35-day cycles. The ORR was 70% with a CR rate of

TABLE 5. Early-Phase Data for Selected Miscellaneous Investigational (Nonmarketed) Agents for iNHL Under Preliminary Testing

Agent	Molecular Target/Pathway	Disease(s)	Notable Outcomes	Reference(s)
ABT-199	BCL-2	FL, MZL	73% RR in FL	81
CAR T cells	Multiple, primarily CD19	CLL, FL	CRs, PRs; very limited data	77-80
Panobinostat (with everolimus)	HDAC	FL, CLL	33% RR, high toxicity	71
Pidilizumab	PD-1	FL	66% ORR, no grade 3 or higher toxicity	82
Polatuzumab vedotin	ADC: CD79b (BCR) and mitotic function	FL	67% ORR as single-agent	75
SAR3419	ADC: CD19 and mitotic function	FL	29% ORR, 43% SD	74
TRU-016 (with bendamustine and rituximab)	SMIP: CD37	FL, SLL	83% ORR	76

Abbreviations: FL, follicular lymphoma; MZL, marginal-zone lymphoma; RR, response rate; CAR, chimeric antigen receptor; CLL, chronic lymphocytic leukemia; PR, partial response; HDAC, histone deacetylase; ORR, overall response rate; ADC, antibody-drug conjugate; SD, stable disease; SMIP, monospecific protein therapeutic; SLL, small lymphocytic lymphoma.

40%. The discontinuation rate was 7%, with grade 1 to 2 neuropathy experienced by 16% of patients. There was no grade 3 or higher neuropathy. Other grade 3 to 4 adverse events included neutropenia (5%), fever (5%), and infection (5%).[67] Bortezomib and rituximab represent a potentially efficacious therapy combination. Extrapolating from the multiple myeloma literature, subcutaneous bortezomib administration may reduce nonhematologic toxicity without compromising efficacy, a key consideration for older patients.

Bortezomib has not yet been FDA-approved for iNHL, although in WM bortezomib is a standard agent in both frontline and relapsed settings; that topic has been reviewed elsewhere.[60] The second-generation proteasome inhibitor carfilzomib has been utilized as a neuropathy-sparing approach in WM. A phase II study of 31 patients of median age 61 evaluated carfilzomib, rituximab, and dexamethasone, which led to an 87% ORR. Grade 3 or higher toxicities included hyperglycemia (23%), hyperlipasemia (16%), neutropenia (10%), and cardiomyopathy (3%). There was no grade 3 or 4 neuropathy.[68] Carfilzomib may also have activity against other histologies in the relapsed or refractory setting: a phase I trial of carfilzomib included six patients with FL and one patient with CLL/SLL; carfilzomib treatment resulted in stable disease in four of the patients with FL and the patient with CLL/SLL.[69]

FUTURE DIRECTIONS: OTHER AGENTS

Additional classes of agents have shown promise in treating iNHL, including histone deacetylase inhibitors,[70,71] hypomethylating agents,[72,73] antibody-drug conjugates (ADCs),[74,75] monospecific protein therapeutics[76]; chimeric antigen receptor T cells directed against CD19,[77-80] BCL-2 inhibitors,[81] and programmed cell death (PD)-1 T cell inhibitory receptor antibodies[82,83] (Table 5). Among these, histone deacetylase inhibitors, ADCs, and PD-1 antagonists have potential for excellent tolerability in older patients and might prove highly useful in early-line combination regimens or as later-line single agents for patients with advanced age or extensive comorbidities. Hopefully, further trials that emphasize older patients with the above investigational therapies and recently approved agents will lead to more data that can be used to address one of the largest unmet needs in the treatment of indolent hematologic malignancies: providing well-tolerated drugs across multiple lines of therapy for older patients.

Hematopoietic Cell Transplantation for Myelodysplastic Syndrome

H. Joachim Deeg, MD

OVERVIEW

Although high-dose chemotherapy may cure a small subset of patients with myelodysplastic syndrome (MDS), allogeneic hematopoietic cell transplantation (HCT) is the only currently available modality that is curative in a large proportion of patients. Approximately 30% to 40% of patients with high-risk MDS and 60% to 80% of patients with low-risk MDS survive long-term in remission. Disease classification and risk assessment schemes, such as the World Health Organization (WHO) Prognostic Scoring System (WPSS), the Revised International Prognostic Scoring System (IPSS-R), and patient characteristics as assessed by the HCT Comorbidity Index (HCT-CI) or other scores, provide guidance for patient management. First, by defining the prognosis of patients without HCT, these tools help physicians decide who should and who should not be transplanted. Second, they predict at least in part how successful a transplant is likely to be. Pretransplant cytogenetics and marrow myeloblast count are the strongest risk factors for post-transplant relapse. The HCT-CI allows physicians to estimate the probability of nonrelapse mortality after HCT; recent data suggest that there is also a relationship to the development of graft-versus-host disease (GVHD). In general, the emphasis has shifted from high-dose therapy, aimed at maximum tumor-cell kill, to reduced-intensity conditioning (RIC), relying on the donor cell-mediated graft-versus-tumor (GVT) effects to eradicate the disease. GVT effects are most prominent in patients who also develop GVHD, especially chronic GVHD. Thus, ongoing work is directed at reducing GVHD while maintaining potent GVT effects and at exploiting the growing knowledge of somatic mutations for the development of targeted therapies.

Although high-dose chemotherapy may cure a small subset of patients with MDS, allogeneic HCT is currently the only modality shown to be curative for 30% to 80% of patients, depending on patient and disease characteristics, the source of stem cells, and the transplant strategy applied. The availability of human leukocyte antigen (HLA)-matched unrelated donors, HLA-identical siblings, (HLA-nonidentical) cord blood, and HLA-haploidentical relatives allows for the identification of suitable stem cell donors for the vast majority of patients. However, despite considerable progress, problems remain in regards to the prevention of GVHD while maintaining the desired graft-versus-leukemia (GVL) effect—an essential factor in disease eradication and optimization of transplant conditioning regimens.

DISEASE CLASSIFICATION AND TRANSPLANTATION

The WHO classification,[1] evolving from the classic French-American-British (FAB) schema,[2] has identified MDS subcategories, such as del(5q) with superior prognosis or, conversely, refractory cytopenia with multilineage dysplasia with inferior prognosis relative to refractory anemia, and has categorized all patients with 20% or more marrow myeloblasts as having acute myeloid leukemia (AML; Table 1). An additional poor risk factor is the presence of marrow fibrosis.[3] These parameters are important when considering indications for HCT. The incorporation of cytogenetic information and transfusion needs and the degree of peripheral blood cytopenias in risk assessment scores such as the WPSS[4] or the IPSS-R[5] (Table 2 and the inclusion of age, for example, in the MD Anderson score,[6] have refined our prognostic ability and thereby provided guidance for HCT—specifically a more conservative, observing strategy for good risk and a more aggressive, intensive treatment approach for patients with poor-risk disease.

TRANSPLANT RISK ASSESSMENT
Patient Characteristics

Older age has long been considered a contraindication for transplantation. Studies over the past decade have shown that more than chronologic age, comorbid conditions that may be associated with advanced age (but could also be present in younger patients) are the dominant factors that negatively affect transplant outcome. Those conditions have been cataloged in the HCT-CI, and results clearly show inferior outcome with increasing HCT-CI scores, which include prior diagnosis of a solid

tumor, hypertension, or impaired pulmonary function, among others.[7] Other classification schemes have also included transplant characteristics, in particular, the stem cell source,[8] and more recently have applied a modified system to patients transplanted with reduced-intensity conditioning (RIC) regimens.[9]

Conditioning Regimens

The optimum conditioning regimen has not been determined. In general, however, the emphasis in allogeneic HCT has shifted from high-dose (myeloablative) therapy, aimed at cytotoxic tumor-cell kill, to low (nonmyeloablative) or RIC, relying on immune effects mediated by GVT effects to eradicate the disease.[10-13] RIC regimens have reduced the incidence and severity of treatment-related toxicity and day 100 mortality to less than 10% or even 5% but generally have resulted in a higher incidence of MDS relapse than observed with high-intensity regimens.[14] In fact, a recent multi-institutional U.S. trial involving patients with MDS or AML (BMT CTN 0901) was closed prematurely because of inferior outcome in patients conditioned with RIC regimens.

Donor–Host Immunity

Allogeneic HCT carries the risk of the adverse effects of the bidirectional reactivity of donor and host cells. Host-versus-donor reactivity leading to rejection of the graft is an infrequent event. Donor-versus-host reactivity leading to clinical manifestations, however, occurs in about half of all patients.[15,16] Although GVT effects contribute to disease eradication, those effects are most prominent in patients who also show clinical evidence of GVHD. In fact, the most prominent GVL effects are observed in patients who develop chronic GVHD, which occurs in 40% to 60% of patients transplanted with unmanipulated donor cells[17]; the incidence tends to be lower in patients receiving T cell–depleted grafts[18] and, possibly, patients administered post-transplant cyclophosphamide,[19] which appears to be capable of inactivating host-reactive donor cells.

KEY POINTS

- Hematopoietic cell transplantation provides curative therapy for patients with myelodysplastic syndrome.
- The clonal karyotype is the strongest predictor of post-transplant relapse.
- The availability of human leukocyte antigen (HLA)-matched related and unrelated donors, HLA-haploidentical relatives, and umbilical cord blood helps identify donors for the vast majority of patients.
- Additional research is needed to prevent graft-versus-host disease while maintaining the graft-versus-tumor effect.
- As myelodysplastic syndrome is primarily a disease of older age and quality of life is a top priority for most older individuals, discussions regarding transplantation in older patients must include not only the acute effects of transplantation but also delayed effects.

Further, immune-incompetence early after HCT and GVHD-associated immunosuppression severely increases the risk of systemic infections—another cause of post-HCT morbidity and mortality.[20]

Stem Cell Source

Peripheral blood progenitor cells are currently the preferred source of stem cells, because of their rapid kinetics of engraftment and more potent GVL effect than marrow cells, albeit at the risk of a higher incidence of GVHD.[15] Cord blood cells are typically associated with slow engraftment and the associated risk of bleeding and infections.[21,22] The incidence of relapse, however, in many studies has been lower than with stem cells obtained from adult donors. Transplantation of HLA-haploidentical cells carries an increased risk of graft rejection, although recently used conditioning regimens have reduced that risk, and the incidence of GVHD has been similar to or lower than that observed with HLA-matched donor cells, presumably related to the post-transplant administration of cyclophosphamide.[23] Data from patients with MDS are too limited to draw firm conclusions regarding the effect on relapse.

TRANSPLANT INDICATIONS AND OUTCOME

Based on several retrospective and decision analyses, HCT is typically offered to patients with intermediate-2 or high-risk disease (by IPSS criteria) or (intermediate) poor- and very poor–risk by IPSS-R (or similarly by WPSS) criteria, whereas patients in lower-risk categories are often managed more conservatively, for example, with hypomethylating agents, since significant advantages of HCT in regard to duration of survival have been shown only in those patients at higher risk.[24-26] Nevertheless, there is a tendency to offer HCT also for lower-risk disease, particularly for younger patients.[12,27] Not unexpectedly, long-term survival in remission (following HCT from HLA-matched related or unrelated donors and high-intensity conditioning) is in the range of 75% for patients with low-risk disease, approximately 60% with intermediate-1, 45% with intermediate-2, and 30% for patients with high-risk MDS.[27,28] The major factors with a negative effect on relapse-free survival are pre-HCT karyotype and marrow blast count. Patients with very poor cytogenetics, including monosomal karyotype, have a 10% or less probability of long-term survival.[27,29]

Caution is indicated when advising patients who are considered transplant candidates to undergo a trial with hypomethylating agents. Clearly, a proportion of patients (approximately 45%) will respond to hypomethylating therapy, on average, for 9 to 10 months. However, when transplantation is carried out in patients whose disease has progressed while receiving such therapy, results are poor, although the median survival is prolonged to about 14 months in comparison to only 5 to 6 months for all "5-azacitidine failures." On the other hand, patients who are responding or not progressing while receiving hypomethylating treatment have an approximately 30% probability of being transplanted successfully.[30]

The effect of disease risk is modified by the presence of comorbidities; patients with HCT-CI scores of 3 or higher experience

TABLE 1. WHO Classification

Disease	Blood Findings	Bone Marrow Findings
RCUD (RA, RN, RT)	Unicytopenia or bicytopenia*	Unilineage dysplasia $\geq$ 10% of the cells in one myeloid lineage
	No or rare blasts ($<$ 1%)**	$<$ 5% blasts
		$<$ 15% of erythroid precursors are ring sideroblasts
RARS	Anemia	$\geq$ 15% of erythroid precursors are ring sideroblasts
	No blasts	Erythroid dysplasia only
		$<$ 5% blasts
RCMD	Cytopenia(s)	Dysplasia in $\geq$ 10% of the cells in $\geq$ 2 myeloid lineages (neutrophil and/or erythroid precursors and/or megakaryocytes)
	No or rare blasts ($<$ 1%)**	$<$ 5% blasts in marrow
	No Auer rods	No Auer rods
	$<$ 1 $\times$ 10^9/L monocytes	$\pm$ 15% ring sideroblasts
RAEB-1	Cytopenia(s)	Unilineage or multilineage dysplasia
	$<$ 5% blasts**	5%-9% blasts**
	No Auer rods	No Auer rods
	$<$ 1 $\times$ 10^9/L monocytes	
RAEB-2	Cytopenia(s)	Unilineage or multilineage dysplasia
	5%-19% blasts†	10%-19% blasts†
	Auer rods $\pm$†	Auer rods $\pm$†
	$<$ 1 $\times$ 10^9/L monocytes	
MDS-U	Cytopenias	Unequivocal dysplasia in 10% of cells in one or more myeloid lineages when accompanied by a cytogenetic abnormality considered as presumptive evidence for a diagnosis of MDS
	$<$ 1% blasts**	$<$ 5% blasts
MDS associated with isolated del(5q)	Anemia	Normal to increased megakaryocytes with hypolobated nuclei
	Usually normal or increased platelet count	$<$ 5% blasts
	No or rare blasts ($<$ 1%)	Isolated del(5q) cytogenetic abnormality
		No Auer rods

Abbreviations: WHO, World Health Organization; RCUD, refractory cytopenia with unilineage dysplasia; RA, refractory anemia; RN, refractory neutropenia; RT, refractory thrombocytopenia; RARS, refractory anemia with ring sideroblasts; RCMD, refractory cytopenia with multilineage dysplasia; RAEB, refractory anemia with excess blasts; MDS-U, Myelodysplastic syndrome-unclassified.
*Bicytopenia may occasionally be observed. Cases with pancytopenia should be classified as MDS-U.
**If the marrow myeloblasts percentage is $<$ 5% but there are 2% to 4% myeloblasts in the blood, the diagnostic classification is RAEB-1; cases of RCUD and RCMD with 1% myeloblasts in the blood should be classified as MDS-U.
†Cases with Auer rods and $<$ 5% myeloblasts in the blood and less than 10% in the marrow should be classified as RAEB-2. Although the finding of 5% to 19% blasts in the blood is, in itself, diagnostic of RAEB-2, cases of RAEB-2 may have $<$ 5% blasts in the blood if they have Auer rods or 10% to 19% blasts in the marrow or both. Similarly, cases of RAEB-2 may have $<$ 10% blasts in the marrow but may be diagnosed by the other two findings, Auer rod+, and/or 5% to 19% blasts in the blood.

TABLE 2. IPSS-R Prognostic Scores[5]

	Score						
Variable	0	0.5	1	1.5	2	3	4
Cytogenetics	Very Good		Good		Intermediate	Poor	Very Poor
Marrow blasts (%)	$\leq$ 2		$>$ 2-$<$ 5		5-10	$>$ 10	
Hemoglobin	$\geq$ 10		8-$<$ 10	$<$ 8			
Platelets	$\geq$ 100	50-$<$ 100	$<$ 50				
Neutrophils	$\geq$ 0.8	$<$ 0.8					

Abbreviation: IPSS-R, Revised International Prognostic Scoring System.

survival rates that may be substantially lower than for patients without scored comorbidities.[11,31,32] We have shown, for example, in patients transplanted for chronic myelomonocytic leukemia (considered under the heading of MDS) from HLA-matched related or unrelated donors that the overall survival in remission was 40%. However, a breakdown by HCT-CI showed a probability of 53% for patients with HCT-CI scores of 0 to 2 but only 26% for patients with scores of 3 or higher.[31]

As MDS is primarily a disease of older individuals who often present with comorbid conditions and who are less likely to tolerate high-intensity conditioning regimens, recent studies have analyzed the relevance of disease classi-

fication for the decision of transplantation. Koresh et al[33] used a Markov decision model and quality-of-life utility estimates to assess transplant success in 514 patients with de novo MDS who were age 60 to 79. Results showed that for patients with low- or intermediate-1-risk MDS (by IPSS criteria)[34] and conditioned with reduced-intensity regimens, life expectancy was 38 months on average, compared to 77 months in patients with nontransplanted disease. In patients with intermediate-2 or high-risk MDS, the corresponding figures were 36 and 28 months, clearly showing an advantage for transplantation, associated with a quality-adjusted survival benefit. These data support the recommendation for or against transplantation on the basis of disease stage.

Encouraging results have been achieved recently with treosulfan-based regimens, which are associated with low toxicity and excellent efficacy. In a trial conducted at the Fred Hutchinson Cancer Research Center, 60 patients with MDS or AML were prepared with a regimen of fludarabine (30 mg/m^2 × 5) and treosulfan (12 g or 14 g/m^2 × 3) for HCT from HLA-matched related or unrelated donors. Two-year nonrelapse mortality was less than 10%, and relapse-free survival for patients with standard- or intermediate-risk cytogenetics was 80%.[35] Patients with high-risk karyotype, in contrast, showed long-term relapse-free survival of only 35% to 40%. Ongoing trials suggest that with the addition of low-dose (2 Gy) total body irradiation to fludarabine and treosulfan, relapse-free survival may increase to 65%, even among patients with high-risk cytogenetics.[36]

Although cytogenetics have been shown to have the strongest effect on post-transplant relapse and, as a result, relapse-free survival,[27] emerging data suggest that somatic mutations further modify the outcome. Bejar et al have shown that mutations in p53, DNMT3A, or TET2 each decrease the probability of post-transplant survival by a factor of three to four.[37] On the other hand, data show that mutations in SF3B1 are associated with a superior leukemia-free and overall survival, possibly affecting the decision on and the timing for transplantation.[38]

OUTLOOK

Clearly, more effective strategies are needed for the prevention of GVHD and relapse. Various strategies of post-HCT therapy, for example, with hypomethylating agents or cellular therapy with natural killer cells or genetically modified T cells (directed, for example, at Wilms tumor 1), are currently being explored in efforts to prevent relapse.[39] The use of post-HCT administration of cyclophosphamide, in the hands of several investigators, has been effective in preventing GVHD after HLA-haploidentical transplants and is also being tested in patients receiving HLA-matched transplants where acute or chronic GVHD (or both) occur about in half of all patients and, particularly with unrelated HCT, involvement of the intestinal tract proves life threatening.[23]

The use of HCT in growing numbers of older patients with MDS, even in their 70s, poses special challenges, particularly with the intensity of conditioning. Currently those patients are highly selected, and results cannot be extrapolated to that age segment in general. Further, first-line therapy with steroids, although effective in a portion of patients, is often poorly tolerated in older individuals.[40] Metabolic abnormalities, infections, and long-term effects on muscles and skeleton can severely affect quality of life. Thus, not only comorbidities before HCT but also complications developing after HCT must be prioritized when discussing HCT with older patients, for whom quality of life (rather than quantity of life) is often a top priority.

Clearly, the rapidly expanding understanding of the effect of various mutations in clonal cells will affect disease risk classification and may also lead to novel antirelapse strategies aimed at molecular targets.[41,42]

Diagnosing and Managing Advanced Chronic Myeloid Leukemia

Michael W. Deininger, MD, PhD

OVERVIEW

Clinical staging of chronic myeloid leukemia (CML) distinguishes between chronic phase (CP-CML), accelerated phase (AP-CML), and blastic phase (BP-CML), reflecting its natural history in the absence of effective therapy. Morphologically, transformation from CP-CML to AP/BP-CML is characterized by a progressive or sudden loss of differentiation. Multiple different somatic mutations have been implicated in transformation from CP-CML to AP/BC-CML, but no characteristic mutation or combination of mutations have emerged. Gene expression profiles of AP-CML and BP-CML are similar, consistent with biphasic evolution at the molecular level. Gene expression of tyrosine kinase inhibitor (TKI)–resistant CP-CML and second CP-CML resemble AP/BP-CML, suggesting that morphology alone is a poor predictor of biologic behavior. At the clinical level, progression to AP/BP-CML or resistance to first-line TKI therapy distinguishes a good risk condition with survival close to the general population from a disease likely to reduce survival. Progression while receiving TKI therapy is frequently caused by mutations in the target kinase BCR-ABL1, but progression may occur in the absence of explanatory BCR-ABL1 mutations, suggesting involvement of alternative pathways. Identifying patients in whom milestones of TKI response fail to occur or whose disease progress while receiving therapy requires appropriate molecular monitoring. Selection of salvage TKI depends on prior TKI history, comorbidities, and BCR-ABL1 mutation status. Despite the introduction of novel TKIs, therapy of AP/BP-CML remains challenging and requires accepting modalities with substantial toxicity, such as hematopoietic stem cell transplantation (HSCT).

It is thought that CML is initiated when a hematopoietic stem cell acquires the t(9;22)(q11;34) reciprocal translocation, which the cytogenetic correlate is the Philadelphia chromosome (Ph). Based on the increase in CML incidence in survivors of the atomic bombings on Japan, the latency between this initial event to the clinical manifestation is estimated to be approximately 8 years.[1] Whether or not a clonal genetic lesion predates the acquisition of Ph or whether additional genetic abnormalities are required to produce CP-CML is a matter of debate. However, recent next-generation sequencing studies suggest both scenarios are possible.[2] Without effective therapy, CP-CML invariably progresses to an acute leukemia termed BP-CML, sometimes through an intermediate stage referred to as AP-CML. BP-CML may have a myeloid (70%), B-lymphoid (20%), or mixed phenotype (10%).[3] Observations from the 1920s, when therapeutic options were limited to splenic irradiation and arsenic trioxide, suggest that the natural duration of CP-CML may be approximately 2.5 years. In the developed world, the vast majority of patients are diagnosed in the chronic phase, frequently when an abnormal complete blood count leads to a diagnostic workup. Presentation with AP/BP-CML is more common in countries with lower socioeconomic status, probably reflecting delays in diagnosis as a result of insufficient access to medical care. The term "advanced CML" is not clearly defined and variably used to include AP/BP-CML only or also CP-CML resistant to standard therapy.

DEFINING ADVANCED CHRONIC MYELOID LEUKEMIA: CHRONIC PHASE, ACCELERATED PHASE, AND BLASTIC PHASE

Several different classification systems have been developed to define the phases of CML based on morphologic and clinical criteria, including the International Bone Marrow Transplant Registry (IBMTR), The University of Texas MD Anderson Cancer Center (MDACC), and World Health Organization (WHO) classifications (Table 1). The simultaneous use of different systems has generated considerable confusion, as different classifications may assign patients to different disease phases and some of the criteria lack a precise definition. For example, the WHO definition of AP-CML uses increasing white blood cells and spleen size unresponsive to therapy as defining criteria. Another important discrepancy is the bone marrow or blood blast percentage that defines BP-CML. Whereas the WHO classification uses 20% or greater as the cutoff (in line with acute myeloid leukemia [AML]), MDACC and IBMTR classifications use 30% or greater. The MDACC criteria defining AP-CML were prospectively validated as independent prognostic variables, and

TABLE 1. Definitions of Accelerated- and Blastic-Phase Chronic Myeloid Lymphoma

	Modified MDACC Criteria*	WHO Criteria	IBMTR
Accelerated Phase	Blood or marrow blasts 15-29%	Blood or marrow blasts 10-19%	Hb < 8 g/dL
	Blood or marrow blasts and promyelocytes ≥ 30%	Blood basophils > 20%	WBC > 100 × 10^9/L
	Blood basophils > 20%	Plts < 100 × 10^9/L or >1,000 × 10^9/L	Plts < 100 × 10^9/L or > 1,000 × 10^9/L
	Plts < 100 × 10^9/L	Increasing spleen size and WBC	Splenomegaly unresponsive to busulfan and hydroxyurea
	CCA/Ph$^+$	CCA/Ph$^+$	Extramedullary disease
			CCA/Ph$^+$
			Blood or marrow blasts > 10%
			Blood or marrow blasts plus promyelocytes > 20%
			Blood basophils and eosinophils > 20%
Blastic Phase	Blood or marrow blasts ≥ 30%	Blood or marrow blasts > 20%	Blood or marrow blasts ≥ 30%
	Extramedullary blasts (apart from spleen)	Extramedullary blast proliferation	Extramedullary blasts (apart from spleen)
		Large foci or clusters of blasts on bone marrow biopsy	

Abbreviations: MDACC, The University of Texas MD Anderson Cancer Center; WHO, World Health Organization; IBMTR, International Bone Marrow Transplant Registry; CCA/Ph$^+$, clonal cytogenetic abnormalities in Ph$^+$ cells; Plts, platelets; WBC, white blood cells; Hb, hemoglobin.
*Commonly used in clinical trials.

were used (in some cases with minor adaptations) in the major practice-defining prospective clinical trials and therefore are recommended.[4-6] In the future, molecular classifications may replace morphology and blood counts. An uncommon clinical presentation is chloroma, which establishes a diagnosis of BP-CML, irrespective of marrow and blood. Biopsy is required and a diagnosis of chloroma requires the presence of blasts, whereas mature granulocytic infiltrates in extramedullary sites other than the spleen or liver may be reactive to inflammation or infection and should not be confused with BP-CML.

The Sokal and Hasford scores were developed in patients treated with chemotherapy or interferon alfa (IFN-α), respectively, but were subsequently validated in prospective TKI studies. The EUTOS score was developed in a cohort of patients treated with imatinib, but was not universally confirmed in subsequent studies.[10] All three prognostication systems are based on laboratory and clinical parameters obtained in untreated patients. Any form of therapy, including hydroxyurea, may generate misleading results and must be avoided. Although patients with high Sokal or Hasford scores are less likely to achieve deep responses to TKIs and

RISK STRATIFICATION IN CHRONIC-PHASE CHRONIC MYELOID LEUKEMIA

Clinical scoring systems to risk stratify CP-CML include the Sokal, Hasford (European), and EUTOS scores (Table 2).[7-9]

KEY POINTS

- Chronic myeloid leukemia (CML) progresses in phases that represent the most fundamental risk stratification.
- Multiple different somatic mutations have been associated with transformation from chronic to advanced CML.
- Disease progression while receiving first-line tyrosine kinase inhibitor (TKI) therapy and accelerated or blastic phase CML are associated with reduced overall survival.
- BCR-ABL1 kinase domain mutations are the best characterized mechanism of TKI resistance, but fail to explain many cases of clinical resistance.
- Selection of salvage therapy depends on prior TKI exposure, comorbidities, and BCR-ABL1 mutation status.

TABLE 2. Risk Stratification in Chronic-Phase Chronic Myeloid Lymphoma

Risk Score	Calculation	Risk Groups
Sokal	Exp 0.0116 × (age − 43.4) + 0.0345 × (spleen − 7.51) + 0.188 × [(platelet count ÷ 700)^2 − 0.563] + 0.0887 × (blast cells − 2.10)	Low: < 0.8
		Intermediate: 0.8-1.2
		High: > 1.2
Hasford	0.666 when age ≥ 50 + (0.042 × spleen) + 1.0956 when platelet count > 1,500 × 109L + (0.0584 × blast cells) + 0.20399 when basophils >3% + (0.0413 × eosinophils) × 100	Low: ≤ 780
		Intermediate: 781-1,480
		High: > 1480
EUTOS	Spleen × 4 + basophils × 7	Low risk: ≤ 87
		High risk: > 87

Abbreviation: EUTOS, European Treatment Outcome Study.

have a higher risk or progression, they are not considered as having advanced CML. Given that the distinction between CP-CML and BP-CML can hinge on minute differences in the white blood differential count, it is obvious that the separation of high-risk CP-CML from AP-CML may be more theoretical than practically relevant. Consistent with this, gene expression profiling studies on CP-CML, using mononuclear cells or CD34$^+$ cells, have revealed overlap between poor-prognosis CP-CML and BP-CML.[11-13]

MOLECULAR UNDERPINNING OF BLASTIC TRANSFORMATION

The salient morphologic feature of BP-CML is loss of cellular differentiation capacity, which may occur suddenly or gradually through the intermediate stage of AP-CML. Progression is frequently associated with clonal cytogenetic evolution. The distinction between major (+8, isochromosome 17q, additional Ph, +19) and minor route abnormalities (all others) is of limited clinical significance once transformation has occurred. However, in newly diagnosed CP-CML major route abnormalities are associated with a poor outcome with imatinib treatment.[14] At the molecular level, multiple somatic mutations have been identified upon transformation, but there is no characteristic molecular abnormality (Table 3).[15] Unsurprisingly, lymphoid BP-CML resembles Ph$^+$ acute lymphoblastic leukemia (ALL), whereas mutations typical for AML and myelodysplastic syndromes are dominant in myeloid BP-CML. Core binding factor mutations such as AML1-ETO and CBFB-MYH11 are uncommon in BP-CML, suggesting that the differentiation block of BP-CML has a different molecular basis. Epigenetic dysregula-

TABLE 3. Mutations Associated with Blastic-Phase Chronic Myeloid Lymphoma

Mutation/Mutated Gene	% Prevalence
Double Ph	38%
Isochromosome 17q	30% (myeloid)
Trisomy 8	53% (lymphoid)
Trisomy 19	23% (myeloid)
p53	20-30% (myeloid)
p16	50% (lymphoid)
NUP98-HOXA9	NR
AML1-EVI1	NR
GATA-2	18% (lymphoid)
RUNX1	38% (myeloid)
CDKN2A/B	50% (lymphoid)
IKZF1	55% (lymphoid)
ASXL1	20.5% (myeloid)
TET2	7.7% (myeloid)
WT1	15.4% (myeloid)
NRAS/KRAS	5.1/5.1% (myeloid)

Abbreviation: NR, not reported.

tion is likely to play a major role, for example through increased BCR-ABL1 expression that in turn suppresses the myeloid transcription factor CEBPA.[16,17]

APPROACH TO THE PATIENT PRESENTING WITH ACCELERATED-PHASE/BLASTIC-PHASE CHRONIC MYELOID LEUKEMIA

As presentation of CML in AP or BP is uncommon in the developed world, there is limited data for this group of patients. However, second-generation TKIs are preferred over imatinib. In the salvage setting, dasatinib has shown slightly higher response rates and more durable responses in CML-AP and is currently the only second-generation TKI approved for BP-CML.[18] In the case of blastic transformation, TKIs are usually combined with AML- or ALL-type multiagent chemotherapy, whereas this is not typically the case for AP.[19] All patients with AP/BP-CML should be considered for an allogeneic stem cell transplant, with TKI therapy used to restore a second chronic phase and bridge the time to transplant. Therefore, human leukocyte antigen typing and a transplant consultation are essential parts of the initial workup for patients who present in AP/BP. Whether or not to proceed to allografting in a patient with AP/BP-CML who attained a very good response to TKI can pose an extremely challenging clinical decision, and it is wise to discuss this eventuality before starting TKI therapy. Transplant risk, comorbidities, and the patient's personal preferences are critical factors.

DEFINING TREATMENT FAILURE
Resistance to Tyrosine Kinase Inhibitors

Clinical TKI resistance is grouped into primary and acquired resistance. At a mechanistic level, resistance can be classified as BCR-ABL1–dependent or BCR-ABL1–independent. In BCR-ABL1–dependent resistance, there is reactivation of BCR-ABL1 kinase, which implies that responses may be recaptured if BCR-ABL1 inhibition is restored. In BCR-ABL1–independent resistance, alternative pathways substitute for BCR-ABL1 kinase activity.[20]

BCR-ABL1 Kinase Domain Mutations

The best characterized mechanism of TKI resistance is point mutations in the *BCR-ABL1* kinase domain that impair drug binding.[21] Solving the crystal structure of ABL1 in complex with an imatinib analog was instrumental to understanding how kinase domain mutations cause resistance.[22] In contrast to expectations, imatinib was found to bind an inactive conformation of ABL1, with the activation loop of the kinase in a closed position. Additionally, there was extensive downward displacement of the ATP-binding loop. Mutations in the kinase domain can cause resistance by steric hindrance or elimination of hydrogen bonds, most impressively in the T315I mutation at the gatekeeper position. A different type of mutation affects

the ATP-binding loop, preventing the rearrangements required for optimal drug binding. Examples include Q252H, Y253(H/F), and E255(K/V). Last, mutations in the activation loop such as H396P stabilize an open conformation, to which imatinib cannot bind.[23] Although imatinib is vulnerable to a broad range of mutations, the spectrum is much more limited for nilotinib and dasatinib, reflecting their greater potency and, in the case of dasatinib, less stringent binding requirements.[24] Clinical resistance mutations are precisely predicted by in vitro assays, which enable the development of preemptive strategies to overcome this type of resistance.[25-27] Mutation testing is recommended upon disease progression and if milestones are not met. Most laboratories use Sanger sequencing, which has a sensitivity of approximately 20% mutant allele. This level of sensitivity seems to provide the right balance between sensitivity and specificity. More sensitive assays such as next-generation sequencing are under development and may replace Sanger sequencing in the future. Biochemical and cell proliferation data have been used to rank kinase domain mutations according to the degree of TKI resistance they confer.[28] Although these data are based on in vitro studies, they tend to correlate with clinical responses.[29,30] However, correlations are not as tight as one might suspect, suggesting that additional mechanisms govern clinical resistance. The exception to this rule is the T315I mutation that confers complete resistance to all approved TKIs, except ponatinib. For several other mutants, the difference in sensitivity is sufficient to support the use of dasatinib over nilotinib, or vice versa (Fig. 1). An in-depth discussion of the many reported mutations and their sensitivity profiles is beyond the scope of this chapter and the reader is referred to detailed reviews of this subject.[31-33]

Activation of Alternative Signaling Pathways

In contrast to kinase domain mutations, BCR-ABL1 kinase–independent resistance is less well understood and seems to involve multiple different mechanisms. For example, activation of SRC family kinases, MAP kinase, STAT5, SYK, and PI3K have all been associated with TKI resistance, despite sustained inhibition of BCR-ABL1.[34-38] Extrinsic factors such as cytokines may also play a role.[39,40] Targeting these diverse pathways is therapeutically challenging and common downstream effector molecules such as pSTAT3 or processes such as nuclear cytoplasmic transport may be more promising.[41-43]

FIGURE 1. Activity of Imatinib, Bosutinib, Dasatinib, Nilotinib, and Ponatinib against Mutated Forms of BCR-ABL1

APPROACH TO THE PATIENT WITH TYROSINE KINASE INHIBITOR RESISTANCE

The European Leukemia Net and the National Comprehensive Cancer Network have defined therapeutic milestones for patients receiving TKI therapy (Table 4).[6,44] Although both systems are generally aligned, the European Leukemia Net uses the category of "warning" to denote a situation that does not meet the criteria for failure, but gives rise to concern that a poor outcome is possible. Failure to achieve therapeutic milestones is consistent with primary resistance. Loss of response from a given level suggests acquired TKI resistance. Both should trigger a thorough evaluation. TKI resistance is a clinically important diagnosis that is associated with inferior outcomes compared with those of the average CML population. The first call of order is to assess medication adherence through a thorough history. Drug level testing may be useful in isolated cases, but is not widely available. Additionally, patients have been found to make up for skipped doses during the last few days before the office visit.[45] Second, drug interactions must be considered, especially in patients on multiple comedications, including over-the-counter remedies such as St. John's Wort, which can drastically lower imatinib plasma concentrations.[46] Predicting drug interactions in patients on polypharmacotherapy is challenging, particularly in cases with impaired renal or hepatic function and consultation of a clinical pharmacologist is advisable. A frequent challenge is a rise in the level of *BCR-ABL1* mRNA as assessed by quantitative polymerase chain reaction. Interpretation of changes in *BCR-ABL1* mRNA must take into account the performance of the diagnostic laboratory. In most cases, only rises greater than five-fold or greater than 10-fold are clinically relevant, particularly in patients with a low level of residual disease.[47] In the absence of other signs of relapse, repeating the *BCR-ABL1* quantitative polymerase chain reaction in 4 to 6 weeks is recommended, before additional diagnostic studies are initiated. If nonadherence or drug interactions are unlikely, a complete resistance work-up is indicated that includes a physical exam, complete blood count, bone marrow aspirate and biopsy, bone marrow metaphase karyotyping, and *BCR-ABL1* mutation analysis. TKI resistance defines a high-risk situation and should be approached as a diagnosis with important clinical implications. Key pieces of information derived from this workup are disease phase, *BCR-ABL1* mutation status, and karyotype, including CCA/Ph$^+$.

Progression of Chronic-Phase Chronic Myeloid Leukemia

Progression with first-line imatinib. Patients whose disease develops resistance to first-line imatinib, but who are still in chronic phase, are switched to a second-generation TKI, the selection of which is based on the first-line TKI, past medical history to avoid specific side effects, and (if present) the type of *BCR-ABL1* mutation (Fig. 1). Patients with first-line imatinib failure have a 40% to 50% chance of achieving complete cytogenic response (CCyR) on a second-generation TKI.[48,49] Overall, however, the prognosis of these patients is guarded. In a retrospective study, overall and progression-free survival at 4 years were 81.9% and 35.3%, respectively, indicating that most patients will eventually require an alternative therapy.[50] Close molecular monitoring is required. One study showed that only 7% of patients without a minor cytogenetic response ($\leq 65\%$ Ph$^+$ metaphases) at 3 months were in major cytogenic response at 12 months, whereas major cytogenic response at 12 months predicted progression-free and overall survival (OS).[51] Another study reported that achieving less than 10% BCR-ABL1^{IS} at 3 months was predictive of OS (91.3% vs. 72.1%, p = 0.02) and event-free survival (49.3% vs. 13.0%, p < 0.001). Taken together, these data suggest that the 3-months evaluation is critical for determining whether the first salvage is likely to work.

Progression during second-generation tyrosine kinase inhibitor therapy and failure of multiple tyrosine kinase inhibitors. Selecting the optimal approach in patients in whom second-generation TKI first-line therapy fails is challenging. Current guidelines recommend using an alternative second-generation TKI, but limited data are available regarding the efficacy of this strategy. Retrospective studies of dasatinib, nilotinib, and bosutinib as third-line therapies after failure of imatinib show limited efficacy, with CCyR rates of approximately 20%.[52,53] Moreover, responses are frequently not durable, raising the question of ponatinib as a more effective and durable salvage therapy. In the Ponatinib Ph$^+$ ALL and CML Evaluation (PACE) trial, 46% of CP-CML patients achieved CCyR, 91% of which were maintained at 12 months. In most (93%) patients, two or more TKIs had previously failed, making ponatinib a strong consideration for patients in whom multiple TKIs have failed.[54] Ponatinib is the drug of choice for patients with the BCR-ABL1^{T315I} mutation. The

TABLE 4. Therapeutic Milestones: National Cancer Center Network versus European Leukemia Net

Month		Optimal	Warning	Failure
3	ELN	Ph+ $\leq$ 35% or BCR-ABL1 < 10%	Ph+ 65-95% or BCR-ABL1 > 10%	No CHR or Ph+ > 95%

broad range efficacy of ponatinib must be balanced against its substantial cardiovascular toxicity, which is enhanced by preexisting risk factors such as diabetes, hypercholesterolemia, and hypertension.[54] Failure of ponatinib indicates a patient is a candidate for non-TKI therapies, including omacetaxine, a clinical trial, or HSCT.[44] This is particularly true for patients with compound mutations that include T315I as one component and may confer resistance to all currently approved TKIs.[28] Dense qPCR monitoring is critical for patients in whom second-generation TKIs failed, and those in whom multiple TKIs have failed. When to proceed to HSCT in a patient with CP-CML is a difficult clinical decision that must take into account the transplant risk as well as the risk of progression to AP/BC-CML. It is good clinical practice to refer any transplant-eligible patient with progression on first-line therapy to a transplant center for an initial evaluation and preliminary clarification of donor options.

Progression to Accelerated-Phase/Blastic-Phase Chronic Myeloid Leukemia

Patients who progress to AP/BP-CML are treated with the appropriate TKI, taking into account prior TKI exposure history and *BCR-ABL1* mutation status. Given the limited therapeutic options, more TKI toxicity is acceptable. Decisions whether or not to combine TKI salvage with chemotherapy must be individualized based on performance status and the availability of allogeneic stem cell transplant as a potentially curative salvage strategy.[19] Given the absence of controlled studies in this fortunately rare patient population, the value of adding chemotherapy is not completely clear, particularly in patients with myeloid transformation. All eligible patients should be offered an allogeneic stem cell transplant, and avoiding unnecessary toxicity in potential transplant patients is an important consideration.

ALLOGENEIC STEM CELL TRANSPLANTATION

Allogeneic HSCT was the first treatment modality that restored Ph-negative hematopoiesis and induced durable responses.[55] Before the introduction of imatinib, allografting was recommended to all eligible patients and even today it is still regarded as the only therapy with curative potential. Only one study prospectively compared allotransplant versus drug therapy. Newly diagnosed patients with CML-CP were biologically randomly assigned to a matched sibling transplant versus IFN-based drug therapy, the best nontransplant treatment available when the trial was initiated.[56] Patients managed with drug therapy had superior survival, with the biggest difference observed in low-risk patients. After approximately 8 years, the survival curves crossed, suggesting that transplant would be superior in the long-term if IFN was the alternative. However, given the efficacy of TKIs in the first-line setting, and that early transplant-related mortality is clearly higher than the risk of early disease progression, allotransplant is no longer justifiable in newly diagnosed patients with CML-CP, except in unusual circumstances.[57]

Risk scores for allografting in CML were developed by the European Group for Blood and Marrow Transplantation (EBMT) in the pre-imatinib era and identified disease duration of longer than 12 months, more advanced disease, higher age, unrelated donor type, and the combination of a male recipient with a female donor as adverse prognostic factors.[58] Disease phase had the greatest effect on outcome. Although somewhat historic, the EBMT score is still useful for prognostication. There is consensus that allotransplant should be offered to all patients with progression to AP/BP. A more individualized approach is required for patients in whom dasatinib or nilotinib have failed in chronic phase, given that ponatinib is effective, albeit at the cost of cardiovascular toxicity.[54] Fortunately, there is no evidence that imatinib or other TKIs before allografting negatively affect the outcome. On the contrary, for unknown reasons, imatinib before allotransplant seems to reduce the risk of chronic graft-versus-host disease and possibly relapse risk.[59-61] Results from the German CML study group reassert the importance of transplanting patients while they are still in chronic phase: 3-year OS was 91% for patients transplanted in CP after imatinib failed versus 59% for patients transplanted in AP/BP.[62] There is an emerging consensus that bone marrow is preferred over peripheral blood stem cells in patients with CML-CP, in whom graft-versus-host disease is a greater concern than disease control.[63] This assessment is different for patients with transformation to AP/BP, even if they have achieved a second chronic phase. High relapse–risk patients should receive a TKI post-transplant; *BCR-ABL1* mutation analysis at the time of resistance will help match the optimal TKI to individual patients. Given the high median age at the time of diagnosis, many patients will be eligible only for reduced intensity conditioning regimens. An in-depth discussion of the various conditioning regimens, selection of bone marrow versus peripheral blood stem cells, and post-transplant immunosuppression is presented elsewhere.

PERSPECTIVE

Despite the unparalleled success of TKI in CML, progression during first-line TKI therapy, and transformation to accelerated- or blastic-phase continue to carry a poor prognosis. Although BCR-ABL1 mutations are a well-established mechanism of TKI resistance, many cases of clinical resistance remained mechanistically unexplained and are thought to be a result of activation of alternative signaling pathways. In these patients, salvage therapies are currently nonspecific. The hope is that diverse upstream pathways may activate a limited set of downstream effector molecules, thus providing an opportunity for rationally targeted therapies that are applicable to a wider population of patients. Early identification of patients with TKI failure or at risk of transformation is critical, so that therapy can be adjusted in a timely fashion to maximize the chances of successful salvage therapy. Despite the introduction of new TKIs such as ponatinib, the prediction is that allogeneic stem cell transplant will retain its position as the salvage therapy of choice for patients who progress to AP/BC-CML.

From Philadelphia-Negative to *JAK2*-Positive: Effect of Genetic Discovery on Risk Stratification and Management

Naveen Pemmaraju, MD, and Alison R. Moliterno, MD

OVERVIEW

The 2005 discovery of the *JAK2* mutation redefined the diagnosis and natural history of myeloproliferative neoplasms (MPNs). Most importantly, this improvement in the pathobiologic conceptualization has focused our evolution of this field from being defined as what it is not (e.g., Philadelphia [Ph]-negative) to what it is (e.g., *JAK2*-positive, *CALR*-positive) in the majority of MPN cases. In the ensuing 10 years, the field has experienced a paradigm shift in terms of understanding of the biologic basis of the development of MPNs, an explosion of knowledge of the genetics of MPNs, and has translated disease knowledge into effective targeted therapies. With greater uniformity and agreement on the diagnosis and differences among the individual MPNs, augmented by improved cytogenetic and molecular classification, attention has turned now to addressing the need for uniformity in risk stratification of patients in the clinic for both disease complications and disease transformation. This article will highlight the developments in the field with regard to risk stratification and prognostication in MPNs with focus on the clinical aspects of the patient who presents with either essential thrombocytosis (ET), polycythemia vera (PV), or myelofibrosis (MF).

Myeloproliferative neoplasms represent a family of clonal hematopoietic stem cell disorders that exhibit a wide variety of clinical, biologic, and phenotypic heterogeneity. MPNs serve as the model of acquired somatic genetic lesions as the causal basis of cancer (so-called drivers), from the first genetic lesion ascribed to cancer, the Philadelphia (Ph) chromosome in chronic myelogenous leukemia (CML), to the more recent discoveries of lesions in *JAK2, MPL,* and *CALR* in what were previously called Ph-chromosome–negative MPN. MPNs cause a substantial amount of morbidity and mortality during a patient's lifetime, including increased cardiovascular, thrombotic, and hemorrhagic events, and increased lifetime risk for transformation to acute myeloid leukemia (AML), bone marrow failure, or MF. In the 10 years since the *JAK2V617F* discovery, the MPN field has experienced a profound increase in both clinical and basic research with regard to further understanding of the pathobiologic basis for the disease, especially illustrated by the more recent discoveries of diagnostic and prognostic significance of *JAK2, MPL, CALR, ASXL1*, and other molecular markers. Importantly, genetic discovery in CML and MPN have been translated to effective, targeted therapy, capable of altering the natural history of the MPN.[1-6] This review will focus on the most recent advances in risk stratification of the patient with MPN, and how risk stratification can be translated to disease- and patient-specific therapy.

ACQUIRED SOMATIC MUTATION IN THE MPN: IDENTIFICATION OF CAUSAL LESIONS

Chronic myeloproliferative disorders (MPDs) were recognized as clinical entities in the 19th century, but the 20th century brought precise clinical classification and their genetic basis into being. The 21st century has, and continues to, unravel their causal genetic basis. The primary nature of bone marrow's overproduction was compared with that of leukemia, and both CML and PV were considered as neoplasms of the hematopoietic tissue. William Dameshek theorized that these entities might be driven by a shared stimulus intrinsic to the marrow itself, and coined the term MPDs.[7] The identification of the Ph chromosome as specific to CML and not to the rest of the MPD class was not only an advance in disease classification within MPNs, but, ultimately, confirmed the causal association of an acquired genetic lesion in the generation of human cancer.[8]

Given the similarities of Ph-chromosome–negative MPN to Ph-positive–MPN (stem cell basis, overproduction of mature myeloid elements, tendency to evolve to MF or acute leukemia), lesions in tyrosine kinase pathways critical to erythropoietin, thrombopoietin, and granulocyte-colony stimulating factor signal transduction were investigated. Advances in DNA sequencing technology led several investigators to resequence the *JAK2* gene in patients with PV because of its specific activity in primary PV cells, its identity as a ty-

---

TABLE 1. Acquired Somatic Lesions in the World Health Organization 2008 Myeloproliferative Neoplasm Classification

	Lesions	Combined Frequency
Polycythemia Vera	JAK2V617F, JAK2 exon 12	99%
Essential Thrombocythemia	JAK2V617F, CALR, MPL	Approximately 80%
Primary Myelofibrosis	JAK2V617F, CALR, MPL	Approximately 80%
Chronic Myelogenous Leukemia	BCR-ABL1	100%
Chronic Neutrophilic Leukemia	CSFR3	Approximately 80%
Mastocytosis	KIT	Approximately 80%

rosine kinase, or its location in the chromosome 9p loss of heterozygosity region highly prevalent in MPNs.[9-12] *JAK2* mutations are identified in nearly 100% of patients with PV, and are also highly prevalent in patients with thrombocytosis (ET) and primary MF (PMF; Table 1). Like BCR-ABL1, evidence that driver lesions are causative in MPNs are as follows: recapitulation of MPN disease in transgenic murine models,[13-15] gene-dosage effect of *JAK2V617F* on MPN phenotype,[16] and hematologic remissions corresponding to molecular remissions.[4,5] The *BCR-ABL* and *JAK2* discoveries also have hastened the discovery of other causative MPN lesions by allowing for enrichment of lesion-negative MPNs in global resequencing studies.[14,17-19] Table 1 outlines the high-frequency causal driver lesions identified to date and their relative frequency in MPNs. Given the relative prevalence of the various MPNs and the frequency of driver lesions within MPNs, *JAK2V617F* is the most common lesion in this group. The term Ph-chromosome–negative MPN was applied because the Ph discovery was the first. This term is no longer relevant as identified lesions in Table 1 now have come to define their clinical entities.

OVERVIEW OF RISK ASSESSMENT IN MPNs

In contrast to CML, a disease with a fairly uniform sequential natural history driven by BCR-ABL1, marked variability ex-

KEY POINTS

- Genetic discovery has transformed the diagnosis of the chronic myeloproliferative neoplasms (MPNs).
- Risk stratification in MPNs has been redefined by genetic discovery.
- Global risk assessment for MPNs includes disease-specific and patient-specific risk factors.
- Genetic discovery has informed both thrombosis and disease transformation risk stratification.
- Inclusion of constitutional symptoms into prognostic scoring systems signifies the continued importance of patient-reported outcomes in risk stratification.

ists in the natural history of *JAK2-, CALR-, MPL-,* and *KIT*-mutation–positive disease. For instance, *JAK2V617F* in many individuals is latent and may be asymptomatic or aphenotypic for undisclosed periods, as evidenced by its detection in large unselected population surveys.[20] Moreover, cells that have acquired *JAK2V617F* often acquire an additional copy of *JAK2V617F* via mitotic recombination events, such that *JAK2V617F* mutation dosage is a variable to be accounted for both at diagnosis and during disease monitoring. In these diseases, particularly in *JAK2V617F*-positive MPN, factors such as age at diagnosis, sex, treatment exposure, host genetic background, gene dosage, and other acquired genetic lesions, to a large part, contribute to risk for disease acquisition,[21,22] disease evolution or progression, and thrombosis.[23,24] Thus, risk stratification in MPNs must take into account disease class, specific genetic lesions, lesion burden, and host factors and requires large observational prospective cohorts to establish risk. Estimating risk throughout decades of disease is challenging and often confounded by the individual, and by the lack of knowledge of somatic mutations and their roles. In diseases where survival is measured in decades, risk assessment includes not only long-term risks of disease evolution or transformation, but also ongoing symptom burden risk assessment.

RISK STRATIFICATION IN MPNs
Essential Thrombocytosis

ET is an MPN that features a risk for morbidity and mortality secondary to either thrombotic or hemorrhagic events, as well as transformation to PV, MF, and AML, and represents a distinct entity from PV.[25] Historically, underlying molecular abnormalities of ET remained elusive until discovery of the *JAK2V617* mutation (present in 50% to 60% of cases), *MPL* mutations (4% of cases), and, most recently, *CALR* mutations (15% to 24% of cases; Table 1).[26,27] In terms of thrombosis risk stratification in the clinic, a dual risk factor system has been used based on older age of the patient and a personal history of prior thrombotic (or hemorrhagic) events.[28] Several groups have subsequently put forward additional clinical and laboratory features to be considered. In 2012, the International Working Group for Myeloproliferative Neoplasms Research and Treatment reported on the International Prognostic Score for Essential Thrombocytosis (IPSET).[29] This study analyzed 867 patients with World Health Organization (WHO)-defined ET and found that three factors informed prognosis by multivariate analysis: (1) age 60 or older, (2) white blood cells (WBC) of 11K/uL or greater, and (3) personal history of a thrombotic event. Ultimately, patients were put into one of three risk groups: low, intermediate, and high risk. The IPSET model was able to predict significant differences in survival (median overall survival: low risk, not reached; intermediate risk, 24.5 years; and high risk, 13.8 years). Additionally, the model had the ability to predict thrombotic event rate occurrence. It was unable to account for transformation to MF.

Another recent ET scoring system from a retrospective study focused on the risk for thrombosis in patients with ET, termed the IPSET-thrombosis model.[30] This important

model was validated with internal and external datasets, again demonstrating improved prognostication for risk for thrombosis among patients with ET. Among 891 patients with WHO-classified ET, multivariate analysis and risk scoring found four factors to be significant in terms of predicting thrombotic risk: (1) age older than 60, (2) prior thrombotic history, (3) cardiovascular risk factors, and (4) *JAK2V617* mutation positivity. The model demonstrated three distinct at-risk thrombotic groups: low risk, 1.03% of patients per year; intermediate risk, 2.35% of patients per year; and high risk, 3.56% of patients per year. Notably in this model, the presence of WBC count is removed as a significant factor, and, instead, both cardiovascular risk factors and the *JAK2V617* mutation are added and demonstrate significance. As this model is based on retrospective data, the prospective validation of this model will be warranted and the presence of leukocytosis and presence of *JAK2V167* mutation and its corresponding allele burden and overall thrombotic risk will need to be further explored, as prior reports have demonstrated that a higher JAK2 allele burden may not necessarily correlate with a higher thrombotic risk in all patients with ET.[31]

In a recent study of 1,150 patients with ET from four Italian centers, Finazzi et al retrospectively sought to analyze if the presence of the newly defined *CALR* mutation would affect prediction of thrombosis by the IPSET-thrombosis model.[32] Among the 1,150 patients, 164 patients (14%) were found to be *CALR* mutated. There was a higher incidence of *CALR* mutation among the low- and intermediate-risk groups as compared with the high-risk IPSET group, and there was a trend toward lower rate of thrombosis noted in the patients with *CALR*-mutated disease as compared with patients with *JAK2V617*-mutated disease (1.30% vs. 1.95% of patients per year), but this was not significant. This finding, as noted by the authors, was mitigated by the fact that *CALR* mutation was also more commonly found among patients with ET with fewer prior thrombotic events and younger patients (Table 2).

ET, regardless of genetic driver, carries significant risks during the lifetime of a patient for transformation to PV and MF. Transformation to PV is a function of time and is closely associated with *JAK2V617F*-positive status, in addition to increasing JAK2V617F allele percentage. Post-ET MF, in con-

TABLE 2. Thrombotic Risk Factors Associated with the Myeloproliferative Neoplasm

Risk Factor	Comments
MPN class	PV > MF > ET
Prior thrombotic event	
Presence of cardiovascular risks	
Age > 60	
Hematocrit > 45%	Validated in PV
JAK2V617F	Strongly associated with BCS

Abbreviations: MPN, myeloproliferative neoplasm; PV, polycythemia vera; ET, essential thrombocytosis; BCS, Budd-Chiari syndrome.

TABLE 3. Risk Factors for Disease Evolution in Myeloproliferative Neoplasm

Evolution	Clinical Risk Factors	Genetic Risk Factors
ET to PV	Disease duration	JAK2V617F, JAK2V617F allele %
ET to MF	Disease duration, male sex, age	JAKV617F allele %, ASXL1, 20q deletion, 13q deletion, trisomy 8
PV to PPVMF	Disease duration	Trisomy 9, ASXL1, 20q deletion, 13q deletion, trisomy 8
MPN to AML	Age, disease duration, karyotypic complexity, myelofibrosis phase, P32, alkylator exposure	JAK2V617F allele %, complex karyotypic lesions, TP53, RUNX1 lesions

Abbreviations: ET, essential thrombocytosis; PV, polycythemia vera; MF, myelofibrosis; PPVMF, postpolycythemia vera myelofibrosis; MPN, myeloproliferative neoplasm; AML, acute myeloid leukemia.

trast, occurs in all ET settings, and is associated with not only disease duration, but also acquisition of additional genetic lesions and male sex (Table 3).[33]

Polycythemia Vera

Historically, risk stratification in PV incorporated age of the patient (older than 65) and prior thrombotic history.[34] More recently, Tefferi et al reviewed outcomes among a large group of patients (1,545 patients) with WHO-specified PV.[24] In this multivariate analysis, the authors found that leukocytosis, advanced age, abnormal cytogenetics, and history of a venous thrombotic event portend a more adverse outcome in terms of overall survival. This model system also further analyzed factors important for predicting transformation to AML, and found that three out of the four factors for survival were still significant for this outcome (all but venous thrombotic event; Tables 2 and 3).

About 20% of patients with PV may experience a thrombotic event during the course of their disease. Thrombotic events occur on the arterial and venous circulation, microvascular, or thromboembolic, such as transient ischemic attacks, myocardial infarction, deep venous thrombosis, or pulmonary embolism. Venous thrombosis in unusual circulations may occur in the patient with PV, particularly in the portal and hepatic (splanchnic), splenic vein, and cerebral venous sinuses. An important element in risk stratification of the patient with PV is a comprehensive assessment of a patient's underlying risk factors for thromboembolism, including an understanding of the patient's cardiovascular risk factors, including smoking use and history.[35] The importance of hematocrit control, in addition to controlling traditional cardiovascular risks, was established by the CYTO-PV Collaborative Group, whereby an aggressively pursued threshold of hematocrit 45 or greater resulted in a three- to four-times risk reduction in terms of cardiovascular morbidity and mortality, as compared with the group with less strict hematocrit regulation.[36]

Thrombotic risk in MPNs has also led to risk stratification in patients with occurrence of idiopathic Budd-Chiari syn-

drome (BCS) and portal vein thrombosis (PVT). In a series by Kiladjian et al, 241 patients with splanchnic vein thrombosis (SVT) were examined. *JAK2V617F* mutation was found in 45% of the BCS cases, and 34% of the PVT cases; whereas, *JAK2* exon 12 and *MPL* mutations were not identified in any.[37] A meta-analysis showed that because of the close association of *JAK2V617F*-positive MPN in patients with new SVTs, routine screening with *JAK2V671F* mutation was warranted in all patients presenting with idiopathic SVTs, even in patients where MPN phenotype is masked.[38,39] Risk factors associated with presentation of BCS as a consequence of MPN appear to be *JAK2V617F* positivity, PV, and, paradoxically, for thrombosis risks in general, female sex, and younger age (Table 2).

PV may run a course of uncomplicated disease requiring only phlebotomy for decades, or may follow a progressive, malignant course similar to CML in which a relatively short polycythemic phase is followed by transformation to MF (PPVMF) and then to AML, all occurring within a matter of years from the original PV diagnosis. The PPVMF phase of the disease clinically and molecularly resembles de novo PMF, with high stem cell JAK2 allele burdens and the association of chromosome changes such as 20q deletion, 13q deletion, trisomy 9, and mutation of the *ASXL1* gene.[40-42] The nonrandom chromosomal changes that are present in greater than 60% of patients with PPVMF, and their similar prevalence in de novo PMF, suggests that these lesions drive MF physiology and alter the cellular context of JAK2V617F signaling.[43] Recent studies of PPVMF indicated that approximately 15% of patients developed MF at a median of 10 years after PV diagnosis and that this percentage increased to almost 50% after 20 years. These studies also found that a subset of patients with PV who had lower JAK2V617F allele burdens had a significantly lower risk for this outcome compared with the subset of patients with higher allele burdens (Table 3).[44,45]

AML occurring directly out of chronic phase PV is unusual and estimated to occur in as many as 4% of patients with PV; whereas, AML evolving from PPVMF is more common, occurring in as many as 20% of patients with MF.[46] The leukemia-accelerating effects of radioactive phosphorus and the alkylator pipobroman on the natural history of PV is uncontested.[24,47] Moreover, this experience in PV calls any potentially genotoxic therapy into question regarding safety, especially given the long-term exposure to any therapy that some patients with PV will require, and the need for therapy in older patients with PV, where genomic integrity is an issue. Traditional risk factors for AML development include older age, P32 or alkylator therapy, PPVMF, and hemoglobin less than 10 g/dL.[47]

Myelofibrosis

It has long been noted that patients with MF experience markedly different outcomes.[48,49] To better understand and quantitate this phenomenon, a methodical approach to analyzing risk factors associated with higher-risk disease has resulted in the birth of several clinically useful scoring systems that incorporate clinical and laboratory findings in the patient with MF. Cervantes et al examined 1,054 patients with PMF.[50] In this study, the multivariate analysis demonstrated that five risk factors were significantly associated with determination of prognostic score when assessed at time of MF diagnosis: (1) age older than 65 years, (2) leukocytosis (WBC greater than 25 K/uL), (3) circulating blasts of 1% or greater, (4) presence of constitutional symptoms, and (5) anemia of hemoglobin less than 10 g/dL. This divided the patients into groups of low-risk, intermediate-1, intermediate-2, and high-risk, with median overall survivals of 135 months, 95 months, 48 months, and 27 months, respectively. This represents the most widely used scoring system for patients with MF, and, although cytogenetic abnormalities and *JAK2V617* mutation were considered, notably, neither reached independent significance to warrant inclusion in the final scoring system in this original International Prognostic Scoring System (IPSS) model. It is of particular importance that the presence of constitutional symptoms were included and indeed validated in the IPSS model for MF, as this highlights an important part of risk stratification for patients with MPNs: the burden of symptoms experienced in these diseases, even in those patients with lower risk scores, affect not only the quality of life, but also has effects on overall survival outcomes.[51] Several clinical instruments have been developed and validated specifically in patients with MPN, including for patients with MF, to help quantitate and follow these symptom profiles over time.[52,53] These and other widely available instruments will likely continue to be an important part of recording and understanding MPN's risks, comorbidities, and symptoms over time, and be a vital method to reliably follow changes/improvements with disease-modifying agents starting to be used in the clinic.[54]

The IPSS scoring method of risk stratification for patients with MF has had a direct effect on therapeutic investigation and decision making as it helped to select an appropriate patient population for the largest randomized clinical trials testing a novel therapy in patients with MF.[55] On the basis of the IPSS, those patients with intermediate-2 or high-risk MF were included on the original phase III clinical trials testing ruxolitinib, a JAK1/2 inhibitor, against either best available therapy or placebo (COMFORT 1 and 2), thus, identifying the highest-risk/poorest-prognosis patients that might benefit from therapy.[1,6] These trials ultimately led to U.S. Food and Drug Administration approval of ruxolitinib, the first and only therapy specifically approved for patients with MF on the basis of risk stratification, taking into account patient symptom burden and constitutional symptoms into the approval process.[56]

Building on this clinical risk factor model, several other scoring systems for MF have been developed with the aim of providing prognostication for overall survival at any time during disease course, not just at diagnosis, (Dynamic International Prognostic Scoring System [DIPSS])[57] and further refinement with additional risk factors added (DIPSS-plus), including thrombocytopenia, transfusion dependency, and cytogenetic abnormalities.[58] The identification and success-

ful addition of cytogenetic abnormalities to risk stratification for patients with MF recognizes the striking heterogeneity among patients with this disease at the pathobiologic level, reflects the remarkable strides made in these now widely available laboratory assessments, and is in line with prognostic measurement of other myeloid malignancies (MDS, AML) that are all now utilizing cytogenetic analysis as a part of routine risk stratification and treatment decision making.

Besides cytogenetics, it appears that molecular abnormalities may be crucial to understanding the modern risk stratification of the patient with MF.[59] More recent discoveries of the significance of *MPL* and *CALR* mutations added to the already known *JAK2* mutation in diagnosis of MF, however, their significance on risk stratification was unknown until recently.[60] Rumi et al examined the effect of molecular mutations on outcomes in 617 patients with MF. The authors found markedly different outcomes based on the molecular profile: the longest median overall survival was found in *CALR*-mutated (17.7 years), followed by *JAK2*-mutated (9.2 years), *MPL*-mutated (9.1 years), and, finally, a group of patients termed triple-negative (negative for *CALR, JAK2,* and *MPL*) constituted the poorest-prognosis group with median overall survival of only 3.2 years.

Other genetic lesions important in MDS and AML have been identified at a relatively high frequency in MF and may inform risk. For example, mutations in ASXL1 occur in 30% to 36% of patients with MF.[41] Taking some of these newer markers into account, further molecular risk stratification was conducted with inclusion of and assessment of other molecular mutations commonly found in myeloid malignancies that are also found in patients with MF: *IDH, EZH2, SF3B1, SRSF2, U2AF1,* and *ASXL1.*[61] Analyses in large MF cohorts have the power to further refine prognosis based on genetics, with a recent study identifying CALR-negative/ASXL1-positive MF patients exhibiting worse outcomes, suggesting another higher-risk subset.[62]

CONCLUSION

In the 10 years since the discovery of the *JAK2V617* mutation in MPNs, the field has experienced an exponential increase in terms of clinical and basic science research. With improved methods of stratifying risk for patients at the clinical, biologic, cytogenetic, and, now, molecular level, we are entering a new era of recognizing MPN's total burden of disease, and we are beginning to consider assigning targeted treatments based on these assessments. The personalization of MPN diagnosis, prognosis, and treatment will likely include the congruence of clinical factors, formal MPN symptom burden assessment, and cytogenetic and molecular analyses.

Current Therapies and Their Indications for the Philadelphia-Negative Myeloproliferative Neoplasms

Jean-Jacques Kiladjian, MD, PhD

OVERVIEW

The groundbreaking discovery of the Janus-associated kinase 2 (JAK2) V617F mutation 10 years ago resulted in an unprecedented intensive basic and clinical research in Philadelphia-negative myeloproliferative neoplasms (MPNs). During these years, many new potential targets for therapy were identified that opened the era of targeted therapy for these diseases. However, only one new drug (ruxolitinib) has been approved during the past 40 years, and, although promising new therapies are evaluated, the armamentarium to treat MPN still relies on conventional drugs, like cytotoxic agents and anagrelide. The exact role of interferon (IFN) alfa still needs to be clarified in randomized studies, although it has been shown to be effective in MPNs for more than 25 years. The current therapeutic strategy for MPNs is based on the risk of vascular complication, which is the main cause of mortality and mortality in the medium term. However, the long-term outcome may be different, with an increasing risk of transformation to myelodysplastic syndrome or acute leukemia during follow-up times. Medicines able to change this natural history have not been clearly identified yet, and allogeneic stem cell transplantation currently remains the unique curative approach, which is only justified for patients with high-risk myelofibrosis or for patients with MPNs that have transformed to myelodysplasia or acute leukemia.

For decades, the armamentarium to treat Philadelphia-negative myeloproliferative neoplasms (MPNs), including polycythemia vera (PV), essential thrombocythemia (ET), and primary myelofibrosis (PMF), was reduced to a small handful of cytotoxic drugs like hydroxyurea (HU); busulfan; and, in some countries, pipobroman.[1] Since the discovery of the JAK2 V617F mutation 10 years ago followed by the discovery of many other genetic alterations,[2] our knowledge of the pathophysiology of these disorders has dramatically changed, with the identification of deregulated crucial signaling pathways like the JAK-STAT (signal transducer and activator of transcription) pathway or mutations affecting the epigenome. With these major advances, MPNs have entered into a new era of targeted therapy, inaugurated with the approval of ruxolitinib, a JAK1/JAK2 inhibitor to treat myelofibrosis (MF)[3,4] and PV.[5]

With conventional therapies, the treatment of MPNs mainly aims at reducing the risk of vascular events (including thrombosis and hemorrhage), which are the main causes of mortality and morbidity over short and medium time periods.[6,7] However, the outcome of patients with these chronic malignancies is different over the long-term evaluations (i.e., after 15 to 20 years of evolution), when transformation to myelodysplastic syndrome (MDS) or acute myeloid leukemia (AML) becomes a major concern, as demonstrated by the long-term analyses of a randomized study in patients with PV after

more than 16 years of median follow-up time.[8] The development of new therapies raises the hope of new objectives, including reduction of the long-term risk of transformation to MDS or AML; achievement of molecular or histopathologic complete remissions; and, possibly, cure. However, to date, only allogeneic hematopoietic stem-cell transplantation (ASCT) can cure selected high-risk patients with MF.

VASCULAR RISK ASSESSMENT

The evaluation of the risk of vascular complications is a cornerstone of current MPN management, especially in PV and ET. Risk stratification is reviewed in detail in a companion article in this volume (Moliterno and Pemmaraju), and this paragraph will focus on a few elements useful for decision making in MPN therapy. Indeed, in the absence of curative therapy, the aim of this risk-based classification is to avoid the use of cytoreductive therapy in patients who are at low risk of developing thrombosis or hemorrhage. Although many risk factors have been assessed and have had some relevance in retrospective studies, the most reliable parameters remain very easy to collect: age and history of vascular events. Patients younger than age 60 and without any previous thrombosis or bleeding related to their MPN are at low risk of developing vascular complications. In contrast, patients with one or both these features are at high vascular risk and will benefit from cytoreductive therapy.

Scores predicting overall survival in PV and ET also are available; however, considering the long survival of these patients, they currently are not used for therapeutic choices.[9,10] In contrast, in PMF, the overall median survival being is 6 years, and the relevant endpoint for prognostication is survival. The International Prognostic Scoring System (IPSS)[11] is used at diagnosis to distinguish four risk categories (low, intermediate 1, intermediate 2, and high risks). This system has been refined further by the development of the dynamic IPSS (DIPSS),[12] which may be used at any time during follow-up periods, and the DIPSS-plus score,[13] which incorporates thrombocytopenia, transfusion requirements, and cytogenetics. The role of *CALR*[14,15] and other mutations (i.e., *EZH2, ASXL1, SRSF2, IDH1/2* mutations), which comprise a high molecular risk category in PMF,[16] has been underscored but has yet to be incorporated in a new prognostic model.

TREATMENT OF POLYCYTHEMIA VERA

PV therapy must address both short- and long-term objectives. In the short term, therapeutic aims are to reduce the risk of occurrence and recurrence of thrombosis, first via reduction of the hematocrit—a simple parameter reflecting blood viscosity. However, although very simple to use and reliable, hematocrit is not the unique suspect, and many other abnormalities play a role in the occurrence of thrombosis in patients with PV. Quantitative but also qualitative abnormalities (with features of aberrant activation) of leukocytes, platelets, and even red cells have been reported to take part in the prothrombotic state of patients with PV (and, more generally, with MPN).[17,18] Finally, general cardiovascular risk factors (e.g., smoking, hypertension, diabetes, dyslipidemia) should not be neglected and require a particularly careful evaluation in patients with PV, because thrombosis is often multifactorial and caused by an accumulation of adverse factors. A strict control of these standard risk factors, therefore, is a major component of successful PV therapy.

Regardless of their risk category, treatment recommendations[1] for all patients with PV include antiplatelet therapy with low-dose aspirin (100 mg/day) and phlebotomy to maintain a hematocrit less than 45%. Patients who are age 60 or older and/or who have a history of thrombosis are high-risk patients and should receive cytoreduction with HU or recombinant IFN-alfa. HU is the preferred option for high-risk patients in many countries where the off-label use of IFN-alfa is not possible (Table 1).

First-Line Therapy

Phlebotomy can be an emergency therapy at diagnosis, in patients who present with very high hematocrit and clinical signs of hyperviscosity, as well as a long-term maintenance therapy to control the hematocrit in low-risk patients.[19] The optimal target of hematocrit levels was a matter of debate, but a recent multicenter, randomized clinical trial (Cyto-PV) showed that a hematocrit maintained strictly at less than 45% during follow-up periods was significantly associated with a lower incidence of thrombosis (p = 0.007).[19] Low-dose aspirin is the second cornerstone of PV therapy, because it has been shown in a large European, double-blind, placebo-controlled, randomized trial (the ECLAP study) to significantly reduce a primary combined endpoint that included cardiovascular death, nonfatal myocardial infarction, nonfatal stroke, and major venous thromboembolism.[6]

In addition to this strategy, a cytoreductive drug should be prescribed in high-risk patients with PV (i.e., age older than 60 and/or with a history of a vascular event). The European LeukemiaNet (ELN) recommendations for the management of PV suggested that HU and IFN-alfa were the cytoreductive treatments of choice as first-line therapy for high-risk patients with PV.[1] HU is a well-known drug with good efficacy and tolerance in the majority of patients. This efficacy is often

KEY POINTS

- Therapy for myeloproliferative neoplasms currently is based on the risk for vascular complications (thrombosis and hemorrhage) and requires a strict control of other well-known cardiovascular risk factors (e.g., smoking, hypertension, diabetes, dyslipidemia).
- Phlebotomy to maintain the hematocrit less than 45% and low-dose aspirin are the cornerstone of therapy for polycythemia vera, although patients older than age 60 or who have a history of thrombosis (i.e., high-risk patients) should receive a cytoreductive agent.
- First-line therapy for high-risk polycythemia vera includes hydroxyurea or interferon alfa, whereas ruxolitinib has been approved recently for patients whose disease is resistant to or who are intolerant to hydroxyurea.
- Patients with essential thrombocythemia may receive low-dose aspirin plus hydroxyurea when they are at high risk. Anagrelide often is preferred as second-line therapy, whereas interferon alfa also may be useful in subgroups of patients.
- Treatment of myelofibrosis is often symptom driven, and ruxolitinib currently is the treatment of choice in patients with intermediate- or high-risk disease who have symptomatic splenomegaly and disabling symptoms.

TABLE 1. Risk-Based Therapy of Polycythemia Vera and Essential Thrombocythemia

Risk-Based Treatment Group	PV	ET
All Patients	Management of cardiovascular risk factors	
Low-Risk Patients	Aspirin	Aspirin
	Phlebotomy	
High-Risk Patients		
First line	HU or IFN-alfa	HU
Second line	Switch IFN-alfa or HU	Anagrelide
	Ruxolitinib	
Other	Busulfan	IFN-alfa

Abbreviations: PV, polycythemia vera; ET, essential thrombocythemia; HU, hydroxyurea; IFN, interferon.

maintained in the long-term period, although skin toxicity and secondary resistance may develop over time and may lead to treatment discontinuation in 10% to 20% of patients.[5] Another issue for patients with PV in the very long-term period is the risk of disease transformation. In the unique randomized trial comparing HU with another cytoreductive drug (pipobroman) in PV, the cumulative incidence of AML and MDS at 10, 15, and 20 years was 6.6%, 16.5%, and 24%, respectively, in the HU arm and 13%, 34%, and 52%, respectively, in the pipobroman arm.[8] Other studies from registry data and from a prospective analysis with a shorter follow-up time failed to attribute a clear leukemogenic risk to HU.[20,21] Overall, there is no definitive evidence for (or against) a leukemogenic risk of HU, but it should be emphasized that this risk may appear after prolonged exposure to this drug. Thus, it seems reasonable to adopt a conservative approach and to consider alternative treatments in young patients and in those previously treated with other myelosuppressive agents.

IFN-alfa has been shown to induce a high rate of hematologic response and to significantly reduce the malignant clone, as shown by the percentage of JAK2 V617F-mutated alleles in independent phase II studies.[22-24] In selected patients, complete hematologic, molecular, and histopathologic remissions were observed, suggesting a possible impact on the natural disease history. IFN-alfa has never been suspected to be leukemogenic, which is another potential property favoring its use in younger patients.[25] The main toxicity and contraindications for IFN-alfa are well known because of the wide use of this drug in patients with viral hepatitis. Overall, approximately 20% to 30% of patients have to discontinue therapy with pegylated forms of IFN-alfa for toxicity reasons.[26] However, this drug (in any of its various presentations) is not approved for the treatment of PV. Two important ongoing, prospective, randomized clinical trials comparing pegylated forms of IFN-alfa with HU in high-risk patients with PV should provide the critical information needed to determine the exact role of IFN-alfa in this setting (NCT01259856 and NCT01949805).

Patients with PV may experience a broad-ranging symptom burden that includes fatigue, pruritus, and painful splenomegaly.[27] The combined symptom burden experienced by some patients with PV is associated with reductions in quality of life (QoL). Among these symptoms, aquagenic pruritus may be a disabling symptom in some patients with PV; JAK inhibitors and IFN-alfa are the best options to treat this symptom. Other nonspecific choices that may be helpful include antihistamines, selective serotonin-reuptake inhibitors, and PUVA (psolarens plus ultraviolet A) therapy.[28,29]

Second-Line Therapy

The choice of second-line myelosuppressive drugs for PV should be evaluated carefully, because some drugs administered after HU may enhance the risk of AML.[30] Therefore, one may switch drugs between HU or IFN-alfa when used as first line (Table 1).

Very recently, the JAK1/JAK2 inhibitor ruxolitinib was evaluated in patients with PV who were intolerant of or resistant to HU in a phase III, randomized trial versus the best available therapy (NCT01243944).[5] The primary endpoint was a composite of hematocrit control and a 35% or greater reduction in spleen volume at week 32. This endpoint significantly favored ruxolitinib, having been met by 21% of patients in the ruxolitinib arm versus 1% in the standard therapy arm (p < 0.0001). In addition, a greater proportion of patients receiving ruxolitinib achieved complete hematologic remission and experienced a significantly better improvement of PV-related symptoms. Overall, ruxolitinib was tolerated by most patients; 85% of patients randomly assigned to ruxolitinib remained on treatment after a median follow-up time of 81 weeks. The most frequent grade 3 or 4 adverse events reported by patients receiving ruxolitinib were thrombocytopenia (5.5%), dyspnea (2.7%), anemia (1.8%), and asthenia (1.8%). Other adverse events of interest included herpes zoster infection, which was observed in 6.4% of patients in the ruxolitinib arm (all grade 1 or 2), and non-melanoma skin cancer, which occurred in four (3.6%) patients. Based on the results of this study, ruxolitinib was recently approved by the U.S. Food and Drug Administration (FDA) for the treatment of patients with PV who have had an inadequate response to or are intolerant of HU, and it is a clear new option for second-line therapy in these patients.

In selected patients, alkylating agents like busulfan may still be useful when other drugs have failed or are contraindicated, although they may increase the leukemogenic risk.[1]

TREATMENT OF ESSENTIAL THROMBOCYTHEMIA

In contrast with PV, the potential benefit of aspirin therapy has never been assessed in a randomized, controlled trial in ET. In addition, there is a concern that bleeding is a particular risk for patients with ET who have extreme thrombocytosis (greater than $1,500 \times 10^9$/L) because of acquired von Willebrand disease.[31] Considering these uncertainties, low-dose aspirin remains recommended for high-risk patients with ET who do not have a clear contraindication to this drug.[1] For patients with low-risk ET, a retrospective analysis suggested that only patients with the JAK 2V617F mutation or those who have cardiovascular risk factors might benefit from antiplatelet therapy.[32] However, on the basis of currently available data, it seems reasonable to use low-dose aspirin for low-risk patients with ET, because thrombosis remains the major clinical hazard. This indication is clearly evident in patients who experience microvascular disturbances.[1] Conversely, the presence of extreme thrombocytosis (greater than $1,500 \times 10^9$/L) temporarily contraindicates the use of antiplatelet agents, a therapy that can be started after reduction of the platelet count with cytoreductive drugs.

Regarding the choice of the first-line cytoreductive therapy for high-risk patients with ET (Table 1), recommendations can be based on three randomized trials.[33-35] HU significantly reduced the rate of thrombosis in high-risk patients with ET versus no myelosuppressive therapy,[33] showing that these patients should receive a cytoreductive drug and not only antiplatelet agents. The use of anagrelide versus HU has been evaluated in two studies: the PT-1 study and the noninferiority ANAHYDRET study. Anagrelide was equivalent to HU

in reducing platelet counts in both studies. In the PT-1 study, an excess of arterial thrombosis was observed in the anagrelide arm compared with HU.[34] However, in the ANAHYDRET study that included patients with ET who were strictly diagnosed using World Health Organization criteria (including a bone marrow biopsy in all patients to rule out early phases of myelofibrosis), study equivalence was reported.[35] Based on these results, HU and low-dose aspirin combined is often the recommended first-line therapy for high-risk patients with ET,[1] but anagrelide also may be appropriate in specific subgroups of patients. Of note, in the absence of ischemic symptoms or vascular complication, platelet reduction should be progressive over a few weeks with increasing doses of cytoreductive drugs to avoid the occurence of thrombocytopenia or leukopenia.

The role of IFN-alfa therapy in ET needs to be clarified, although many small, phase II studies have shown that this drug also was very efficient to control thrombocytosis.[26] In addition, it has been shown that IFN-alfa was able to induce molecular responses by reducing the mutant allele burden in patients harboring mutations in JAK2[23] or in *CALR*[36] genes. Whenever possible, patients with ET should be enrolled in randomized studies evaluating HU compared with IFN, like the ongoing MPD-RC 112 study (NCT01259856). Anagrelide may be used as second-line therapy for patients who are resistant to or intolerant of HU. IFN-alfa and busulfan also are possible options in this setting. The use of cytotoxic agents, in the youngest patients or, especially, in combination should be avoided when possible, and IFN-alfa or anagrelide could be the best options in these situations.

TREATMENT OF MYELOFIBROSIS

Because there is no curative therapy other than ASCT for myelofibrosis, treatment basically is palliative and usually is guided by the principal disease manifestation.

Anemia

Of note, no drug has approval for this particular indication. A hemoglobin of less than 10 g/dL, which is an adverse prognostic factor, usually prompts consideration of treatment, although this threshold obviously is subject to adaptations depending on age and comorbidities. One option is the use of erythropoiesis-stimulating agents, which have been reported to improve anemia in 25% to 50% of patients.[37,38] Patients who have low endogenous erythropoietin levels (less than 125 mU/mL) may be the best candidates for this therapy, whereas patients who have major splenomegaly or transfusion dependence are unlikely to experience clinically relevant improvement. Androgens also have reportedly improved anemia in a similar proportion of patients. In this class of drugs, danazol is the treatment of choice, inducing similar results with less toxicity at the recommended dose of 400 mg to 600 mg daily maintained for at least 6 months, then progressively reduced to the minimum necessary for maintenance. Immunomodulating agents also may be useful in managing MF-related anemia. Low-dose thalidomide or low-dose

lenalidomide, combined for the induction treatment with prednisone, provide a 20% to 30% response.[39,40] Of note, lenalidomide as a single agent is the treatment of choice for patients with MF who have a 5q deletion.[41] Corticosteroids alone sometimes may be helpful and provide a modest benefit for patients resistant to the above-mentioned therapies, especially if a hemolytic part can be demonstrated. Last, splenectomy can be useful in patients who have transfusion-dependent anemia that is refractory to any therapy,[42] but it needs careful evaluation because of the risks of complication.

Splenomegaly and Other Sites of Extramedullary Hematopoiesis

Usually, treatment of splenomegaly is not necessary per se, at least until the onset of associated symptoms. HU used to be the first-line therapy for symptomatic splenomegaly, and approximately 40% of patients experienced a reduction in spleen size.[43] However, HU efficacy is usually modest (spleen size diminishing only of a few centimeters) and not durable; published experience suggests that the majority of patients need an alternative treatment after a median time of 12 months. HU currently is clearly superseded by JAK inhibitors in this indication. Splenectomy is sometimes required in patients who have large and painful splenomegaly that is refractory to medical therapy.[42] Splenectomy requires an experienced surgical team and critical care support to minimize the risks associated with the procedure, because mortality and morbidity rates of 5% to 10% and 25%, respectively, have been reported in a large, single-center experience.[42] Splenic irradiation is another alternative treatment of refractory and symptomatic splenomegaly.[44] However, this treatment should be used with caution (fractionated, low dose) because of a high risk of severe cytopenias. In addition, the benefit is only transient. In contrast, low-dose radiation is the therapy of choice for symptomatic extramedullary hematopoiesis in sites other than the spleen and liver (e.g., skin, central nervous system).[45]

The Role of JAK Inhibitors

This new class of drugs clearly has changed our management of MF for a significant proportion of patients and has provided unanticipated benefits. These drugs were designed to target the dysregulated JAK-STAT signaling pathway, a typical feature of patients with MPN independent of the presence of the JAK2 V617F mutation. Better knowledge of the complexity of the mutational landscape of MPNs clearly demonstrates now that the story of these drugs will not be similar to that of tyrosine kinase inhibitors in chronic myeloid leukemia. In addition, currently available JAK2 inhibitors are not selective for the mutant form and, thus, inhibit wild-type JAK2 signaling as well (explaining the on-target hematologic toxicity usually observed with these agents). To date, only ruxolitinib, the first-in-class oral JAK1/JAK2 inhibitor, has been approved for MF treatment. Two independent, phase III studies have shown significant efficacy of ruxolitinib to reduce splenomegaly and improve symptoms compared with placebo (COMFORT-1 study)[4] or the best available therapy (COMFORT-2 study).[3] These benefits usually occur within a few days after ruxolitinib initiation and are durable

throughout therapy, but they are strictly drug and dose dependent; a reduction in the dose will rapidly result in a slight re-increase in spleen size, whereas discontinuation of the drug will lead to a return of signs and symptoms to their baseline levels within a week. Of note, sudden ruxolitinib withdrawal has been reported to potentially induce severe complications, like shock-like syndrome, because of the re-emergence of the suppressed inflammatory cytokines.[46] Although such dramatic adverse events have not been observed in the two COMFORT phase III studies, abrupt interruption should be avoided, and withdrawal of the drug should be tapered. Thrombocytopenia is a frequent adverse event observed with ruxolitinib (contraindicated in patients who have platelet counts less than 50×10^9/L), and it requires dose adaptation but very rarely drug discontinuation. New onset or worsening of anemia also can be anticipated when ruxolitinib therapy starts, especially during the first 3 to 6 months of therapy. This drug also is associated with an increased risk of infection, which requires patient counseling and sometimes prophylactic measures (as reviewed by Heine et al[47]).

A survival advantage for patients treated with ruxolitinib was first shown from an historic comparison with matched MF populations.[48,49] Extended follow-up evaluation of the phase III studies indicated a survival advantage for patients who received ruxolitinib.[50] However, there is still little evidence of a disease-modifying effect, although case reports suggest that reduction in JAK2 mutant allele burden and bone marrow fibrosis can be achieved with the long-term use of ruxolitinib in selected patients.[51]

Other JAK inhibitors currently are being evaluated in clinical studies, but several clinical development programs have been terminated because of emergent toxicity, in particular neurologic toxicity, with some of these drugs.[52] Among JAK inhibitors currently being tested in phase III studies, pacritinib may have the peculiarity of a lack of toxicity on the megakaryocytic lineage that allows its use in patients with thrombocytopenia.[53] Momelotinib, despite its potent anti-JAK2 activity, may have a positive impact on the anemia of transfusion-dependent patients.[54] However, these potentially useful properties for subgroups of patients with MF who have these two unmet needs have to be confirmed in the ongoing phase III studies.

The Role of Stem-Cell Transplantation for Myelofibrosis in the Era of JAK Inhibitors

The role of ASCT has decreased dramatically in chronic myeloid leukemia since the advent of tyrosine kinase inhibitors, but the situation is not yet comparable in classical MPNs. ASCT currently remains the only curative treatment approach for myelofibrosis, which results in resolution of bone marrow fibrosis, molecular remission, and restoration of nonmalignant hematopoiesis.[55,56] Overall, in recent series, approximately 40% to 70% of patients may have been cured with ASCT,[55,56] but transplant-related mortality is not negligible and justifies careful patient selection. Of note, patients with chronic-phase PV or ET are not eligible for ASCT, a situation that changes when their disease progresses into MF or

secondary AML.[57] The best candidates for ASCT are high-risk patients with MF (intermediate 2 and high-risk categories according to IPSS), the limit of age being discussed according to conditioning intensity.[1] The use of ruxolitinib before transplantation with the objective of spleen size reduction in patients who have massive splenomegaly (to avoid pretransplantation splenectomy) and to improve general performance status is evaluated in prospective studies and should, therefore, be considered presently as experimental. In patients with massive splenomegaly, pre-transplant splenectomy should be discussed to improve engraftment and transplant outcome.[55–57]

MPN THERAPY DURING PREGNANCY

The treatment of patients with MPN during pregnancy is a nonexceptional challenge in clinical practice, in particular considering that there is a peak incidence of ET in young women. Pregnancy in MPN clearly is possible in the majority of patients, and the disease, per se, is not a contraindication. However, loyal information about the risks of complications should be provided, and the project of pregnancy should be prepared in close collaboration among the patients, the hemato-oncologist, and a specialized obstetrical team used to manage high-risk pregnancies. Available data about pregnancies in ET and PV mainly are retrospective and, therefore, possibly biased; randomized or controlled studies do not exist in such patients. During pregnancy, similar types of complications have been observed in both ET and PV (with different incidences), and the overall success rate of pregnancy was approximately 60% to 70%. None of the drugs useful to treat MPNs has a license for use during pregnancy. However some recommendations have been produced.[58] Patients should be screened for thrombophilia, an additional risk factor for complication that may change the management (with the use of heparin). HU and anagrelide should be stopped before conception, with a washout period of several weeks whenever possible. Low-dose aspirin should be continued (or started) and maintained throughout the pregnancy, relayed by low-molecular-weight heparin (easier to manage in case of bleeding complications) a couple of weeks before delivery. In patients with PV, phlebotomy can usually help control the hematocrit if needed. In patients with ET, if cytoreduction is necessary, IFN-alfa can be proposed.[25] Close fetal monitoring (including echography and Doppler) should be planned, especially during the last trimester, which is a period of high risk for placental vascular complications. Blood counts of the mother in the postpartum period should be monitored carefully, because a rebound in platelet counts can be observed within few days after delivery, which is a period of high risk for thrombosis that should be prevented by the use of a low-molecular-weight heparin for up to 6 weeks after delivery.[58]

THE FUTURE OF MPN THERAPY

One possible avenue for MPN therapy is the development of personalized medicine. Indeed, among cancers, MPNs could be

ideal candidates for such strategy. There is evidence to show that the mutational profile found in hematopoietic cells has an influence on treatment efficacy. For example in ET, patients with or without a JAK2 mutation display different responses to HU, and the control of the platelet count requires lower doses of HU in patients who are positive for JAK2 V617F.[59] In addition, a reduced prevalence of arterial thrombosis was observed in patients with a JAK2 V617F–positive status who were receiving HU compared with anagrelide, whereas no difference was found in patients with a JAK2 V617F–negative status for the same endpoint. In PV, IFN-alfa had a differential impact on malignant clones according to the presence of JAK2 or TET2 mutations; the JAK2-mutated clones were much more sensitive to IFN-alfa than the clones with the TET2 mutation.[60] These findings suggest that the mutational profile could provide important information not only in terms of prognosis but also for the choice of therapy. This could be particularly important in patients with MF, because they have a poorer life expectancy and often-complex mutational profiles. To validate such a personalized approach, there is a need for prospective studies in cohorts of patients fully characterized for mutations that may change the response to therapies. This characterization could be available soon in a number of centers with the rapid development and wider availability of next-generation sequencing techniques.

In terms of new therapies, two classes of drugs currently are being evaluated in early-phase studies and may play a role in MPN management in the future. First, histone deacetylase inhibitors have shown some efficacy, like panobinostat in PMF[61] or givinostat in PV.[62] The most promising results with these drugs may result from a combination with JAK inhibitors by targeting parallel signaling pathways involved in disease development. A telomerase inhibitor, imetelstat, also has had efficacy in ET and PMF and currently is being evaluated for efficacy and safety.[63]

Myelodysplastic Syndromes and Myelodysplastic/Myeloproliferative Neoplasms: An Update on Risk Stratification, Molecular Genetics, and Therapeutic Approaches Including Allogeneic Hematopoietic Stem Cell Transplantation

Olatoyosi Odenike, MD, Francesco Onida, MD, and Eric Padron, MD

OVERVIEW

Myelodysplastic syndromes are a heterogeneous group of clonal hematopoietic stem cell disorders characterized by ineffective hematopoiesis, peripheral cytopenias, and a variable propensity for leukemic transformation. In recent years there has been an explosion of information on the molecular genetic changes underlying these disorders. This information has substantial prognostic implications, and the influence on therapeutic approaches and the treatment of patients is evolving. Allogeneic hematopoietic stem cell transplantation (alloSCT) is the only known cure for these diseases, but appropriate patient selection is of utmost importance from a risk-benefit perspective. This review focuses on the factors influencing risk stratification in MDS and optimal choice of front-line therapy in the current era, including the interplay of clinical factors and molecular genetic factors, and factors that determine eligibility for alloSCT. The myelodysplastic/myeloproliferative diseases also will be discussed, including the increasing effort to understand the molecular genetics and natural history of these disorders and treatment approaches.

The myelodysplastic syndromes are a clinically and molecularly heterogeneous group of clonal stem cell disorders with management options ranging from observation and growth-factor therapy to more intensive approaches, such as hypomethylating agent (HMA)–based therapies, intensive induction chemotherapy, and alloSCT.[1] During the last decade, rapid developments centered around high-throughput molecular technologies have resulted in remarkable advancement toward the understanding of MDS pathogenesis.[2-6] These technologies are anticipated to translate to innovative targeted agents that will radically affect the natural history of this disease. Presently, however, alloSCT remains the only curative treatment option in patients with MDS.[2,7-9] Even if substantially reduced during the last 20 years, mortality and morbidity risks associated with alloSCT continue to represent a major limit to the feasibility of such a therapeutic strategy in the large number of patients.[8,10,11] Therefore, the accurate selection of patients—together with optimal timing of transplantation—represent critical issues for maximum improvement of the alloSCT risk-benefit ratio in MDS.

As such, important advancements have been made toward the dissection of MDS clinical heterogeneity that have incorporated both clinical and molecular characteristics. In this review, we will discuss recent refinements to prognosis for patients with MDS based on clinical, cytogenetic, and molecular risk factors. We also will discuss the approach to the selection of front-line therapy in MDS, including a particular focus on alloSCT. Lastly, we will highlight myelodysplastic/myeloproliferative neoplasms (MDS/MPNs), including recent insights into the molecular genetics and emerging therapeutic approaches in patients with these diseases.

PROGNOSTIC STRATIFICATION IN MYELODYSPLASTIC SYNDROMES

MDS is a disease found in older adults, with a median age at diagnosis of age 71. The estimated 3-year survival rate of patients with MDS is 45%,[12] although there is substantial variability in outcomes even within the same French-American-British (FAB)[13] classification system and the more recent World Health Organization (WHO) morphologic subtypes.[14] This heterogeneity in outcomes underscores the need for accurate prognostication and has fuelled the evolution of various prognostic scoring models.

Prognostic Classification Models

The international prognostic scoring system (IPSS), a widely validated system currently in use, originally was created from data from 816 patients. The IPSS encompasses karyotype, blast percentage, and the number of cytopenias, thus stratifying patients with de novo MDS into four risk categories. These include lower risk MDS comprising low and intermediate-1 risk categories, and higher risk MDS comprising intermediate-2 and high-risk categories; with median survivals ranging from 5.7 to 0.4 years.[15]

Limitations associated with the IPSS include the lack of consideration of the severity of cytopenias, and transfusion dependency; underweighting of the prognostic import of karyotype relative to marrow blast–percent; and the fact that this model is applicable only at diagnosis. Several of these limitations were addressed by the development of other models, including the WPSS,[16] which incorporates transfusion dependency and WHO subtype, among other factors. It is a dynamic model that can be applied at diagnosis and follow-up. The University of Texas MD Anderson Cancer Center (MDACC) prognostic model includes a broader population of patients, such as patients with therapy-related MDS and patients with chronic myelomonocytic leukemia (CMML).[17] An additional prognostic model focused on lower-risk disease (LR-PSS) has been developed at MDACC.[18]

The revised IPSS (IPSS-R),[19] which was created from an evaluation of more than 7,000 patients, incorporates a comprehensive 5-tiered cytogenetic risk stratification system that comprises 15 cytogenetic subtypes (Table 1).[20] It also accounts for the degree of cytopenias and provides a more discriminant assessment of bone marrow– blast percentage. The predictive value of cytogenetics in MDS has long been recognized, and the comprehensive cytogenetic strata included in the IPSS-R assure that chromosomal aberrations of prognostic importance are accorded appropriate weight in the model relative to bone marrow blast–percent. Five risk groups are

identified—very low, low, intermediate, high, and very-high with median survival ranging from 8.8 to 0.8 years.

Similar to the IPSS, the IPSS-R was generated on data from patients evaluated at diagnosis and censored at the time of receipt of disease-modifying therapy. Despite these issues, the IPSS-R has been rapidly validated by several groups to be more discriminant than the IPSS and the WPSS,[21] and to retain its predictive value even in patients treated with disease-modifying agents.[22,23] Therefore, in just a few short years since its introduction, IPSS-R is rapidly being adopted as the preferred clinical prognostic tool for risk stratification in MDS.

The Evolving Role of Molecular Genetics on Risk Prediction

A comprehensive evaluation of the prognostic relevance of point mutations in refining risk stratification in MDS was first established in a study of 439 patients with MDS.[24] Using next-generation DNA sequencing and mass spectrometry genotyping to evaluate 111 genes, mutations in five genes (*TP53, EZH2, ETV6, RUNX1,* and *ASXL1*), which collectively occurred in approximately one-third of patients, were found to confer poor risk prognosis, independent of established clinical risk factors such as IPSS. Within each IPSS subgroup, the presence of one or more of these mutations was demonstrated to result in a decline in overall survival, which approximated that of the next-highest IPSS risk group.[24]

The same group has since validated the prognostic effect of these mutations (*EZH2, RUNX1, TP53,* and *ASXL1*) in patients with lower-risk MDS. The presence of these mutations was found to be associated with a shorter overall survival independent of the LR-PSS.[25] In a multivariate analysis that included LR-PSS and other mutations, only *EZH2* mutations retained independent prognostic significance. The clinical implication of upstaging for the risk group is recognition that patients in lower-risk IPSS categories have a worse prognosis, which may result in consideration of more intensive treatment approaches for such patients.[24,26]

It is now evident that more than 40 genes are mutated in MDS.[4,27-29] Approximately 90% of patients with MDS harbor at least one mutation, with a median of two or three mutations detected per patient (range, 1 to 12). Mutations could be categorized into subgroups that affect specific functional pathways (Fig. 1), including the spliceosome machinery (*SF3B1, SRSF2, U2AF1, U2AF2, ZRSR2*); DNA methylation (*TET2, DNMT3A, IDH1, IDH2*); chromatin modification (*ASXL1, EZH2*); RAS and other kinase signaling pathways (*NRAS, KRAS, CBL, JAK2*); transcription factor (*TP53, RUNX1, EV1, GATA2*); cohesin; and DNA repair pathways. Of these, mutations affecting RNA splicing and epigenetic dysregulation (DNA methylation and chromatin modification) were commonly observed, underscoring the critical importance of these pathways in MDS pathogenesis. In particular, more than 50% of patients had a mutation in a component of the spliceosome machinery, identifying prem-RNA splicing as the most frequently altered biologic pathway in these diseases.

TABLE 1. MDS Cytogenetic Risk Stratification System

Risk Group	Frequency (%)	Karyotypic Abnormalities	Median Survival (y)	Time until 25% of Patients Developed AML (y)
Very good	4%	-Y, del(11q)	5.4	NR
Good	72%	Normal, del(5q), del(12p), del(20q), double including del(5q)	4.8	9.4
Intermediate	13%	Del(7q), +8, +19, i(17q), any other single or double independent clones	2.7	2.5
Poor	4%	-7, inv (3)/t(3q), double including -7/del(7q), complex with 3 abnormalities	1.5	1.7
Very poor	7%	Complex (> 3 abnormalities)	0.7	0.7

Abbreviations: MDS, myelodysplastic syndromes; y, years; AML, acute myeloid leukemia; NR, not reported.

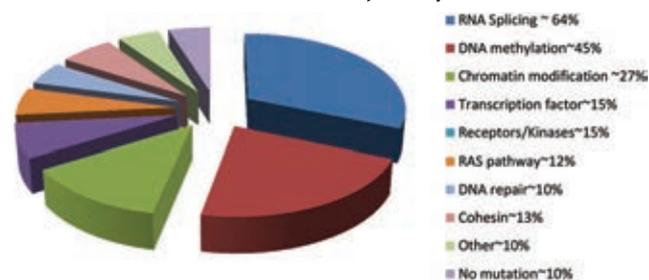
These studies also provided several additional insights into the role of the molecular genetic profile in determining clinical and phenotypic heterogeneity associated with the disease. For example, the high frequency (75%) of *SF3B1* mutations in MDS subtypes associated with ring sideroblasts was confirmed, implying that this mutation is a significant predictor for the presence of ringed sideroblasts in the marrow. Only mutations in *SF3B1* were associated with a better clinical outcome. In contrast, the average number of mutations was higher per patient in the higher-risk WHO morphologic categories (i.e., refractory anemia with excess blasts (RAEB1 and RAEB-2), which is consistent with a higher degree of clonal evolution in these subtypes). Leukemia-free survival in patients with MDS was found to negatively correlate with the combined number of oncogenic and cytogenetic lesions. The number ranged from 49 months in patients with one lesion to 4 months in patients with six or more mutations. Furthermore, the number of oncogenic mutations provided independent prognostic information after stratification by the IPSS.[4]

Insights into clonal evolution and clonal architecture of MDS also have been obtained from studies[4,30] with mutations in genes involved in RNA splicing or epigenetic regulation with a higher variant allele fraction, which suggests that these mutations occurred earlier during clonal evolution. Both clonal and subclonal events within the same genes, however, retained similar prognostic significance. This suggests that the finding of a mutation in a minor subclone is clinically relevant, thus emphasizing the potential utility of a targeted deep-sequencing approach that is sensitive enough to detect minor subclonal events.

Mutations within the same functional pathways often were mutually exclusive (e.g., *TET2* and *IDH1/2* mutations, which both affect DNA hydroxymethylation). Similarly, mutations involving the spliceosome machinery rarely co-occur. Biologically relevant interactions also were found in patterns of co-occurrence. For example, *SF3B1,* which is associated with good prognosis, was mutually exclusive with *ASXL1* and *IDH2,* which both confer a poor prognosis. However, *SRSF2* showed a clear propensity to associate with *TET2* and its co-mutation is highly associated with monocytosis.[4,27,31] It is plausible that such biologic insights also will be of clinical value in the design and use of targeted therapies.

These molecular profiling efforts successfully demonstrate that the integration of clinical, morphologic, and cytogenetic information already encompassed by the IPSS and IPSS-R, along with the comprehensive molecular genetic profile now available via targeted deep sequencing techniques, has the potential to substantially refine risk stratification in MDS.[27] In the 21st century, it is highly anticipated that such combined risk models—once validated prospectively—will enter into common clinical use to refine prognosis and potentially determine treatment approaches for patients with MDS.

FIGURE 1. The Mutational Complexity of MDS

- RNA Splicing ~ 64%
- DNA methylation~45%
- Chromatin modification ~27%
- Transcription factor~15%
- Receptors/Kinases~15%
- RAS pathway~12%
- DNA repair~10%
- Cohesin~13%
- Other~10%
- No mutation~10%


This chart illustrates the mutational complexity of MDS, with mutations organized into functional pathways affecting RNA splicing (includes: *SF3B1, SRSF2, ZRSR2, U2AF1/2*); DNA methylation (includes *TET2, DNMT3A, IDH1/2*); chromatin modification (includes *ASXL1, EZH2*); transcription factor (includes *RUNX1, TP53, BCOR, PHF6, NCOR, CEBA, GATA2*); receptors/kinases (*JAK2, MPL, FLT3, GNAS, KIT*); RAS pathway (*KRAS, NRAS, CBL, NF1, PTPN11*); DNA repair (*ATM, BRCC3, DLRE1C, FANCL*); and cohesins (*STAG2, CTCF, SMC1A, RAD21*). In approximately 10%, no mutation could be identified. Overlapping mutations (co-occurrence of two or more mutations in patients with MDS) are not depicted on this chart, thus percentages add up to more than 100%. Chart is created from data derived largely from targeted deep sequencing of 104 genes in a cohort of 944 patients with MDS, published by Haferlach et al.[27]

FRONT-LINE THERAPY IN MYELODYSPLASTIC SYNDROMES

The concept of individualized therapy is particularly relevant in the selection of optimal therapeutic strategies in this disease, and it should incorporate a consideration of both patient- and disease-specific elements. Higher-risk patients generally are offered more intensive therapeutic options, including HMA therapy and an early consideration of stem cell transplantation, which is discussed in substantial detail below. Lower-risk patients are offered therapies that range from observation (in patients who are asymptomatic with relatively well-preserved blood counts), to growth factors

such as erythropoietin (in patients with anemia), to immunosuppressive therapy (in patients with multiple cytopenias). Therefore, elements that factor into risk stratification are of critical therapeutic importance. Contemporary approaches to risk refinement, including the use of more discriminant prognostic models, such as the IPSS-R, are highly encouraged. Data are evolving to support the potential utility and applicability of models that combine comprehensive targeted molecular profiling with clinical models, such as the IPSS-R, in making treatment decisions, and they deserve prospective validation.

Supportive Care/Growth Factor Therapy

Lower-risk patients with anemia may benefit from erythropoietin (EPO) therapy. Predictors of response include lower serum EPO level (< 500 U/L) and a lower transfusion requirement (< 2 units of red cells per month). Response rates in such patients may be as high as 60%; however, it is substantially lower (less than 10%), in the absence of the above criteria.[32] Since most responses to EPO will occur within 8 weeks, a time limited trial of 8 weeks is reasonable when EPO is being used for treatment of MDS.

Immunosuppressive Therapy

Immunosuppressive therapy (IST) with antithymocyte globulin (ATG)-based therapies[33] are reasonable to consider in lower-risk patients with MDS who have multiple cytopenias, who are younger (< age 55), and who are positive for the HLA DR15 allele. These latter factors were positive predictors of response to IST.[34] A hypocellular marrow, which suggests a disease more closely aligned with aplastic anemia, also has been found in some studies to be predictive of response, but it has not been confirmed in others.[35,36] Since activated T cells are the target of IST, a predictive model that consists of a T-cell activating signature and duration of disease also has been proposed.[37]

Lenalidomide

In patients with deletion 5q (del[5q]) and lower-risk disease who require red cell transfusions, the use of lenalidomide is associated with a transfusion independence rate in the 70% range, with a median duration of response of 2.2 years.[38] In lower-risk patients with MDS without the del(5q), the response rate is in the 25% range and response duration is substantially shorter.[39] High karyotypic complexity, lower platelet count, and TP53 mutations tend to be associated with lenalidomide resistance, even in the presence of del(5q).[40] Lenalidomide currently is being investigated in combination with erythropoietin in a phase III trial in lower-risk patients with MDS. In this trial, it is hypothesized that the combination of lenalidomide and EPO will potentiate erythroid response in patients who have failed to respond to EPO or in whom EPO is predicted to have a low probability of being effective. The trial is based at least in part on promising results from an early phase trial that investigated the combination.[41] Recently, a novel mechanism of action involving lenalidomide-induced degradation via cereblon— of casein

kinase 1, alpha-1 (CSNK1A1), located on 5q32, and which results in further reduction of haploinsufficient expression of CSNK1A1—has been implicated in the sensitivity of del(5q) MDS to lenalidomide.[42]

Hypomethylating Agents

The U.S. Food and Drug Administration (FDA) has approved hypomethylating agents (HMAs) 5-azacytidine (azacitidine) and 5-aza-2′deoxycitidine (decitabine) for treatment of patients with MDS. These compounds become incorporated into DNA—although azacitidine also gets incorporated into RNA—and form a covalent complex with the DNA methyltransferase (DNMT) enzyme, which results in trapping and degradation of the enzyme and progressive loss of DNMT activity within the cells and subsequent DNA hypomethylation. When administered at very high doses, the cytotoxic effects of the agents predominate. However, lower doses in the range used for treating patients with MDS are postulated to allow the hypomethylating effect and, thus, epigenetic modulation to occur.[43]

Both agents have been investigated in randomized trials of patients with MDS. They are associated with similar objective response rates of complete response and partial response in the 15% range, although an additional 15% to 30% of patients will experience hematologic improvement, manifested primarily as an improvement in cytopenias and transfusion requirements.[44-46] Improvements in quality of life also have been demonstrated.

In addition, azacitidine has been associated with an overall survival advantage in patients with higher-risk MDS, when compared to prespecified conventional care regimens (including supportive care, low-dose cytarabine, and acute myeloid leukemia (AML) type–induction therapy), with median survival of 24.5 months in the azacitidine arm compared with 15 months in the control arm.[44] A population-based study also confirmed this 24-month survival benefit with azacitidine use outside of a clinical trial setting.[47]

Although the benefit associated with the use of HMAs in patients with MDS is indisputable, many patients will not benefit from them. Furthermore, for those who respond, the response is not immediate. The median time to best response is in the range of 3 to 4 months. Therefore, biomarkers that predict response to therapy would be of substantial value. Our increasing knowledge of the molecular genetic landscape of MDS—including the fact that mutations affecting enzymes that are involved in DNA methylation are involved in MDS pathogenesis— has spurred additional efforts in recent years to find predictive biomarkers to HMA therapy. As such, TET2 mutations or DNMT3A mutations were associated with a modest increase in response rates to HMA therapy in earlier reports with conventional Sanger sequencing.[48,49] A more recent report used a more comprehensive molecular profiling approach. It evaluated 40 recurrently mutated genes in 213 patients with MDS treated with HMAs and confirmed clonal TET2 mutations as predictive of response (odds ratio, 1.99).[50] In contrast, TP53 and PTPN11 mutations were associated with shorter overall survival after

HMA treatment, but they did not predict response. These findings require validation in prospective clinical trials. Presently, insufficient evidence exists to suggest that the decision to treat patients with HMAs can be made on the basis of mutational profiling alone, especially since responses to HMAs were observed even in patients with mutations that confer a very poor prognosis.[50]

Combination Therapies

There remains an urgent need for the development of new drug therapies and combinations to treat patients with MDS. An early focus was the combination of HMAs with histone deacetylase inhibitors (HDACi).[51-55] This was based on the hypothesis that inhibiting two pathways of epigenetic deregulation would be potentially synergistic, and abundant preclinical evidence of synergy. Early phase trials investigating the combination of azacitidine with the HDACi entinostat or vorinostat,[52,56] or the immunomodulatory agent lenalidomide,[57] yielded promising results, which has led to randomized trials conducted in the intergroup setting.

The results of randomized trials conducted in the U.S. intergroup setting (E1905) comparing azacitidine versus azacitidine plus entinostat,[58] and preliminary results of the recently concluded three-arm randomized phase II North American intergroup trial (S1117) comparing single-agent azacitidine to azacitidine plus vorinostat and azacitidine plus lenalidomide combinations,[59] respectively, however, have shown no significant advantage to the combination arms as to improvement in response rates. Therefore, azacitidine remains the standard of care. Survival endpoints, either progression-free or overall survival, may be more relevant primary endpoints of future large randomized efforts that compare single-agent HMA therapy to novel combinations and approaches.

ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

Individual decision making on whether to consider alloSCT as a possible treatment option in treating patients with MDS requires the accurate assembling of several disease- and patient-characteristics.

Disease Characteristics

In general, MDS includes an extremely heterogeneous group of myeloid malignancies with different natural courses and life expectations. Therefore, a risk-based approach for individual decision making on treatment strategy is highly suggested, and it is mandatory when referring patients for alloSCT.[8,10,60] Together with the nosological classification methods (such as the FAB and, more recently, the WHO classification schemes), prognostic scoring systems in MDS have been considered the most appropriate tools for treatment stratification. For almost 15 years, the IPSS[15] has been universally recognized as the landmark reference method for risk-stratification with patients classified in high-risk catego-

ries (including intermediate-2 and high-risk groups) as generally being considered for early alloSCT. However, a different treatment plan usually is recommended for patients in the lower IPSS risk categories (i.e., low and intermediate-1). In a foremost decision-analysis study that included patients younger than age 60, delayed transplantation was shown to associate with maximal life expectancy, with an even more marked survival advantage for patients under age 40.[61] In 2007, a time-dependent WHO classification-based prognostic scoring (WPSS) incorporating transfusion dependence was proposed for untreated patients.[16] Different from IPSS, the WPSS identifies five risk groups of patients with different survival, and it allows for real-time assessment of prognosis in MDS. Its relevance after alloSCT was validated in a subsequent study from the GITMO group that included 406 patients,[62] in which a multivariate Cox survival analysis also included age and sex of patient, time between diagnosis and alloSCT, year of transplantation, disease stage at transplantation, source of stem cells, type of donor, and type of conditioning, WPSS showed a prognostic significance on both overall survival and probability of relapse. The validity of WPSS in predicting outcomes after alloSCT in patients with MDS recently was confirmed in a population of 60 Southeast Asian patients.[63]

Cytogenetics appears to be the most critical factor in determining survival in patients with MDS. However, the cytogenetic categories included in all of the proposed prognostic scoring systems were derived from large series of patients who were only treated with supportive care. Because alloSCT represents a treatment strategy that is potentially capable of eradicating the hematopoietic malignant cell clone, it could be postulated that the prognostic significance of cytogenetics would persist using this treatment approach. However, the negative effect of poor-risk cytogenetics on the outcomes of patients with MDS undergoing alloSCT has been confirmed.[64-69] For example, a recent retrospective analysis from the European Society for Blood and Marrow Transplantation (EBMT) demonstrated that poor-risk cytogenetics, as defined by standard IPSS scores, were associated with a relatively poor survival after alloSCT from HLA-identical siblings, except in patients with low marrow blast count (i.e., RA/RARS) who were transplanted up front.[69]

In 2012, the revised IPSS (IPSS-R) for MDS was generated by analyzing 7,012 patients in a new international collaborative effort. Based on a new comprehensive cytogenetic score,[20] and considering severity of cytopenias by incorporating different cutoff points, the IPSS-R stratifies five risk groups with different clinical outcomes.[19]

The ability of the new cytogenetic risk classification to predict post-transplant outcome was promptly confirmed in a series of 1,007 patients who underwent alloSCT at the Fred Hutchinson Cancer Research Center in Seattle. A substantially higher rate of relapse and mortality rate was found in patients with very poor cytogenetics compared to patients with good-risk cytogenetics.[70]

An additional disease characteristic recently has been shown to negatively affect the prognosis of patients with

MDS. Not included in any of the previously described scoring systems is the presence of a monosomal karyotype (MK) (i.e., the presence of two or more distinct autosomal monosomies or a single monosomy associated with a structural abnormality).[71-74] However, an association of MK with lower survival, higher relapse incidence, and overall mortality after alloSCT— even among patients with a complex karyotype— has been reported consistently.[70,75-77]

The effect of the IPSS-R on alloSCT outcomes recently was demonstrated in an analysis from the Italian GITMO cooperative group that included 374 patients with primary MDS. Both IPSS-R and monosomal karyotypes were independently associated to a lower overall survival and a higher relapse probability by multivariate analysis.[78] In this study, a predictive model of post-transplant outcome in patients with MDS (Transplantation Risk Index) was originated based on the age of the patient, IPSS-R category, monosomal karyotype, hematopoietic cell transplantation (HCT)-specific comorbidity index, and refractoriness to induction chemotherapy.

In addition to cytogenetics, other disease characteristics have been associated with a poor prognosis in patients with MDS. These include severe bone marrow fibrosis,[79,80] refractory life-threatening cytopenias,[81-83] and gene mutations.[2,18,24,25,28,29,84-89]

As to the effect on alloSCT outcome, bone marrow fibrosis, a recent EBMT retrospective analysis of 721 patients with MDS demonstrated that only severe fibrosis was shown to affect survival, whereas patients with mild or moderate fibrosis had an alloSCT outcome comparable to patients without bone marrow fibrosis.[79] For gene mutations, an independent association with a shorter post-transplant overall survival, after adjusting for clinical variables and complex karyotype status, recently has been reported for mutations in *TP53* and *TET2*.[90]

Patient Characteristics

Apart from disease characteristics, host-specific risk assessment in determining indications for alloSCT always should be grounded on essential patient-related factors, including age, comorbidities, and donor availability.

Although usually considered as a treatment option for patients younger than age 60, over the last 2 decades the development of reduced-intensity conditioning (RIC) regimens, together with substantial progress in supportive care measures, have resulted in an increase in the upper age limit to age 70 (occasionally even older) in carefully selected very-fit patients. Because MDS are much more common in older people (median age at diagnosis, over age 70), with only 10% of patients younger than age 50, this age-limit extension translates to a considerable expansion in the proportion of patients for whom an alloSCT treatment strategy might be presently contemplated.[91,92] Indeed, an international collaborative retrospective comparison of two well-balanced cohorts of medically fit patients with high-risk MDS defined by age 60 to 70 and ECOG PS of 2 or less, treated with alloSCT (103 patients) in case of donor availability, or 5-azacytidine (75 patients) in case of no donor availability, suggested a survival advantage in favor of allogeneic transplantation.[93] Ad-

ditionally, recently reported results of an international collaborative decision analysis (evaluating both life expectancy and quality-adjusted life expectancy) indicated a significant benefit (p < 0.001) of RIC alloSCT versus nontransplantation therapies in patients' age 60 to 70 with intermediate-2/high-risk IPSS de novo MDS.[94]

However, a sophisticated statistical analysis of a large population of older patients with advanced MDS compared alloSCT (247 patients, reported to the EBMT) with nontransplant approaches (137 patients, reported to the Düsseldorf registry). The analysis indicated a possible nonsignificant survival disadvantage for the transplant cohort because of the higher nonrelapse mortality.[95] These results suggest that a prospective controlled randomized study that addresses the "intention to go for transplant" question is absolutely necessary.[95]

Comorbidities have been shown to crucially affect alloSCT clinical outcomes in several hematological malignancies. These data led to the development of a hematopoietic cell transplantation-specific comorbidity index (HCT-CI) as a useful tool for risk assessment before transplantation.[96] The risk-stratification ability of the HCT-CI in patients transplanted for AML and MDS subsequently was confirmed both in the reduced-intensity and myeloablative conditioning strategies.[97-100] The HCT-CI also was prospectively validated by the GITMO group in a consecutive cohort of 1,937 patients receiving alloSCT in Italy over 2 years, including 199 patients with MDS. In 2011, a time-dependent MDS-specific Comorbidity Index (MDS-CI) was developed on a learning cohort that included 840 patients diagnosed in Pavia, Italy. It was subsequently validated in an independent cohort of 504 patients diagnosed in Düsseldorf, Germany.[101] Since it has been shown to provide additional prognostic information on patients stratified according to the IPSS-R, the MDS-CI may represent a valuable tool in support of the HCT-CI when evaluating patients for possible transplant indication.

High-serum ferritin and iron overload secondary to pretransplantation transfusion also is associated with a substantial negative effect on nonrelapse mortality after alloSCT.[102-110] Thus, transfusion history in patients with MDS should be considered for transplantation decision-making as well as for initiation of a timely iron chelation therapy to prevent iron accumulation before transplant.

When to Transplant

Although very heterogeneous, the natural course of MDS typically is characterized by a disease progression with patients exhibiting gradual worsening of peripheral blood cytopenias, which eventually lead to transfusion dependency. Sequential marrow examination, especially in the presence of myeloblast excess (i.e., ≥ 5%), often can demonstrate an increase in marrow blast– count culminating in AML evolution. Cytogenetics tend to remain stable, even though the occurrence of chromosome aberrancies (or additional ones, when already present at diagnosis) occasionally may be observed. Time-dependent disease modifications are outlined

as phase progression by the WPSS and the IPSS/IPSS-R classification system, IPSS-R.[15,16,19]

The Markov retrospective analyses cited above have shown a substantial survival advantage for patients who are in high-risk categories of MDS (intermediate-2 and high-risk, according to IPSS) undergoing early alloSCT from HLA-matched donor, whereas a transplant deferment until disease progression seems to confer longer life expectancies in patients with lower-risk MDS (low- and intermediate-1 risk, according to IPSS).[61,94] In general, because the status of the disease at transplant has a major effect on all outcomes, better long-term results seem to be achieved when transplantation is performed earlier during the course of the disease.[62,111,112] In addition to disease progression, risk associated with transplant delay may include occurrence of infectious complications, acquisition of transfusion refractoriness, iron overload secondary to transfusion history, performance status decline, and acquisition of additional comorbidities, which lead to a substantially higher risk of nonrelapse mortality following transplantation. Nonetheless, the question of the optimal time for alloSCT in individual patients may be difficult, because of the unavoidable morbidity and nonrelapse mortality risks associated with the transplantation procedure and to the current availability of alternative treatment options, such as HMAs. In a recent GITMO decision study that included 660 patients with MDS who received best supportive care and 449 who underwent transplantation, a continuous-time multistate Markov model was applied to describe the natural history of the disease and to evaluate the effect of alloSCT on survival.[113] Results of this study indicate that a delayed transplantation is advisable only for patients with early disease (low-risk by IPSS, very low- and low-risk by WPSS), with the best survival benefit deriving from alloSCT for patients classified in the intermediate-1, according to IPSS (in the presence of multilineage dysplasia and/or transfusion dependency) or the intermediate WPSS risk category.

Furthermore, new and interesting information that could be combined for clinical decision making in patients with MDS may originate from a further retrospective GITMO study. This study was recently performed in a large population of 529 patients with MDS without a compatible family donor but with plain indication for alloSCT. A competing risk analysis unveiled high pretransplant risk of disease evolution and mortality resulting from the time spent waiting for the identification of a suitable unrelated donor, both on the entire population of patients with MDS and on specific subgroups stratified by disease risk and age (GITMO Registry, M. Della Porta, personal communication, 2015). If confirmed in other series, these findings would support selection of haploidentical donors to perform immediate alloSCT in patients with high-risk MDS without a promptly available HLA-matched donor.[114,115]

Apart from obviously depending on donor availability, the decision on when to transplant in MDS often has to consider potential treatment to be administered before transplantation, especially in patients with a higher percentage of marrow to possibly downstage the disease to a lower-risk category.[116-118] Because AML-like induction chemotherapy, besides being rather toxic in older patients, is frequently leading to disappointing results in MDS, especially in the presence of high-risk cytogenetics, HMAs frequently are preferred in the interim period before transplantation. Life expectancy has been shown to be very dismal for patients with loss of response to azacitidine.[119,120] In patients whose disease responds, alloSCT possibly should be offered before disease progression, if a donor is available. Presently, because of the absence of randomized studies, optimal pre-transplantation therapy is unknown,[121] although trials with HMAs employed as a bridge to transplant are currently ongoing.

In conclusion, individual decision making on the best treatment strategy pertaining to allogeneic transplantation is usually the consequence of a difficult composite judgment that includes disease-, patient-, and transplant-characteristics together with the patient's expectations and opinions.

GENETICS IN MYELODYSPLASTIC SYNDROMES/MYELOPROLIFERATIVE NEOPLASMS

MDS/MPNs represent an optimal disease model for the clinical implementation of broad spectrum mutational profiling. First, the clinical and pathologic characteristics of MDS/MPNs are challenging to recognize, and they often can change within the context of cytoreductive agents or other therapies. Second, the spectrum of mutations in MDS/MPNs is relatively well-characterized and allow for the sensitive annotation of clonality in most patients. Lastly, although substantial overlap occurs among recurrent mutations in MDS/MPNs, it could be argued that each disease entity is characterized by a unique genetic fingerprint that may aid in diagnosis. Emerging evidence suggests that these genetic lesions are independently prognostic and may aid in therapeutic decisions. Below is a disease-specific summary of recurrent mutations and their clinical relevance (Table 2).

Chronic Myelomonocytic Leukemia

The hematologic phenotype of chronic myelomonocytic leukemia (CMML) is defined by a peripheral monocytosis and dysplasia.[122] The recurrent genetic mutations associated with this CMML phenotype converge on diverse pathways that include mutations of signal transduction (*NRAS, KRAS, CBL, JAK2*); DNA methylation (*DNMT3A, TET2, IDH 1/2*); transcriptional regulation (*ETV6, RUNX1*); chromatin modification (*EZH2, ASXL1*); and the RNA splicing machinery (*SF3B1, SRSF2, ZRSR2, U2AF1*).[123-125] Although the pathways affected are heterogeneous, a genetic clonal event can be identified in greater than 90% of CMML cases by sequencing only nine genes. In fact, mutations in *TET2, ASXL1*, and *SRSF2* are highly recurrent with each identified in up to 45% of patients.[125-127] This allows for the CMML clinician to obtain evidence of clonality in almost all cases of suspected CMML, making it straightforward to parse malignant from reactive monocytosis. Additionally, co-mutation of *SRSF2*

TABLE 2. Frequency of Recurrent Mutations among WHO-defined MDS/MPNs[4,136,139,144]

Mutation	CMML	JMML	aCML	MDS/MPN-U	RARS-T	Clinical Significance
ASXL1	40	0	69	Unknown	15	Adverse
CALR	0	0	0	0	<1	Unknown
CBL	10*	15**	0	Unknown	4	Adverse/Favorable
CSF3R	0	0	Variable	0	0	Predictive
DNMT3A	2	0	Unknown	Unknown	15	Unknown
ETV6	<1	0	Unknown	Unknown	3	Unknown
EZH2	5	0	Unknown	10	Unknown	Unknown
IDH1/2	6	0	Unknown	Unknown	Unknown	Unknown
JAK2	8	0	7	19	57*	Favorable
JAK3	Unknown	12	Unknown	Unknown	Unknown	Neutral

ZRSF2	8	0	Unknown	Unknown	3	Unknown

Abbreviations: WHO, World Health Organization; MDS/MPNs, myelodysplastic syndromes/myeloproliferative neoplasms; CMML, chronic myelomonocytic leukemia; JMML, juvenile myelomonocytic leukemia; aCML, atypical chronic myeloid leukemia; MDS/MPN-U, myelodysplastic syndromes/myeloproliferative neoplasms-unclassifiable; RARS-T, refractory anemia with ring sideroblast and thrombocytosis.

and *TET2* is highly specific for patients with CMML, which aids in the diagnosis of the treated CMML patient when historic monocytosis may be unclear and current monocytosis may be suppressed by HMAs or cytoreductive agents.[31]

The prognostic significance of recurrent mutations in CMML also has been tested. Interrogation of the most common mutations in CMML has identified *ASXL1* to be independently prognostic.[48,73] This has led to its incorporation into two independent prognostic scoring systems. However, larger data sets will be required to fully annotate the prognostic significance of single and combination mutations in CMML.

Juvenile Myelomonocytic Leukemia

Although the monocytic phenotype of juvenile myelomonocytic leukemia (JMML) is similar to that of CMML, the genetic fingerprint of JMML is distinct.[128] Greater than 90% of recurrently mutated genes in JMML cluster on RAS pathway activation.[129] These gene mutations include *NF1, N-RAS, K-RAS, PTPN-11,* and *CBL*.[130,131] Both somatic and germline mutations of these genes have been identified, with the latter most associated with congenital genetic syndromes such as Noonan syndrome (PTPN11) and Neurofibromatosis type 1 (NF1).[132-134] Secondary events in *JAK3* and *SETBP1* also have been described and suggest a poor prognosis.[135,136] This genetic landscape, along with its characteristic GM-CSF

hypersensitivity, has resulted in major advances in the molecular understanding of JMML.[128] Further, the presence of these mutations can alter treatment decisions and management. Patients with *CBL* mutations and its associated congenital syndrome can manifest a JMML phenotype that is self-limited.[131] Therefore, a watchful waiting strategy is often employed in these children, as opposed to allogeneic transplant in other RAS-mutated JMML cases.[137]

Atypical Chronic Myeloid Leukemia

Atypical chronic myeloid leukemia (aCML)Atypi is a disease characterized by severe neutrophil dysplasia and cytopenias in the absence of the BCR:ABL fusion protein. This disease has historically been difficult to diagnose given the pathologic overlap between it and other MDS/MPNs, particularly MDS/MPN-Unclassifiable. Further, the diagnostic difficulty present in discerning aCML from chronic neutrophil leukemia (CNL) has made the annotation of aCML-specific mutations challenging.[138] Gene mutations identified in aCML/CNL include *JAK2, SETBP1, NRAS,* and *CSF3R*. Analysis of these genes can identify a clonal event in over 50% of these diseases.[139-141] *CSF3R* mutations are notable because they represent a potential predictive marker for targeted therapy. Preclinical data suggest that truncating CSF3R mutations predict sensitivity to SRC inhibition and *CSF3R* mutations affecting the membrane proximal portion for the receptor

predicts sensitivity to JAK2 inhibition.[139] The latter has been validated in clinical case reports with ruxolitinib therapy in aCML.[142] However, two separate reports have failed to identify CSF3R mutations in a stringently defined aCML cohort and were exclusively seen in CNL.[143,144] Nonetheless, mutational analysis for *CSF3R* should be performed if aCML is suspected, given the potential therapeutic implications.

Myelodysplastic Syndromes/Myeloproliferative Neoplasms–Unclassifiable

The genetic study of MDS/MPN-Unclassifiable (U) has been limited by difficulties in the diagnostic standardization of this entity. MDS/MPN-U is defined by having clinicopathologic features of myeloproliferation, dysplasia, and cytopenias but not meeting criteria for other well-defined MDS/MPNs. It is hypothesized that many MDS/MPN-U cases may be reclassified into other WHO-defined MDS/MPNs with mutational profiling. To this end, a recent retrospective study identified a clinical and genetic signature that could identify aCML among those cases initially identified as MDS/MPN-U.[144] More investigation is needed to better annotate disease-specific genetic fingerprints to confidently allow for reclassification of MDS/MPN cases.

Refractory Anemia with Ring Sideroblast and Thrombocytosis

Refractory anemia with ring sideroblast and thrombocytosis RARS-T) is defined by the presence of ringed sideroblasts and a platelet count of greater than 450×10^8/dL and is included as a provisional category within the group of MDS/MPN-U by WHO.[8,14] Similar to cases of MDS with ringed sideroblasts (RARS), the genetic landscape of RARS-T is dominated by the presence of mutations in *SF3B1* that occur at a frequency reported between approximately 60 to 90%.[28,29,145] Other recurrent mutations identified in both RARS and RARS-T include *TET2*, *ASXL1*, and *EZH2*.[146] However, RARS-T has been demonstrated to additionally harbor mutations in *JAK2* at rates approximating 50% and, less frequently, mutations in other signaling mutations such as *CBL* and *CALR,* which are rarely seen in RARS.[28,146-149] This raises the possibility that mutations in *JAK2* may be responsible for the thrombocytosis uniquely seen in RARS-T.

Although conventional wisdom states that the natural history of RARS-T is relatively benign, emerging data suggest that annotation of mutations in RARS-T may reveal a more aggressive subtype. A recent report identified *SF3B1* and *JAK2* mutations as favorably prognostic and associated with improved survival compared to their mutated counterpart. For example, *SF3B1* wild-type cases of RARS-T had a median survival of 3.3 years compared to 6.9 years in mutated cases.

THERAPIES IN ADULT MYELODYSPLASTIC SYNDROMES/MYELOPROLIFERATIVE NEOPLASMS

No pharmacologic agents have been demonstrated to alter the natural history of MDS/MPNs. As such, the general ap-

proach for the treatment of these groups of diseases is to focus on therapeutic strategies tailored to symptomatology with individual patients. There is little evidence to suggest that patients with asymptomatic MDS/MPN benefit from current standard treatment. However, it is strongly recommended that all patients with MDS/MPN be considered for clinical trial when available. Allogeneic stem cell transplant has the most robust data suggesting a disease modifying effect in MDS/MPNs[94,150-152] and should therefore be considered in higher-risk patients with MDS/MPN. Although there has been substantial progress in the prognostication of CMML cases, challenges remain in adequately risk-stratifying other MDS/MPNs for clinical transplant decision making.[48,153,154] Below is a summary of treatment options and their disease-specific supporting data.

Hypomethylating Agents

Very limited data are available for the use of HMAs for the treatment of aCML, MDS/MPN-U, or RARS-T.[155] However, robust data exist that demonstrate the activity of HMAs in CMML. Several phase II studies have demonstrated that azacitidine is active in CMML and associated with acceptable therapy-associated toxicity.[156,157] Oral azacitidine more recently has been tested for the treatment of CMML with clinical responses seen in 35% of patients previously treated with HMA for MDS and CMML, and in 73% of patients receiving azacitidine as first-line therapy.[158] Decitabine also has been examined in multiple phase II trials, with response rates ranging from 10 to 58% in patients with CMML.[159] However, despite well-documented activity, no evidence exists that HMAs increase overall survival or decrease progression to AML. Therefore, we reserve this therapy for patients with CMML in which cytopenias are the predominant symptom. We would not favor HMAs in rapidly proliferative patients with CMML, given the relatively long median time to HMA response. There is no CMML-specific evidence to favor one HMA over another.

Lenalidomide and Interferon

There has been limited data testing the activity of lenalidomide in CMML and RARS-T. In CMML, lenalidomide has been tested in combination with metronomic doses of melphalan. Although the study was small in number, a 25 and 33% response rate was identified in patients with myelodysplastic and myeloproliferative CMML, respectively.[160] A case study also has reported a proliferative of CMML cases with isolated del(5q) treated with lenalidomide that achieved blast clearance and cytoreduction. In RARS-T, three case reports have demonstrated clinical activity with respect to hematologic and splenomegaly improvement irrespective of cytogenetic abnormalities.[161-163] Interferon has been tested in aCML in a limited number of cases with modest activity.[164,165]

Cytoreductive Agents

Patients with MDS/MPN with rapid and severe myeloproliferative or constitutional symptoms should be considered for treatment with cytoreductive agents. These therapies range

from induction chemotherapy to hydroxyurea and should be chosen based on performance status and other host-specific factors. As with HMAs, a larger clinical experience exists with cytoreductive agent in CMML compared to other MDS/MPNs. Several studies have reported the efficacy of the topo-isomerase inhibitors topotecan and etoposide both as single agent and in combination with cytarabine.[166-168] Other trials have examined combination with arsenic or all-trans retinoic acid (ATRA) with modest results.[169,170] These two trials are notable because they represent two of the only MDS/MPN-specific studies to date. The only randomized study that has been performed in CMML randomly assigned 105 patients with CMML to receive hydroxyurea or etoposide. Surprisingly, this trial demonstrated a median overall survival of 20 months in the hydroxyurea group compared to 9 months in the etoposide arm, suggesting inferior disease-modifying capacity for etoposide in CMML.[168] Induction chemotherapy has been used in CMML based on extrapolation from MDS. In our practice, we recommend induction chemotherapy in patients with extreme or symptomatic leukocytosis, massive splenomegaly, or severe constitutional symptoms that are refractory to hydroxyurea or other less-intensive approaches. Although it is not well addressed in the literature, a minority of patients achieves a complete response and are capable of being considered for allogeneic stem cell transplant. However, limited evidence is available that carefully weighs these response rates against the substantial toxicities associated with induction-type chemotherapy.

Future Therapies

Although other therapeutic options have the potential to improve the symptomatology of patients with MDS/MPN, the current pharmacologic landscape is limited. Ongoing studies testing JAK2 inhibitors in aCML and CMML hold promise[171] (NCT02092324 and NCT01776723). However, only a small number of studies currently are addressing MDS/MPN cases specifically. Hopefully, improved molecular understanding of MDS/MPNs will lead to disease-specific clinical trials with promising agents that will affect the natural history of this group of lethal diseases.

CONCLUSION

Our burgeoning knowledge of the molecular complexity of MDS and MDS/MPNs is rapidly providing novel insights into the pathobiology of these diseases. The clinical application and relevance of these insights currently is largely limited to the refinement of prognostic risk models. Hopefully, this knowledge ultimately will translate into targeted therapies with the potential to change the natural history of these diseases. Presently, judicial selection of patients for treatment with currently available therapies, including alloSCT and nontransplant disease-modifying therapies, coupled with an improved knowledge into the best approaches to use these therapies, is of paramount importance. Given the current paucity of effective therapies for these diseases, an urgent need remains for the development of novel approaches and combinations with the potential of moving the field forward.

Beyond "Second-Line" in Non–Small Cell Lung Cancer: Therapy and Supportive Care

Renato G. Martins, MD, Craig H. Reynolds, MD, and Gregory J. Riely, MD, PhD

OVERVIEW

Although there once was a single algorithm for the treatment of patients with advanced lung cancer, the modern treatment of advanced lung cancer has multiple treatment pathways that depend on multiple factors, including histology and molecular subtype of disease. New molecular targets, targeted agents, and modes of therapy for patients, including immunotherapy, are being identified at an accelerating pace. These advances are changing outcomes and the treatment landscape, but they also highlight situations with inadequate data to support the use of cytotoxic chemotherapy. In this article, we provide an overview of data regarding cytotoxic chemotherapy and targeted therapy and their value after second line, review the critical role of supportive care and palliative care, and emphasize the importance of advance care planning with our patients. Although this article focuses primarily on NSCLC, the comments about palliative care and advanced care planning also apply to patients with small cell lung cancer.

Although there once was a single algorithm for the treatment of patients with advanced lung cancer, the modern treatment of advanced non–small cell lung cancer (NSCLC) has multiple treatment pathways that depend on many factors including histology and molecular subtype of disease. In addition, new molecular targets, targeted agents, and modes of therapy, including immunotherapy, are being identified at an accelerating pace. These advances are changing outcomes and the treatment landscape, but the rapid introduction of many new therapies may be somewhat bewildering for the practicing oncologist. In this context, a discussion of therapy's role beyond second line is outdated. However, more relevant than ever is the medical oncologist's role in advocating for patients to have access to these advances, discerning the patient's care goals, and sparing them from the toxicities of unproven therapies.[1] This article will review critical factors for decision making in this changing treatment environment.

THE ROLE OF CHEMOTHERAPY IN THIRD-LINE AND BEYOND

Unlike the data establishing the role of docetaxel in the second-line treatment of advanced NSCLC,[2] there are no randomized trials evaluating chemotherapy in the third- and fourth-line treatment of advanced NSCLC. There are multiple single-institution and retrospective analyses (selected data is presented in Table 1). The results of chemotherapy in the third and fourth line are strikingly variable across these studies. This may reflect different patient characteristics or underlying tumor biology. Results from Asia—which are generally more favorable than those from the West—are consistent with previous observations that Asians have a better prognosis. There clearly is some heterogeneity in progressive lung cancer, and some patients will respond better than others to further treatment. There is a suggestion that response to previous treatment and continued good performance status are predictors of benefit from third- and fourth-line chemotherapy, but these conclusions must be viewed with caution given the absence of randomized data.

TARGETED THERAPIES FOR PATIENTS WITH A TARGET

Today broad molecular profiling is the standard of care for patients with lung adenocarcinomas,[3] and the identification of actionable molecular targets in squamous NSCLC is an area of active investigation.[4] Furthermore, the number of effective therapies has expanded. As an example, for patients with ALK-positive lung cancers, four lines of therapy have shown meaningful clinical benefit (two "targeted" and two "conventional"). Survival for some molecular subtypes of NSCLC is now measured in years rather than weeks.

Although evidence supporting the use of third- and fourth-line standard cytotoxic chemotherapy is largely retrospective and of poor quality, prospective data support the use of targeted therapies in patients with defined molecular targets, even when patients have had multiple prior lines of therapy.

TABLE 1. Selected Retrospective Series Describing Outcomes to Third- and Fourth-Line Chemotherapy in NSCLC

Author	Patients	ORR	mOS
	Third Line/ Fourth Line	Third Line/ Fourth Line	Third Line/ Fourth Line
Massarelli[22]	43/14	2%/0%	5 mo/6 mo
Asahina[23]	230/106	17%/11%	12 mo/10 mo
Younes[24]	214/NA	7%/NA	8 mo/n/a
Chen[25]	123		13 mo/13 mo

Abbreviations: NSCLC, non-small cell lung cancer; ORR, overall response rate; mOS, median overall survival; mo, months; NA, not available.

In 2011, crizotinib was approved for treatment of patients with metastatic ALK-positive lung cancer. In the phase I trial that led to the accelerated approval of crizotinib, more than 53% of patients had two or more lines of prior therapy.[5] In all treated patients, the overall response rate was 61% and the median progression-free survival was 10 months. Importantly, in patients with two prior therapies, the response rate was 65%, and in those with three or more prior therapies, the response rate was 59%, emphasizing that when ALK rearrangements are present, use of this targeted ALK inhibitor is beneficial to the patient. Consonant with this notion, the U.S. Food and Drug Administration's approval of crizotinib for ALK-positive lung cancer does not refer to a line of therapy (unlike the label for all cytotoxic chemotherapies). Similarly, after the identification of ROS1 as a target for crizotinib, a group of patients was prospectively identified and treated with crizotinib.[6] Forty-four percent of patients in this study had two or more prior lines of therapy. The overall response rate of patients in this study was 72%, and the median progression-free survival was 19 months.

Although the use of epidermal growth factor receptor (EGFR) tyrosine kinase inhibitors in first-line treatment of patients with EGFR-mutant NSCLC has clear benefit, patients typically develop clinically acquired resistance to erlotinib, gefitinib, or afatinib within 1 year. As a mechanism of resistance, many patients develop a secondary mutation, EGFR T790M, that alters the binding of tyrosine kinase inhibitors, allowing continued

KEY POINTS

- Although there are no randomized studies, data suggest patients with good performance status and previous response to chemotherapy are more likely to benefit from further chemotherapy.
- Targeted therapy can have significant benefit in previously treated patients, particularly when new targets are identified.
- All patients with advanced lung cancer should receive palliative care.
- Advanced care planning and conveyance of realistic expectations about outcomes should be discussed with all patients.

growth of the cancer.[7] More recently, drugs, including AZD9291 and rocelitinib, have been developed that target EGFR T790M. In studies exploring the efficacy of these agents, the enrolled patients have had multiple prior lines of therapy. For both AZD9291 and rocelitinib, the median number of prior therapies for patients treated was three, with some patients having as many as 12 prior lines of therapy.[8,9] For AZD9291 in 205 evaluable patients, the response rate was 53%. For rocelitinib, among the 40 patients with EGFR T790M–positive evaluable disease treated in the therapeutic dose range, the response rate was 58%.

Taken together, these data with crizotinib, AZD9291, and rocelitinib suggest that, in patients who have the target of interest, multiple prior lines of therapy did not affect the patient's likelihood of benefit. Therefore, for patients with NSCLC, it is imperative that we identify all targetable driver oncogene alterations. For those patients who had insufficient tissue for molecular testing at the time of diagnosis, in some clinical situations it is reasonable to consider repeat biopsy solely for molecular testing. In addition, new targets such as BRAF and MET have recently emerged, and other new targets continue to emerge. This may allow patients to enroll in clinical trials evaluating new targets and agents. Although it is hardly a sufficient predictor of likelihood of a targetable driver oncogene, never-smoking history is associated with the highest likelihood of presence of ROS1, ALK, or EGFR mutations. A recent analysis showed that a broad hybrid capture–based next generation sequencing (NGS) assay identified actionable genomic alterations in 65% of tumors from never or light smokers with lung cancers.[10] Notably, these results were from patients who had prior negative testing for actionable genomic alterations using non-NGS approaches. These findings support profiling of NSCLC tumors using NGS as a more comprehensive and efficient strategy than non-NGS testing.

THE IMPORTANCE OF PALLIATIVE CARE

The initial trials demonstrate a benefit of chemotherapy for patients with advanced NSCLC who were randomly assigned to best supportive care or best supportive care plus chemotherapy. However, the significance of supportive care, as well as some key elements of supportive care, were not appreciated until 2010 when Temel and collaborators published their single-institution, randomized trial demonstrating the benefit of early palliative care when integrated with standard oncologic care.[11] Patients with newly diagnosed metastatic NSCLC were randomly selected to receive a palliative care team (i.e., a board-certified palliative care physician and advanced-practice nurses) in addition to standard oncology care or standard oncology care alone. Palliative care visits occurred at least monthly. Patients assigned to early palliative care had a better quality of life as measured by the Functional Assessment of Cancer Therapy–Lung scale, experienced less depressive symptoms, and received less aggressive therapy at the end of life. In the control arm, 54% received aggressive end-of-life care compared with 33% on the palliative care arm (p = 0.05). Despite less aggressive therapy, patients who received early palliative therapy had a median sur-

vival of 11.6 months, compared with 8.9 months on the control group (p = 0.02).

It is unclear how this single-institution trial, with a specific group of physicians, translates to general practice. Whether these benefits of early palliative intervention can only be achieved by a specialized palliative care team is unknown, as is how easily the results could be achieved in the community oncology setting where access to such support services is often limited. Indeed, in 2010 only 59% of National Cancer Institute–designated comprehensive cancer centers and 22% of community cancer centers had outpatient palliative care programs.[12] A more recent survey of California hospitals with inpatient palliative care programs found that only one-fifth provided outpatient palliative services, and around the clock outpatient services were available in only one-quarter of those.[13] However, this work strongly suggests that more aggressive therapy at the end of life is not associated with a better survival.

Multiple studies have found that a significant number of patients with advanced NSCLC receive chemotherapy in the last month of life. A 2001 review of almost 8,000 Medicare patients found that 11% received chemotherapy in the last month of life.[14] An Italian review of four cancer centers found 33% of patients received chemotherapy in their last month of life (only one-third of these had lung cancer).[15] Fifteen percent of patients experienced grade 3 to 4 toxicity in the last month of life, and there were two treatment-related deaths. A clinical benefit was observed in 10%. A more recent retrospective chart review was conducted in 10 community oncology practices, which included 417 patients that were diagnosed with advanced NSCLC in 2000 to 2003.[16] Chemotherapy was given within 1 month of death in 43% and within 2 weeks of death in 20%. Of those receiving chemotherapy in the last month of life, 39% were first line, 28% second line, and 21% third line. The authors attributed this high use of treatment at the end of life to the availability of new agents and an increase in the length of time patients receive treatment.

ADVANCED CARE PLANNING

Emerging data suggest that interventions in community practice can affect end-of-life care. The US Oncology Network's My Care My Wishes program (MCMW) gives formal counseling to patients with advanced cancer, including discussions of prognosis and desires regarding code status and end of life. A recent analysis suggests that MCMW improves documentation of code status in electronic medical records in the community setting, perhaps reducing the likelihood of unwanted and futile end-of-life interventions.[17] A study at this meeting suggests that advanced care planning reduces hospitalization and increases hospice referrals in patients with advanced cancer.[18]

In 2014, the Institute of Medicine released "Dying in America: Improving Quality and Honoring Individual Preferences Near the End of Life."[19] This document addresses all patients with potentially terminal illness, not just oncology patients. There were five main recommendations:

- Person-centered, family-oriented palliative care should include extra efforts to manage transitions, avoid unneeded hospitalizations, and support family caregivers.
- Clinician–patient communication and advance care planning should be prioritized and improved to ensure that patients have opportunities to articulate their preferences while they are still able to.
- Professional education and development should extend the new discipline of hospice and palliative medicine into medical and nursing school curricula—across professional silos—and it should include improving physician communication skills.
- Policies and payment systems must be reorganized to incentivize care coordination and palliative care provision and to discourage excessive use of inpatient days and multiple care transitions.
- Public education and engagement about end-of-life care is crucial; efforts must be made to normalize conversations about death and dying.

Medicare fails to adequately compensate long outpatient discussions, typical of end-of-life care. Using the 2013 National Medicare Fee Schedule, a physician who spends 35 minutes discussing the lack of benefit of additional cancer-directed therapy and hospice referral received 27% lower compensation than he or she would by seeing two patients for a 15-minute visit entirely dedicated to describing the schedule of administration and side effects of a new line of therapy.[20] During the discussions about the approval and implementation of the Affordable Care Act, there was a proposal to compensate for end-of-life discussions. The goal was to stimulate the counseling of patients and families to avoid futile and expensive care near the end of life. Most medical oncologists likely would agree that discussions about of end-of-life care are critical for our patients, their families, and society in general. In a recent sign of progress, the American Medical Association has released codes for advanced care planning.[20] This is an important step for Medicare to consider the coverage of end-of-life discussions.

GUIDELINES

Choosing Wisely is an American Board of Internal Medicine Foundation initiative supported by more than 60 medical specialties.[21] It aims to promote discussions between providers and patients to achieve care that is "supported by evidence; not duplicative of other tests or procedures already received; free from harm; truly necessary." The American Society of Clinical Oncology (ASCO) has joined Choosing Wisely and proposed two lists with a total of 10 interventions "whose common use and clinical value are not supported by available evidence." The very first of these listed procedures applies to the discussion of palliative chemotherapy not supported by existing evidence:

- "Do not use cancer-directed therapy for solid tumor patients with the following characteristics: low performance status (3 or 4), no benefit from prior evidence-based interventions, not eligible for a clinical trial, and

no strong evidence supporting the clinical value of further anticancer treatment.

- Studies show that cancer-directed treatments are likely to be ineffective for solid tumor patients who meet the above stated criteria.
- Exceptions include patients with functional limitations due to other conditions resulting in a low performance status or those with disease characteristics (e.g., mutations) that suggest a high likelihood of response to therapy.
- Implementation of this approach should be accompanied with appropriate palliative and supportive care."

And in the 2013 List of Recommendations:

- "Do not use a targeted therapy intended for use against a specific genetic aberration unless a patient's tumor cells have a specific biomarker that predicts an effective response to the targeted therapy."

While the ASCO Clinical Practice Guidelines (2011 Focused Update) do not explicitly discourage the further treatment of lung cancer after patients have progressed on first- and second-line therapies, the guidelines stop short of recommending against third- and fourth-line therapy:

- "When disease progresses on or after second-line chemotherapy, treatment with erlotinib may be recommended as third-line therapy for patients with performance status of 0 to 3 who have not received prior erlotinib or gefitinib.
- Data are not sufficient to make a recommendation for or against using cytotoxic drug as third-line therapy; patients should consider experimental treatment, clinical trials, and best supportive care."

CONCLUSION

After years of slow progress, the speed of innovation in advanced NSCLC has increased greatly, with an explosion of new therapies, targeted therapies, and immunotherapies. Although these new options offer great promise for patients, they may also paradoxically increase the risk of ineffective and potentially harmful treatment near the end of life. When there is general pessimism about the role of treatment in advanced lung cancer, it is less likely to be given, either appropriately or inappropriately. As enthusiasm grows for treatment, practicing oncologist struggles to provide those treatments to patients in a way that maximizes potential benefit and minimizes risk. This is a difficult dilemma given the absence of randomized data in the third- and fourth-line settings. However, the available data suggests some principles:

- Every patient with advanced NSCLC should receive early palliative care and advance care planning with regard to end-of-life care. This will reduce the risk of futile and unwanted treatments, has been shown to improve outcomes, and empowers patients to make informed decisions about their care.
- Routine use of cytotoxic chemotherapy in the third and fourth line is not supported by prospective data. Patients with previous response to therapy and continuing good performance status seem most likely to benefit from further lines of therapy.
- For patients with NSCLC, molecular analysis is a necessary component of care and may identify treatment options even after conventional second-line therapy.

The therapy options for patients with NSCLC have greatly expanded. These therapies have improved the overall survival and quality of life of many patients affected by the disease. Their high cost is a challenge to patients, physicians, and society in general. Medical oncologists have the responsibility to gather all evidence to identify therapies likely to benefit and protect patients from the toxicities of ineffective therapies.

Beyond Adenocarcinoma: Current Treatments and Future Directions for Squamous, Small Cell, and Rare Lung Cancer Histologies

David E. Gerber, MD, Paul K. Paik, MD, and Afshin Dowlati, MD

OVERVIEW

Lung cancer encompasses a diverse spectrum of histologic subtypes. Until recently, the majority of therapeutic advances were limited to the minority of patients with adenocarcinoma. With the advent of comprehensive genomic profiling of squamous and small cell lung cancers, new therapeutic targets have emerged. For squamous tumors, the most promising of these include fibroblast growth factor receptor (FGFR), the phosphatidylinositol 3-kinase (PI3K) pathway, discoidin domain receptor 2 (DDR2), and G1/S checkpoint regulators. In 2014, the antiangiogenic agent ramucirumab was approved for all non–small cell lung cancer (NSCLC) histologies, including squamous tumors. Immunotherapeutic approaches also appear to be promising for these cases. Genomic analysis of small cell lung cancer has revealed a high mutation burden, but relatively few druggable driver oncogenic alterations. Current treatment strategies under investigation are focusing on targeting mitotic, cell cycle, and DNA repair regulation, as well as immunotherapy. Pulmonary neuroendocrine tumors represent a diverse spectrum of diseases that may be treated with somatostatin analogs, cytotoxic agents, and molecularly targeted therapies. Radiolabeled somatostatin analogs and combinations with mammalian target of rapamycin (mTOR) inhibitors also show potential. Large cell neuroendocrine tumors share numerous clinical, pathologic, and molecular features with small cell lung cancer; however, whether they should be treated similarly or according to a NSCLC paradigm remains a matter of debate.

Recent therapeutic advances in lung cancer have been almost exclusively limited to adenocarcinoma histology. Molecular profiling efforts to identify genomic alterations, driver oncogenes, and druggable targets have focused on adenocarcinoma. Until recently, antiangiogenic treatments were limited to nonsquamous NSCLC because of concerns of heightened toxicity (life-threatening hemoptysis) in squamous cases. Additionally, use of the well-tolerated, convenient, and effective cytotoxic agent pemetrexed is also restricted to nonsquamous cases because of inferior outcomes in squamous cases.

Lung cancer encompasses numerous diverse histologic types (Sidebar 1). After decades of inactivity, recent years have seen advances in our understanding and treatment of lung cancer types beyond adenocarcinoma. Genomic alterations that may provide therapeutic targets have been identified in squamous cell carcinoma, and newer antiangiogenic agents appear to be tolerated in this histologic subtype. Gene sequencing efforts in small cell lung cancer have identified one of the highest mutational burdens of any malignancy, and prophylactic cranial irradiation in extensive stage disease has been shown to improve neurologic outcomes and overall survival. Although advances for less common lung tumors, such as large cell carcinoma and bronchial carcinoids, have been hampered by their low frequency and a lack of consensus on disease categorization, recent data suggest that certain molecularly targeted agents, liver-directed therapies, and radiolabeled somatostatin analogs may improve outcomes. This review provides an overview of the current approach and future directions for these diverse malignancies.

SQUAMOUS CELL CARCINOMA

Recently, genotyping efforts—ranging from the comprehensive, such as The Cancer Genome Atlas' squamous lung cancer study, to the individual, such as the characterization of *FGFR1* amplification and *DDR2* mutations— have brought to light a number of putative therapeutic targets that appear to occur in toto in more than half of all patients' tumors. What follows is a summary of recent diagnostic and therapeutic developments aimed at improving the outcomes of patients with this disease.

Squamous tumors account for 20% to 30% of all NSCLC cases.[1] The prototypical squamous cancer is characterized by

---

a tumor that is well differentiated and exhibits classic structural features such as keratinization, intercellular bridges, and pearl formation.[1,2] Histopathologic subtypes include papillary, basaloid, clear cell, and small cell variants. Most squamous lung cancers are marked by the expression of p40/p63, cytokeratins 5/6, high molecular weight keratin, and carcinoembryonic antigen. Most cases do not express cytokeratin 7 and thyroid transcription factor 1 (TTF-1).[3]

There are a number of diagnostic challenges inherent to this disease. Small biopsy specimens and poorly differentiated tumors often lack the histologic hallmarks of squamous differentiation. In such cases, immunohistochemical (IHC) profiling for both p40/p63 (positive in squamous cases) and TTF-1 (negative in squamous cases) has been established as a useful approach for determining lineage.[1,3] A number of studies have also addressed the issue of adenosquamous carcinomas, tumors that have most likely arisen from a common clone but exhibit divergence in histologic appearance. In terms of molecular biology, these tumors appear to be more closely aligned with adenocarcinomas than squamous cell carcinomas, which has important therapeutic implications as it relates to current guidelines for *EGFR* and *ALK* testing.[1]

In 2012, The Cancer Genome Atlas published a comprehensive molecular analysis of 178 early-stage squamous lung tumors and, from a conceptual standpoint, ushered in an era of personalized medicine for patients with this disease.[4] These data, coupled with discoveries made by other researchers,[5-7] crystallized the notion that a potentially actionable oncogenic driver could be found in the majority of squamous cases. Key targets are discussed below, and include

KEY POINTS

- Although most recent lung cancer developments have been limited to adenocarcinoma histology, numerous discoveries for squamous, small cell, and other histologies have also been made.
- A putative oncogenic driver can be identified in the majority of patients with squamous cell lung cancer. Key druggable targets include *FGFR1* amplification, PI3K pathway alterations, cell cycle checkpoint disturbances, and *DDR2* mutations.
- Ramucirumab, a monoclonal antibody against VEGFR-2, is now FDA-approved in conjunction with docetaxel for the treatment of patients with non–small cell lung cancers, including squamous cell lung cancers, making this the first antiangiogenesis drug available to patients with this disease.
- Comprehensive genomic analyses of small cell lung cancer have been conducted. Current experimental treatment approaches are focusing on targeting mitotic, cell cycle, and DNA repair regulation, as well as immunotherapy.
- Pulmonary neuroendocrine tumors represent a diverse spectrum of diseases. Radiolabeled somatostatin analogs and molecularly targeted agents are under investigation.

SIDEBAR 1. World Health Organization Classification of Lung Cancers, Including Modification by IASLC/ATS/ERS Classification of Lung Adenocarcinoma[155]

Preinvasive Lesions
- Bronchial squamous dysplasia/carcinoma in situ
- Atypical adenomatous hyperplasia
- Adenocarcinoma in situ
- Diffuse idiopathic pulmonary neuroendocrine cell hyperplasia

Adenocarcinoma
- Minimally invasive adenocarcinoma ($\leq$ 3 cm lepidic predominant tumor with $\leq$ 5 mm invasion)
- Invasive adenocarcinoma
  - Lepidic predominant (nonmucinous with > 5 mm invasion)
  - Acinar predominant
  - Papillary predominant
  - Micropapillary predominant
  - Solid predominant with mucin

Adenocarcinoma Variants
- Invasive mucinous adenocarcinoma
- Colloid
- Fetal
- Enteric

Squamous Cell Carcinoma (Variants)
- Papillary
- Clear cell
- Small cell
- Basaloid

Small Cell Carcinoma (Variant)
- Combined small cell carcinoma

Large Cell Carcinoma (Variants)
- Large cell neuroendocrine carcinoma (LCNEC) and Combined LCNEC
- Basaloid carcinoma
- Lymphoepithelioma-like carcinoma
- Clear cell carcinoma
- Large cell carcinoma with rhabdoid phenotype

Adenosquamous Carcinoma

Sarcomatoid Carcinoma
- Pleomorphic carcinoma
- Spindle cell carcinoma
- Giant cell carcinoma
- Carcinosarcoma
- Pulmonary blastoma

Carcinoid Tumor
- Typical carcinoid
- Atypical carcinoid

Salivary Gland Tumors
- Mucoepidermoid carcinoma
- Adenoid cystic carcinoma
- Epithelial-myoepithelial carcinoma

FGFR1 amplification, alterations in the PI3K pathway, *DDR2* mutations, and cell cycle checkpoint dysregulation. Many of these alterations are therapeutic targets in Lung-MAP (S1400, NCT02154490), a multi–sub-study randomized phase II trial concept sponsored by the Southwest Oncology Group (SWOG) that is designed to screen and match patients to rationally selected therapies based on tumor molecular profiling. Importantly, many of the genomic alterations identified in squamous lung tumors do not appear to be mutually exclusive (in contrast to the better known alterations in lung adenocarcinoma such as *EGFR* and *KRAS* mutations and *ALK* rearrangements). This will likely complicate the interpretation of efficacy data from treatments directed against single targets (Fig. 1). This section also discusses two novel therapies—ramucirumab, a monoclonal antibody against vascular endothelial growth factor receptor (VEGFR), and necitutumab, a monoclonal antibody against epidermal growth factor receptor (EGFR). These agents have demonstrated significant, although modest, efficacy in randomized phase III trials when combined with chemotherapy. Finally, this section reviews the role of immunotherapy, which has emerged as a distinct therapeutic category of substantial clinical importance for squamous lung cancer.

Fibroblast Growth Factor Receptor 1

The FGFR family consists of four transmembrane receptor tyrosine kinases that participate in the regulation of embryonal development, proliferation, differentiation, and angiogenesis. FGFR1, FGFR2, FGFR3, and FGFR4 bind variably to 22 mitogenic and hormonal ligands. Upon ligand binding, FGFR undergoes dimerization and activates downstream signaling via the phosphatidylinositol 3-kinase (PI3K), RAS/RAF/MAPK, and protein kinase C (PKC) pathways. Alterations in FGFR1–4 were detected in 27% of squamous tumor samples reported by The Cancer Genome Atlas, with *FGFR1* amplification the most common event (17% of cases).[8] Although *FGFR1* amplification is considered an oncogenic event, there is variability in the correlation between gene amplification, mRNA expression, and protein expression in cell lines and tumors.[7,9,10] This is a key point, as not all *FGFR1*-amplified cell lines and xenografts respond to FGFR inhibi-

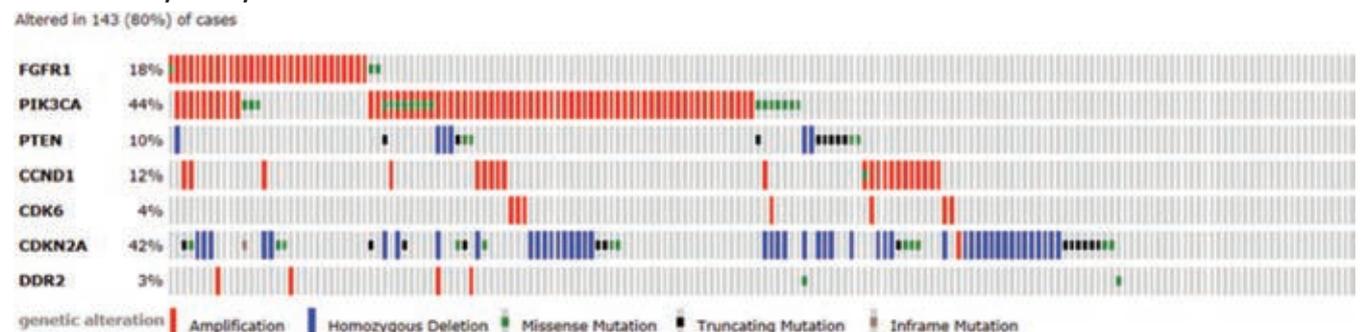
tors.[9,10] In addition, less common mutations in *FGFR1–4* and fusion events with BAG4 and TACC3 have been identified that may, as in other malignancies, predict for response to FGFR inhibition.[4,11]

A few studies have looked at the prognostic implications of *FGFR1* amplification in early-stage disease. In a study by Kim et al, Asian patients with surgically resected squamous lung tumors that harbored *FGFR1* amplification were more often current smokers and had worse overall survival (OS) than those without amplification (51 vs. 115 months; p = 0.002).[12] In contrast, North American patients with *FGFR1*-amplified squamous tumors were found to have no distinct clinical characteristics and no survival disadvantage.[13]

A number of FGFR-specific small molecular inhibitors have been or are being tested in phase I and phase II trials, including BGJ398 (NCT01004224, NCT02160041), AZD4547 (NCT00979134, NCT02154490), and JNJ-42756493 (NCT01703481). All three compounds have low nanomolar IC50s for kinase inhibition against FGFR1, FGFR2, and FGFR3; additionally, JNJ-42756493 has low nanomolar specificity for FGFR4. An FGF ligand trap, GSK3052230, is also being studied in combination with chemotherapy (NCT01868022). Toxicities associated with the small molecule inhibitors include stomatitis, asthenia, nausea/vomiting, corneal/retinal changes, and transaminitis. In addition, hyperphosphatemia, which is an on-target effect of these drugs, is relatively common. Preliminary efficacy data have been presented from patients with advanced squamous lung cancer who were treated with BGJ398[14] and AZD4547.[15] Overall response rate (ORR) ranged from 8% with AZD4547 to 15% with BGJ398; survival data have not yet been presented. Given the modest responses seen with these drugs, additional work will be required to define better predictors of response, including genomic covariates and other markers of FGFR1 pathway activation.

Phosphatidylinositol 3-Kinase Pathway

The PI3K pathway is an intracellular signal transduction pathway for many upstream receptor tyrosine kinases and regulates cell survival, metabolism, motility, and angiogenesis. Abnormalities in this pathway are more common in lung

FIGURE 1. Oncoprint of Selected Oncogenes and Tumor Suppressors from 178 Resected Squamous Cell Lung Cancers Analyzed by the Cancer Genome Atlas[153]


Note the substantial degree of target overlap for many of these patients.

squamous carcinoma than in lung adenocarcinoma, which suggests that there may be an increased dependence on this pathway in squamous tumors.[16-18] This observation is underscored by recent in vivo modeling, in which biallelic inactivation of PTEN and LKB1 led to spontaneous squamous lung tumor formation.[19] Alteration in one of the components of the PI3K pathway was observed in 47% of tumors analyzed by The Cancer Genome Atlas.[8] PIK3CA mutations, predominantly in the catalytic and regulatory domains, occur in approximately 10% of cases,[4] with PIK3CA amplification accounting for 40% of these.[4,18] Complete PTEN loss by IHC was found in 24% of cases,[20] and PTEN was also found to be mutated in 7% of tumors.[4]

Preclinical studies have provided a rationale for targeting upstream PI3K pathway alterations with novel therapies. In particular, squamous tumor cell lines and mouse models harboring PIK3CA mutations or gene amplification and PTEN loss are sensitive to PI3K inhibitors.[21,22] There are a number of ongoing or completed early phase trials of PI3K-alpha specific inhibitors or dual PI3K-alpha/mTOR inhibitors for patients with advanced squamous lung cancer, including studies of GDC0032 (NCT02154490), BKM120 (NCT01297491), and LY3023414 (NCT01655225). To date, no efficacy data have been presented from these trials.

Discoidin Domain Receptor 2

Discoidin domain receptor 2 (DDR2) is a receptor tyrosine kinase that regulates cell adhesion, proliferation, and extracellular remodeling upon binding to its endogenous ligand, type 1 collagen.[23,24] The potential importance of DDR2 mutations in squamous lung cancer was established by Hammerman et al, who found an overall mutation rate of 3.8% in this gene and demonstrated that certain mutations lead to gain-of-function phenotypes that can be reversed with dasatinib, a multikinase inhibitor with activity against both DDR1 and DDR2.[5] Two prior early-phase studies of dasatinib alone or in combination with erlotinib in patients with advanced NSCLC showed little overall efficacy.[25,26] However, one patient with a squamous tumor harboring a DDR2 S768R mutation that was EGFR wild-type achieved a partial response to dasatinib plus erlotinib.[5] A partial response to dasatinib was also reported in a patient with synchronous chronic myelogenous leukemia and an early-stage squamous lung tumor bearing a DDR2 S768R mutation.[27] Given the sporadic nature of DDR2 mutations and limited preclinical data about their functionality, it is unclear what proportion of DDR2 mutant squamous patients might benefit from dasatinib. A phase II study of dasatinib in DDR2 mutant squamous lung cancer was recently terminated as a result of poor accrual (NCT01514864). Additional clinical data will likely rest on the development of a DDR2-specific inhibitor or on case reports of off-label use of dasatinib.

G1/S Checkpoint Inhibition

Cell division, formalized in the various phases of the cell cycle that move the cell from a state of quiescence (G0) to DNA synthesis (G1, S) and ultimately mitosis (G2, M), is an intri-

cately controlled process that depends on a series of negative regulatory mechanisms to ensure replication fidelity and maintenance of homeostasis. These mechanisms can be bypassed through the dysregulation of a handful of cell cycle checkpoint suppressors such as retinoblastoma (RB), P53, and p16 and activators such as the cyclin/cyclin-dependent kinase (CDK) complexes. Cyclins D1–3, which bind to CDKs 2, 4, and 6, are important early regulators under the control of mitogenic signaling. These complexes phosphorylate the tumor suppressor RB, which facilitates dissociation of RB from E2F transcription factors. In turn, E2F activation leads to a transcriptional program that moves the cell from G1 to the S phase.[28]

G1/S checkpoint regulators are commonly altered in squamous tumors.[4] CCND1, which encodes cyclin D1, is amplified in 13% of cases, and CDK6 is amplified in 4%. CDKN2A, which encodes the tumor suppressor p16 that inhibits CDK4 and 6, is mutated or homozygously deleted in 45% of tumors. The frequency of these aberrations has made targeting the cell cycle an attractive concept, although there are limited published preclinical and clinical data to support this strategy.[29-31] Palbociclib, which received U.S. Food and Drug Administration (FDA) approval for use in combination with letrozole for patients with advanced hormone receptor-positive breast cancer, is also being studied in advanced squamous cell lung cancer positive for CCND1 amplification, CDK6 amplification, or CDKN2A deletion/mutation (NCT02154490).

Vascular Endothelial Growth Factor

Vascular endothelial growth factor (VEGF) and its receptor (VEGFR) are key mediators of angiogenesis.[32] Bevacizumab, a monoclonal antibody against VEGF, is FDA approved for the treatment of nonsquamous NSCLC. It is not approved for patients with squamous NSCLC because of safety concerns centered on hemoptysis, which is now thought to be fueled by the common anatomic distribution of this disease (i.e., central cavitary tumors that may abut or invade local vascular structures) rather than any unique intrinsic biologic characteristic.[33-35] Nevertheless, squamous cases were included in the recently published REVEL study, which randomly assigned patients with advanced NSCLC to receive docetaxel with or without the anti–VEGFR-2 monoclonal antibody ramucirumab. The addition of ramucirumab to chemotherapy demonstrated an improvement in overall survival (median OS 10.5 versus 9.1 months; hazard ratio [HR] 0.86, p = 0.02), progression-free survival (PFS, HR 0.76, p < 0.0001), and ORR (23% vs. 14%, p < 0.0001) favoring addition of ramucirumab. There was no disproportionate increase in bleeding events for patients with squamous tumors.[36] Ramucirumab plus docetaxel is now FDA approved for patients with previously treated advanced NSCLC, regardless of histologic subtype.

Epidermal Growth Factor Receptor

The epidermal growth factor receptor (EGFR) is a well-characterized proto-oncogene that, when mutated, engenders a state of oncogene addiction that has been successfully

targeted by small molecular inhibitors.[37,38] The role of wild-type protein overexpression as a target for therapy has been less clear. Both squamous cell cancers and adenocarcinomas are marked by high levels of EGFR expression, although this does not predict sensitivity to EGFR tyrosine kinase inhibitors.[39] Cetuximab, a chimeric monoclonal antibody against EGFR, has efficacy when coupled with chemotherapy in patients with advanced NSCLC.[40] Additionally, a subset analysis showed that patients with squamous cancers that highly expressed EGFR had a significant improvement in OS that favored the cetuximab combination (HR 0.62; 95% CI, 0.43 to 0.88), providing an impetus to study this strategy further.[41] More recently, a randomized phase III trial of cisplatin plus gemcitabine with or without necitumumab, a fully human anti-EGFR monoclonal antibody, showed a significant, though modest, improvement in OS with the addition of necitumumab (median OS 11.5 vs. 9.9 months favoring necitumumab, HR 0.84, p = 0.01). EGFR expression did not predict for therapeutic benefit. Despite the OS benefit, there was minimal improvement in PFS (5.7 vs. 5.5 months, p = 0.020) and ORR (31% vs. 29%, p = 0.4).[42]

Immunotherapy

After decades of efforts to develop cancer immunotherapies, treatments directed against the checkpoints that negatively regulate the adaptive immune response have recently shown promising efficacy across a wide range of malignancies, including lung cancers. Most of this activity is centered on the inhibitory programmed death protein 1 (PD-1), which is expressed on T cells and attenuates T-cell activation upon binding to programmed death-ligand 1 (PD-L1) and PD-L2.[43] A number of monoclonal antibodies against PD-1 or PD-L1 are in clinical development in lung cancer, including nivolumab, pembrolizumab, MEDI4736, and MPDL3280A. Although the initial data for some of these drugs showed heightened activity in patients with squamous lung cancers, subsequent data have shown that histology by itself is not a predictor of response. Instead, PD-L1 expression has emerged as a potentially informative biomarker, with ORRs of between 20% and 30% in patients with PD-L1$^+$ tumors. Notably, a subset of patients have experienced durable responses to treatment captured in the "tails" of the overall survival curves that have been presented, underscoring the need for better predictors of response to these agents.[44-46] Both nivolumab and pembrolizumab have received accelerated FDA approval for the treatment of advanced melanoma and several clinical trials are ongoing in lung cancer.

SMALL CELL LUNG CANCER

Small cell lung cancer (SCLC) is a highly malignant neoplasm representing less than 15% of all lung cancers. It is strongly associated with cigarette smoking. Traditionally the disease has been classified as either limited stage (LS, 20% of cases) or extensive stage (ES). "Limited" refers to the fact that the disease can be encompassed within one radiation portal. The

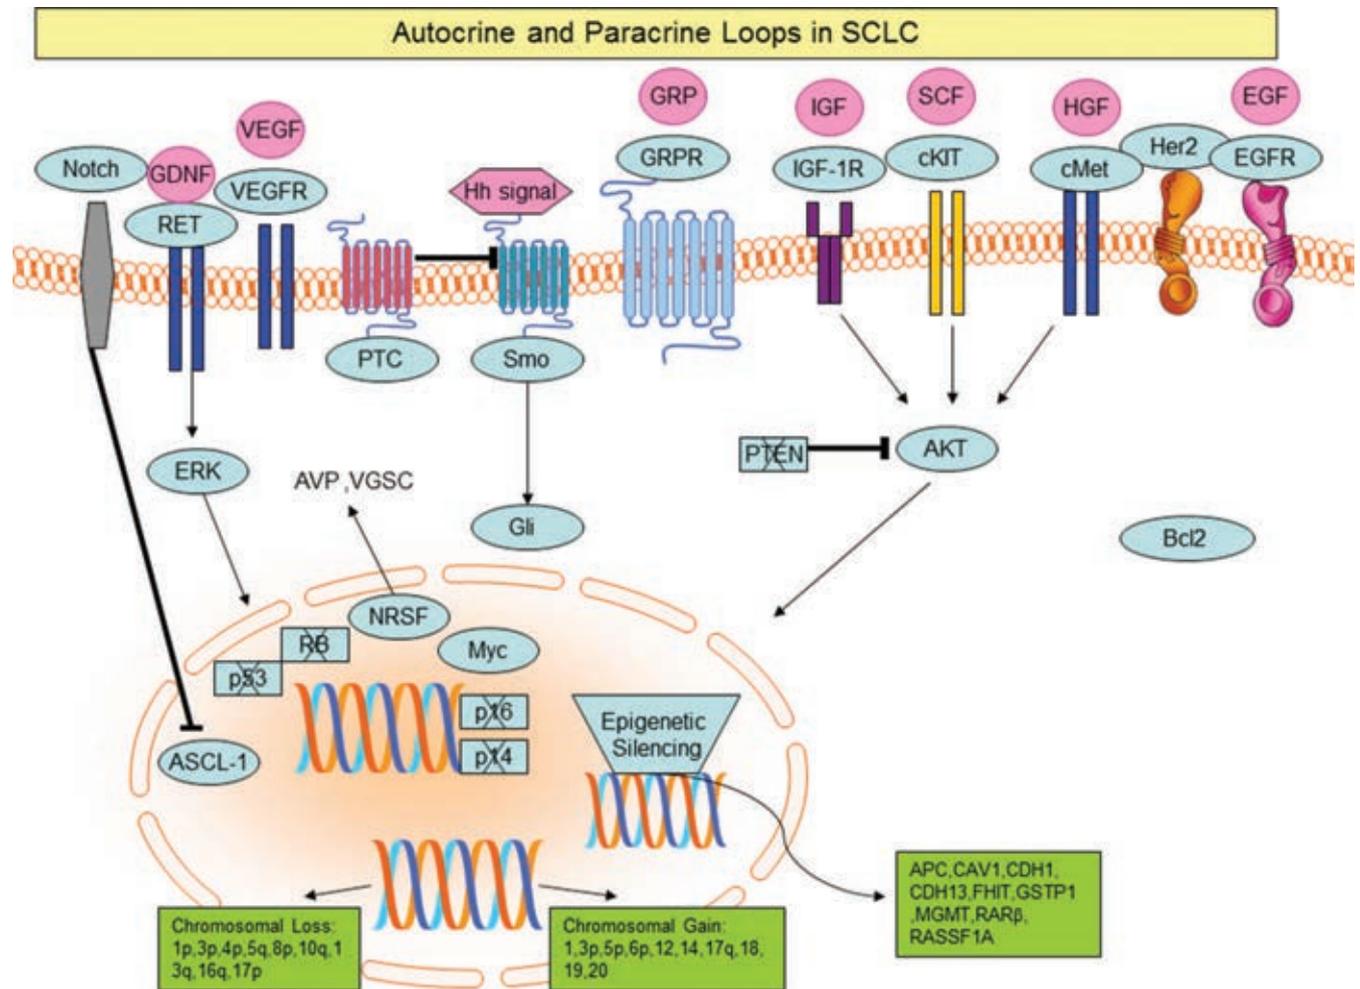
use of the tumor, node, metastasis staging system staging for SCLC has been recently advocated given the fact that within the LS category differences in survival can be seen within stages I, II, and III. In rare cases (less than 1%) SCLC may present as a small peripheral nodule and be amenable to surgical resection. Despite this, analysis of the National Lung Cancer Screening Trial using low-dose CT showed no benefit in the subgroup that was diagnosed with SCLC, indicating the lack of an effective screening strategy for this disease.[47] SCLC may present with elements of NSCLC. This "combined SCLC" entity may be under-reported because of limited tissue sampling availability in many cases.[48] The treatment approach for LS-SCLC is combined modality therapy, with hyperfractionated radiation being superior to standard fractionation and early radiation being better than late radiation.[49-51] For ES-SCLC, systemic chemotherapy is the standard approach, with platinum (either cisplatin or carboplatin) combined with etoposide being the most commonly used treatment. Prophylactic cranial radiation is used for both LS and ES disease and has been shown to decrease relapses in the brain and increase survival.[52,53] However, in a recently reported large Asian trial, PCI appeared to have a detrimental effect on OS in ES-SCLC.[54] Whether this reflects differences in study design, treatment, or populations is not clear. Most recently, the use of consolidation thoracic radiation for ES-SCLC has been shown to confer some benefit.[55] Unfortunately, apart from a proportion of patients with LS-SCLC, all patients will ultimately relapse and second-line therapy is generally ineffective, although topotecan has been approved for this setting. The above data indicate there has been very little improvement in the management of SCLC over the past 3 decades.

Understanding the Biology of SCLC to Find Better Therapies

Figure 2 depicts many, but not all, of the molecular changes seen in SCLC. Alterations in p53, RB, and Myc remain the most frequent. Unfortunately, so far none of these alterations has been amenable to drug targeting. Recently, two publications have comprehensively analyzed the genomics of SCLC.[56,57] These studies collectively showed frequent amplification of *SOX2* as well as recurrent mutations in *CREBBP, EP300,* and *MLL,* three genes that are involved in histone modifications. A major limitation of these studies is that the majority of samples were from patients with resected disease, which is known to be uncommon and may demonstrate a somewhat different biology. This limited access to tissue may be circumvented with novel technology allowing genetic profiling of circulating tumor cells in SCLC.[58] Whole-genome analysis of a single patient with stage IA SCLC also showed copy gains in *hTERT,* a catalytic subunit of the enzyme telomerase.[59]

Clinical Trials in SCLC

Sidebar 2 depicts many, but not all, of the targets that have recently been studied or are the subject of ongoing trials in

FIGURE 2. Overview of Small Cell Lung Cancer Biology


A number of constitutively active signal transduction pathways have been identified. At the nuclear level a number of tumor suppressor genes (denoted by boxes) are inactivated (X within the box). In addition, a number of dominant oncogenes (denoted by the oval shape) are overexpressed, including transcription factors. The antiapoptotic protein Bcl2 is commonly overexpressed in SCLC. Chromosomal gains and loss are common in SCLC. Increased telomerase activity is commonly seen, as well as epigenetic silencing of a number of important genes.

SCLC. Proteins associated with mitotic regulation have been prime targets for drug development. Based on a single-arm study of the aurora kinase inhibitor alisertib, which yielded a 27% response rate in predominantly refractory patients, a randomized phase II trial has been launched. We have also recently demonstrated that 40% to 50% of SCLC cell lines are highly sensitive to low nanomolar concentrations of polokinase inhibitors.[60] Preclinical data suggest that targeting both polokinase and aurora kinases may be particularly effective in tumors with amplification of *Myc*.[61] Studies of polokinase inhibitors in SCLC have yet to be started. Targeting the cell cycle regulatory proteins is also of interest. Our comprehensive drug analysis showed CDK inhibition as a promising target; indeed, a very recent publication has shown that THZ1, a covalent inhibitor of CDK7, is highly potent in SCLC models.[62]

Another attempt to find better therapies for SCLC includes identification of subgroups of SCLC harboring unique oncogenic drivers amenable to targeting. Although a variety of NSCLC subgroups with different oncogenic mutations (e.g., *EGFR*, *ALK*, *RAS*) have been identified, this has not been the case for SCLC. We have recently identified an oncogenic *RET* mutation in SCLC that shows great susceptibility to RET inhibitors in vitro.[63] *RET* mutations may be present in 1% to 2% of patients with SCLC. In addition, a high expression level of wild type *RET* also seems to confer some sensitivity to RET inhibitors. Other investigators have identified frequent changes in the PI3K/AKT/mTOR pathway, including *PTEN* loss, *RICTOR* amplification, and *PIK3CA* mutation. The relevant cell lines showed sensitivity to the dual TORC1/2 inhibitor BEZ235.[64] Anther potential SCLC subgroup with a unique driver may be those cases with *FGFR* amplification.[61] Genomic analysis by Rudin et al showed *FGFR1* amplification in 6% of SCLCs.[56] At the protein level, increases in PARP are commonly seen, and preclinical data shows efficacy of PARP inhibition in animal models.[65] Trials of a PARP inhibitor (veliparib) in conjunction with front-line platinum-based chemotherapy or second-line temozolomide are ongoing.

As with other cancers, there is great interest in determining whether immunotherapy might play a role in the management of SCLC. Many trials of vaccine-based approaches have

failed. Clinicians have long observed that patients with SCLC and autoimmune complications (e.g., paraneoplastic neurologic syndromes) have a better prognosis.[66] Thus, studies of the checkpoint inhibitors of cytotoxic T lymphocyte antigen-4 (CTLA-4) and PD-1/PD-L1 are of great interest and are either ongoing or completed. A randomized phase II trial of phased ipilumumab combined with chemotherapy showed improvements in PFS.[67] A phase III trial of this agent in conjunction with chemotherapy has been completed. Analysis of SCLC samples showed no PD-L1 protein expression by immunohistochemistry in SCLC tumor cells; however, 18% of tumors had PD-L1–positive intratumoral macrophages and 48% had PD-L1–positive infiltrating lymphocytes within the tumor.[68]

In conclusion, these are exciting times for SCLC clinical research. First and foremost, pharmaceutical companies are taking notice of the disease. Second, we are finally approaching SCLC based on its biology and not empirical drug devel-

opment. Third, trial design in SCLC is improving. Phase II randomization is necessary in most settings before moving a drug to phase III clinical trials.[69]

RARE LUNG CANCER HISTOLOGIES

Aside from squamous cell carcinoma and small cell lung cancer, the other nonadenocarcinoma lung cancers are quite rare. As shown in Sidebar 1, the World Health Organization (WHO) organizes these malignancies into the categories of large cell carcinoma, sarcomatoid carcinoma, carcinoid tumors, and salivary gland tumors. Because sarcomatoid features do not necessarily affect disease management, and salivary gland tumors are most commonly considered a category of head and neck cancer, this section focuses on well-differentiated neuroendocrine (carcinoid) tumors and large cell carcinoma variants. Because there have been relatively few recent advances in the treatment of these malignancies and their existing management strategies are complex and nuanced, this section provides an overview of standard treatment as well as new developments.

The Spectrum of Neuroendocrine Lung Tumors

The spectrum of neuroendocrine lung malignancies includes well-differentiated (typical and atypical carcinoid) and poorly-differentiated (large cell neuroendocrine cancer and small cell cancer) cancers. Neuroendocrine tumors (NETs) arise from specialized peptide- and amine-producing neuroendocrine cells (Kulchitsky cells) that have migrated from the embryologic neural crest. These cells can take up and modify amine precursors such as L-dOPA or 5-hydroxytryptophan. Among well-differentiated NETs, the gastrointestinal tract accounts for two-thirds of cases and the lung one-third of cases, with rare cases occurring in the thymus or ovary.[70-72] The incidence of NETs in the United States has increased over time, a trend that has been attributed to greater use of advanced imaging techniques that detect a greater number of asymptomatic tumors and to improved classification.[71,73,74] Because many of these cancers are indolent and have prolonged survival even in advanced stages, the prevalence of neuroendocrine cancers in the United States now exceeds 100,000.[73] SCLC (14% of all lung cancers, discussed previously) is by far the most common pulmonary neuroendocrine cancer, followed by large cell neuroendocrine (3%), typical carcinoid (2%), and atypical carcinoid (0.2% to 0.5%). Pathologically, these cancers differ by morphologic features, proliferative markers, and hormonal secretory function (Table 1). Well-differentiated pulmonary neuroendocrine tumors (typical and atypical carcinoid) may arise in a background of diffuse idiopathic pulmonary neuroendocrine hyperplasia (DIPNECH), an intramucosal proliferation of bland neuroendocrine cells that is confined within bronchial and bronchiolar basement membranes and is associated with varying degrees of airway fibrosis.[75-77] SCLC and

TABLE 1. Features of Neuroendocrine Lung Tumors[155]

	Typical Carcinoid	Atypical Carcinoid	LCNEC	SCLC
NE Features	Well differentiated	Well differentiated	Poorly differentiated	Poorly differentiated
Cell Size	Intermediate	Intermediate	Large to Intermediate	Small to Intermediate
Mitotic Rate	Low	Intermediate	High	High
	< 2 mitoses/2 mm^2	2-10 mitoses/2 mm^2	Median 70 mitosis/2 mm^2	Median 80 mitoses/2 mm^2
NE Markers by IHC	+++	++ to +++	+ to +++	±
Necrosis	-	+ (focal)	+++	+++

large cell neuroendocrine carcinoma do not have identified precursor lesions. Advancing across the pulmonary neuroendocrine spectrum, patient age and smoking rates increase. The average age at diagnosis is age 45 for typical bronchial carcinoids, approximately age 55 for atypical carcinoids, and age 60 to 65 for large cell neuroendocrine tumors.[78-81] Between one-third and two-thirds of patients with well-differentiated tumors are smokers, and these rates may be higher among patients with atypical carcinoids than those with typical carcinoids.[70,78,82,83] Similar to SCLC, more than 85% of patients with large cell neuroendocrine cancer have a history of smoking.[80,81] No other known carcinogens have been linked to carcinoid. Ten percent of bronchial NETs are hereditary (multiple endocrine neoplasia 1 [MEN1]). In contrast to other lung tumors (which are more common in males than females) and other neuroendocrine tumors (which have equal prevalence in males and females), bronchial carcinoids are more common in females.[70,82] Low- and intermediate-grade NETs are further divided into functional (secretory) or nonfunctional (nonsecretory) groups depending on whether there is evidence of a hormone-related clinical syndrome.

Well-Differentiated Neuroendocrine Cancers (Typical and Atypical Carcinoid)

More than 85% of typical bronchial carcinoids are stage I at presentation, and more than 50% of atypical carcinoids present as stage II or III. Approximately 2% of patients with typical carcinoid and 20% with atypical carcinoid will have distant metastatic disease at presentation.[82] Classic teaching purports that, unlike many gastrointestinal NETs from which venous blood flow passes through portal circulation, bronchial neuroendocrine tumors do not require a high burden of liver metastases to cause a clinical carcinoid syndrome. Nevertheless, because of the frequent lack of aromatic amino acid decarboxylase, resulting in lower production of serotonin and its metabolites,[84] carcinoid syndrome is rarely encountered in localized disease and only with large (>5 cm) primary tumors.[85] As such, wheezing at presentation is more likely to be caused by anatomic obstruction than secretion of

bioactive substances. Furthermore, because the risk of carcinoid crisis is considerably lower than with gastrointestinal carcinoids,[86,87] prophylactic treatment with octreotide before biopsy or resection is not typically recommended, although it may be considered before liver-directed therapy. Bronchial carcinoids with liver metastases are associated with carcinoid syndrome in more than 80% of cases.

Clinical features of carcinoid syndrome (flushing, wheezing, diarrhea) have considerable overlap with normal physiology, and may be atypical in cases of bronchial carcinoids. In contrast to physiologic flushing, which tends to involve the entire body, carcinoid flushing has been described as particularly apparent in the face, neck, upper torso, and the palms of the hands or soles of the feet. It is unlikely to be accompanied by diaphoresis. Whereas patients with midgut primaries have typical flushes lasting several seconds to several minutes, those with foregut (including bronchial) primaries may have atypical episodes that last minutes to hours and also feature periorbital edema, disorientation, lacrimation, salivation, hypotension, and tachycardia. In the setting of localized disease, carcinoid syndrome typically resolves after curative resection. For advanced disease, somatostatin analogs such as octreotide (described later) are highly effective. Less commonly (in 1% to 2% of cases), bronchial carcinoids (which are the most common cause of ectopic adrenocorticotropic hormone [ACTH] secretion) may associate with paraneoplastic Cushing Syndrome, which often has acute onset and presents with refractory profound hypokalemia and hypertension.[88-91] Treatment is directed at inhibiting adrenal function and includes high-dose ketoconazole, aminoglutethimide, metyrapone, mitotane, mifepristone, and adrenalectomy.[92] Although this is quite a rare occurrence, bronchial carcinoid is also the most common cause of extrapituitary growth hormone releasing hormone (GHRH), which can result in acromegaly.[93,94]

Diagnostic Evaluation

In 75% of cases, bronchial carcinoids are centrally located and amenable to bronchoscopic biopsy. Atypical carcinoids are more likely to present as peripheral lesions appropriate

for percutaneous biopsy. Computed tomography provides excellent characterization of central lesions (which can be intraluminal, extraluminal, or have components of both). Typically, these appear as well-defined tumors with diffuse or punctate calcification.[95] Because neuroendocrine tumors are highly vascular and can appear isodense with liver on conventional CT depending on contrast phase, multiphase CT or MRI should be used to evaluate liver metastases. High-affinity somatostatin receptor is expressed by the majority of well-differentiated neuroendocrine tumors (80% of typical carcinoids and 60% of atypical carcinoids).[96-98] Accordingly, these tumors may be imaged with the radiolabeled octreotide analog ^{111}In-DTPA-octreotide (somatostatin receptor scintigraphy [SRS], OctreoScan), although this technique has limited specificity because of uptake in other tumor types, granulomas, and autoimmune disease,[84,99-101] SRS may be used both to assess sites of metastases and to assess somatostatin receptor status if treatment with octreotide or lanreotide is considered. However, SRS may have a limited role in cases of apparently localized typical bronchial carcinoid given the low rate (5%) of distant metastases at presentation and improvements in cross-sectional imaging.[70,102] Tumor histology generally predicts which nuclear medicine scan will be clinically useful: SRS for low grade (typical carcinoid); SRS and fluorodeoxyglucose positron emission tomography (FDG-PET) for intermediate grade (atypical carcinoid); FDG-PET for high grade (large cell neuroendocrine, SCLC).

Iodine-meta-iodobenzylguanidine (MIBG) scanning detects the presence of catecholamine transporter proteins expressed by almost all pheochromocytomas, two-thirds of intestinal NETs, and one-third of bronchial NETs. If uptake is evident, I-131 MIBG therapy may be considered.

Numerous biochemical tests may be incorporated into the diagnosis and surveillance of NETs, particularly well-differentiated subtypes. When available, the following markers may be considered selectively according to histologic grade: blood serotonin, 24-hour urine 5-hydroxyindoleacetic acid (5HIAA; >6 mg/24 hours), chromogranin A, pancreastatin (a CgA subunit that tends not to be elevated in nonmalignant conditions), neurokinin A, neuron-specific enolase for well-differentiated NET or "carcinoid"; chromogranin A, neuron-specific enolase for intermediate-grade NET or "atypical carcinoid"; neuron-specific enolase for high-grade or poorly differentiated NET. Serum chromogranin A (CgA), which is elevated in 75% of bronchopulmonary carcinoids but lacks specificity, and 24-hour urine 5HIAA, which is specific but not sensitive, are the most frequently used in clinical practice but are subject to interference from several other conditions and ingestions (Sidebar 3). Given their lack of specificity, these biomarkers have greater utility in disease surveillance than in aiding diagnosis.[102] In particular, CgA levels are lower with bronchial carcinoids than with NETs at other sites and frequently overlap with nonmalignant conditions.[104] Although biomarker pro-

SIDEBAR 3. Factors That Can Modify Chromogranin A and Urine 5-Hydroxyindoleacetic Acid[156,157]

Elevated Chromogranin A

· Gastroenteropancreatic neuroendocrine tumors
  - GI tract (carcinoid tumors)
  - Pancreatic NETs (islet cell tumors [e.g., gastrinomas, VIPomas, somatostatinomas, glucagonomas, non-functioning neuroendocrine tumors])
· Endocrine disease: hyperparathyroidism, hyperthyroidism, pheochromocytoma, pituitary tumors, medullary thyroid carcinoma
· GI disorders: chronic atrophic gastritis, chronic hepatitis, colon cancer, hepatocellular carcinoma, inflammatory bowel disease, irritable bowel syndrome, liver cirrhosis, pancreatic adenocarcinoma, pancreatitis
· Cardiovascular disease: acute coronary syndrome, arterial hypertension, cardiac insufficiency/failure, essential hypertension, giant cell arteritis
· Drugs: proton pump inhibitors, histamine-2 receptor antagonists
· Inflammatory disease: airway obstruction in smokers, chronic bronchitis, systemic rheumatoid arthritis, systemic inflammatory response syndrome
· Renal disorders: renal insufficiency/failure
· Non-gastrointestinal cancers: breast, ovarian, prostate, small cell lung, neuroblastoma

Urine 5HIAA

· Foods to avoid 48 hours prior to testing: avocados, bananas, cantaloupe, eggplant, pineapple, plums, tomatoes, hickory nuts/pecans, plantains, kiwi, dates, grapefruit, honeydew, walnuts
· Avoid coffee, alcohol, smoking
· Medications that can increase 5HIAA: acetaminophen, ephedrine, diazepam, nicotine, glyceryl guaiacolate (found in some cough medicines), phenobarbital
· Medications that can decrease 5HIAA: corticotrophin, ethanol, imiprimine, levodopa, MAO inhibitors, phenothiazines, aspirin, isoniazid, gentisic acid, methenamine, streptozocin, heparin, methyldopa

Abbreviations: 5HIAA, urine 5-hydroxyindoleacetic acid.

gression may precede radiographic progression by up to 6 to 12 months, intrinsic variance in biomarker levels requires confirmation of increasing concentrations.

Treatment

Well-differentiated bronchial NETs are staged in the same fashion as more common lung carcinomas. For early-stage disease, the principal goal of treatment is curative en bloc surgical resection with negative margins and maximal preservation of lung function. Although a number of bronchoplastic techniques such as sleeve, wedge, and flap resections to avoid lobectomy and larger operations have been described,[105-108] extraluminal tumor components usually preclude such approaches. Unless medically contraindicated, lobectomy and lymph node dissection are generally considered the optimal operation for these cancers, as for other lung tumors,[109,110] although some experts support more limited resections (wedge resection or segmentectomy) for peripheral typical carcinoids given the low likelihood of local recurrence.[111] Endobronchial management, such as bronchoscopic resection with neodymium yttrium aluminum garnet (Nd-YAG) laser and cryotherapy, may be considered for central tumors in medically inoperable patients.[112-114] Recommendations regarding adjuvant therapy are confounded by a lack of applicable high-level data and disagreement among disease experts. Although adjuvant therapy (e.g., platinum/etoposide) is recommended by the National Comprehensive Cancer Network (NCCN) for resected stage II or III atypical carcinoid and for stage IIIB typical carcinoid, postoperative chemotherapy is not recommended by the North American Neuroendocrine Tumor Society (NANETS). Both groups recommend observation alone for resected stage I-III typical carcinoid. Thoracic radiation therapy may have a role for atypical carcinoids with residual disease after surgery and for stage III locally advanced tumors not amenable to resection.[115,116]

Systemic therapy of metastatic well-differentiated NETs may include octreotide, chemotherapy, and molecularly targeted therapies. Because of the lack of prospective trials for bronchial NETs, most recommendations come from either retrospective series or extrapolation from experience with clinical trials primarily enrolling gastrointestinal NETs. A proposed approach to treatment is as follows: (1) Low-grade tumor without hormonal syndrome: consider observation with tumor markers and radiographic studies every 3 to 12 months or somatostatin analog (octreotide, lanreotide) if SRS-positive; (2) Low-grade tumor with hormonal syndrome: somatostatin analog; (3) Intermediate-grade tumor without hormonal syndrome: cytotoxic agents or targeted therapies (see below); (4) Intermediate-grade tumor with hormonal syndrome: somatostatin analog plus cytotoxic agents or targeted therapies; (5) High-grade tumor: platinum/etoposide combination chemotherapy. If there is no response to therapy, one may consider subsequent treatment with a regimen for a lower grade tumor.

The somatostatin analog octreotide is available in a short-acting formulation (typically dosed 150 to 250 mcg subcutaneously three times daily) and a long-acting depot formulation (octreotide LAR) dosed 20 to 30 mg intramuscularly monthly. Before initiating long-acting octreotide, a test dose (50 to 100 mcg) of short-acting octreotide to evaluate for allergic reaction may be considered. Short-acting octreotide may also be continued for 10 to 14 days after initiation of octreotide LAR while therapeutic levels are achieved. Approximately one-third of patients will have breakthrough carcinoid syndrome symptoms that cluster the week before LAR dosing, requiring supplementation with short-acting octreotide. Octreotide controls symptoms in about two-thirds of cases of carcinoid syndrome and can slow tumor growth and provide prolonged periods of disease stabilization, although radiographic regression is rare.[117] Evidence for the therapeutic benefit of somatostatin analogs comes from two studies of metastatic intestinal or pancreatic NETs. In the PROMID study, median time to progression was 14.3 months with octreotide LAR versus 6 months with placebo; cross-over was allowed at progression, and there was no significant difference in OS (not reached in octreotide arm versus 84 months in placebo arm).[118] In the CLARINET study of nonfunctioning locally advanced pancreatic or intestinal NETs, median PFS was not reached in the lanreotide arm (currently approved only for acromegaly in the United States) versus 18 months with placebo (HR 0.47).[119] Analogous to use of gonadotropin releasing hormone (GnRH)–modifying agents in metastatic prostate cancer, somatostatin analogs are continued regardless of disease progression because carcinoid syndrome symptoms remain at least partly responsive to these agents. Adverse effects of chronic somatostatin analog therapy include steatorrhea and cholelithiasis.

Multiple cytotoxic agents may be considered for well-differentiated NETs, including temozolomide, capecitabine, 5-FU, dacarbazine, doxorubicin, and platinum-etoposide (although this last option is generally reserved for higher-grade tumors.[120-125] 5-FU combinations with streptozocin, doxorubicin, or dacarbazine plus epirubicin have yielded response rates in fewer than 20% of patients.[122,123] Capecitabine has been combined with oxaliplatin (response rate 30% in well-differentiated NETs) and with liposomal doxorubicin.[126-128] The efficacy of temozolomide was recently reported in a retrospective study of 31 patients with progressive metastatic bronchial carcinoid (14 typical, 15 atypical, 2 not classified): 14% achieved partial response (PR) and 52% stable disease (SD); median PFS was 5.3 months; median OS was 23.2 months.[129]

The mammalian target of rapamycin (mTOR) inhibitor everolimus was evaluated in the RADIANT-2 phase III trial, in which 429 patients with advanced neuroendocrine tumors and carcinoid syndrome were randomly assigned to octreotide LAR with everolimus or placebo.[130] Median PFS was 16.4 months versus 11.3 months, respectively (p = 0.03). In a

subgroup analysis of the 44 patients with bronchial carcinoid (33 received everolimus plus octreotide; 11 received placebo plus octreotide), median PFS was 13.6 months versus 5.6 months.[131] Almost 50% of patients treated with everolimus had grade 3 or 4 adverse events (most commonly diarrhea, stomatitis, and thrombocytopenia). In the ongoing follow-up LUNA trial, 120 patients with lung or thymus NETs will be randomly assigned to pasireotide (a long-acting somatostatin receptor analog), 10 mg everolimus daily, or the combination. In a phase II trial of the multitargeted kinase inhibitor sunitinib enrolling 41 patients with metastatic NETs (of whom 14 had foregut [lung or stomach] primary tumors), the response rate was 2%, and 83% achieved SD.[132]

Interferon alpha has demonstrated antitumor effects in advanced carcinoid, but is usually not administered until failure of somatostatin analogs because of adverse effects.[133-135] Radiolabeled somatostatin analogs remain investigational but trials have yielded encouraging initial findings.[136-139] In a phase II open-label trial, 1,109 patients with NETs (of whom 84 had bronchial carcinoid and 12 had SCLC) received 2,472 cycles of the somatostatin-based radiopeptide 90-yttrium-labeled tetraazacyclododecane-tetraacetic acid modified Tyr-octreotide ([^{90}Y-DOTA]-TOC).[136] Patients were required to have visible tumor uptake on baseline SRS. The radiographic response rate was 34%, 15% had biochemical response, and 30% had improved symptoms related to the hormonal syndrome. Notably, 9% of patients experienced permanent grade 4 to 5 renal toxicity. Tumoral uptake on baseline SRS predicted OS whereas initial kidney uptake predicted severe renal toxicity. Hepatic-directed therapies (surgery, radiofrequency ablation, arterial embolization, chemoembolization, radioembolization)[140-143] may be associated with prolonged survival if control of extrahepatic disease is achieved. Prophylactic octreotide to prevent carcinoid crisis during such procedures may be considered.

Large Cell Tumors

Historically, large cell tumors were considered to be NSCLCs that lacked diagnostic features of small cell, adenocarcinoma, or squamous cell tumors by light microscopy. With increasing use of IHC to distinguish among histologic subtypes, the proportion of cases designated large cell has decreased in recent years and currently represents fewer than 5% of NSCLCs. The large cell cancer category includes large cell neuroendocrine cancer (LCNEC). Whether LCNEC should be treated similarly to other NSCLC types or according to

small cell paradigms has been a subject of ongoing debate.[144] Although the National Comprehensive Cancer Network recommends treating LCNECs as NSCLC, some experts group and treat them as high-grade NETs together with SCLC.[145] Consistent with this approach, some SCLC clinical trials enroll cases of large cell neuroendocrine tumors. Further complicating these considerations is the nuanced and fluctuating terminology describing these diseases (Sidebar 4). Retrospective evidence supporting a SCLC-type approach to large cell neuroendocrine tumors includes the following: (1) poor prognosis, even for resected stage I tumors (33% 5-year survival)[145]; (2) improved survival with adjuvant platinum/etoposide compared to platinum with gemcitabine, vinorelbine, or paclitaxel (44 months vs. 11 months; p < 0.001)[146]; (3) substantially improved outcomes with adjuvant cisplatin/etoposide versus historic controls (5-year disease-free survival 87% vs. 35%; 5-year OS 89% vs. 47%)[147]; (4) rates of brain metastases similar to those seen in SCLC[148]; and (5) gene expression and molecular profiling indistinguishable from SCLC but clearly demarcated from other large cell tumors, lung adenocarcinoma, and well-differentiated bronchial NETs.[149-151] A proposed SCLC-based approach for large cell neuroendocrine cancers includes (1) up to 4 cycles of platinum/etoposide adjuvant chemotherapy for all resected patients, (2) chemoradiation (up to 4 courses of platinum/etoposide chemotherapy) for patients with positive nodes post-resection or unresectable stage III disease, and (3) 4 to 6 cycles of platinum/etoposide chemotherapy for stage IV disease.[145] For other cases of large cell tumors, numerous clinical trials have shown a particular benefit from pemetrexed chemotherapy, perhaps even beyond the differential effect seen in adenocarcinoma cases.[152,153]

CONCLUSION

Although most recent advances in lung cancer advances have been focused on adenocarcinoma tumors, new diagnostic and treatment approaches are emerging for squamous cell, small cell, and the rare lung cancer histologies. These developments will hopefully improve the outcomes of patients with these challenging diseases.

Expectations in the Care of Lung Cancer

Rogerio Lilenbaum, MD, Natasha B. Leighl, MD, and Marcus Neubauer, MD

OVERVIEW

One of the main challenges oncologists face in the care of patients with lung cancer is the decision to incorporate new clinical trial data into routine clinical practice. Beyond the question of statistical significance, which is a more objective metric, are the results meaningful and applicable to a broader population? Furthermore, in an era of value care, do the results justify a potential increase in costs? This article discusses the main points that clinicians consider in their decision-making process and illustrates the arguments with real-life examples.

A daily challenge faced by all oncologists is how to apply the evidence from clinical trials to patients in the real world. Is a clinical trial deemed positive only on statistical or also on clinical grounds? Is the advance truly meaningful to patients, well tolerated, and affordable? Translating data into practice can be a challenge, particularly for clinical scenarios that fall outside the bounds of existing clinical practice guidelines.

In the first section of this article, we discuss trials in advanced non–small cell lung cancer (NSCLC), in which questions about statistical and clinical significance were debated among clinical experts and patient advocates. In the second section, we debate clinical trial endpoints and the applicability of results to clinical practice. In the third section, health care costs, clinical pathways, and value care are addressed.

STATISTICAL VERSUS CLINICAL SIGNIFICANCE
Definitions

When interpreting the results of a clinical trial, physicians interpret the outcomes under two different perspectives: the statistical significance and the clinical significance. The former is an objective, mathematical, and reproducible metric, whereas the latter is often undefined, largely subjective, and mostly left to the reader's judgment. Both are subject to misinterpretation. Physicians often assume that low p values are a measure of the strength of the effect (not necessarily) or that clinical significance implies that the benefit of the intervention can be applied to the entire population at risk (not necessarily). Examples abound of clinical trials that are statistically significant but clinically irrelevant or, perhaps less common, trials that did not meet statistical significance yet had clinical applicability to certain patient subsets.

Statistical significance relates to how likely the observed effect is due to random chance rather than a true difference between the treatment arms. The smaller the p value, the less likely the results were obtained by chance or that the null hypothesis was true.[1] On the other hand, there is no accepted definition of clinical significance. The closest concept is the minimally clinically important difference, which is the smallest treatment efficacy that leads to a change in a patient's management.[2] Others have attempted to define clinical significance by highlighting absolute risk reduction, as opposed to relative risk reduction, or the number needed to treat as a means to translate results of clinical trials into patient management. Quality-of-life issues and patient-reported outcomes also have been proposed as measures of clinical significance.

Chemotherapy

During the modern chemotherapy era, between the 1990s and early 2000s, when the median survival of patients with advanced NSCLC was approximately 8 months, clinical trials were designed to demonstrate a difference in median survival of approximately 2 months, arbitrarily set as a balance between a 1 month or less difference (considered not meaningful) and a 3 month or more improvement (considered very meaningful). Several of such trials, including several thousands of patients, were conducted but showed no significant differences among the various combination chemotherapy regimens.[3] One trial, which compared cisplatin/docetaxel with cisplatin/vinorelbine, raised considerable debate in its interpretation and applicability to clinical practice.[4] The difference in survival, in favor of cisplatin/docetaxel, was borderline statistically significant, but was not considered clinically significant by most clinicians. Although a commonly used combination, cisplatin/docetaxel did not gain widespread endorsement as the "regimen of choice" in advanced NSCLC.

More recently, the combination of cisplatin/pemetrexed was compared with cisplatin/gemcitabine, and a clear advantage emerged for the former in patients with nonsquamous histology.[5] This study debunked an old paradigm as the first

to show a difference in outcome by histologic type in advanced disease. Likewise, the trials that tested the concept of maintenance have yielded solid benefits for patients and are considered both statistically and clinically significant.[6]

Monoclonal Antibodies

Two trials involving monoclonal antibodies illustrate the issues of statistical and clinical significance. The first showed that the addition of bevacizumab to chemotherapy improved survival, albeit at the cost of additional toxicity.[7] Although a similar trial in Europe did not show an overall survival advantage (despite an improvement in progression-free survival [PFS]), bevacizumab has been adopted in the United States for eligible patients. From a clinician's perspective, reluctance to add bevacizumab to chemotherapy is usually related to toxicity concerns and not so much the clinical significance of the trial. The cost-effectiveness implications are discussed below.

The second trial added cetuximab to chemotherapy in advanced NSCLC.[8] Although the study met its primary endpoint of improvement in overall survival, cetuximab was not incorporated in first-line regimens, because the difference in median survival was not felt to be clinically meaningful despite multiple subsequent attempts to refine the target patient population.

More recently, ramucirumab was combined with docetaxel in the second-line treatment of NSCLC and led to a statistically significant improvement in survival compared with docetaxel alone.[9] The magnitude of the difference in median survival was relatively small, but the results are unprecedented in the sense that no other agent, biologic or otherwise, has been shown to improve outcomes when added to a cytotoxic drug in the second-line treatment of NSCLC. It remains to be seen how these results will be interpreted by clinicians and adopted in clinical practice.

Targeted Therapy

The discovery that certain types of lung tumors harbor activating mutations that are sensitive to targeted agents has rev-

olutionized the treatment of advanced NSCLC. Trials that compared a tyrosine kinase inhibitor (TKI) with chemotherapy as first-line therapy in patients with mutated tumors (either *EGFR* or *ALK*) confirmed the benefit of the TKI approach with respect to response rate and PFS.[10] Overall survival, however, was not different, most likely because of crossover, which has led to some debate about the optimal timing and strategy of incorporating these agents in the treatment of NSCLC with sensitizing molecular alterations. In molecularly selected patients treated with the appropriate targeted agents, in comparison to standard therapies, differences in outcome tend to be robust, which illustrates that statistical significance does not always require a large number of patients when the expected treatment effect is meaningful.

ASCO Meaningful Outcomes

Members of the American Society of Clinical Oncology (ASCO) Clinical Research Committee were charged with proposing meaningful outcomes for clinical trials in several tumor types, including advanced NSCLC.[11] The primary goal was to guide the design of clinical trials that would produce meaningful outcomes for patients. In NSCLC with a nonsquamous histology, the baseline for median survival was set at 13 months, and a meaningful incremental improvement was felt to be between 3.25 and 4 months. For squamous cell cancer, the baseline was 10 months and improvement of between 2.5 to 3 months was considered meaningful. Although these goals are aspirational and assume that biomarkers will be utilized in part for the selection of patients, it raises the bar and encourages investigators, sponsors, and patients to demand more of clinical trials.

CLINICALLY MEANINGFUL TRIALS IN LUNG CANCER
Studies of Real-World Effectiveness

Given that clinical trials are conducted under highly controlled circumstances, it is reasonable to expect that trial results will not always be relevant or generalizable to one's daily practice.

Several studies in lung cancer have suggested that the outcomes now seen in clinical trials may be reflected in the general lung cancer population, but patient selection remains important. After the establishment of adjuvant chemotherapy in early-stage NSCLC as a standard, Booth et al[12] demonstrated that, although the uptake of adjuvant therapy in the target population only increased from 7% to 31%, the impact on survival was similar to the magnitude seen in clinical trials, with an increase in 4-year survival from 52.5% to 56.1% with the introduction of adjuvant therapy (p = 0.001).[12] A recent Surveillance, Epidemiology, and End Results (SEER) analysis of the real-world effectiveness of novel agents in advanced NSCLC demonstrated that the use of platinum agents, second-line docetaxel, pemetrexed, and bevacizumab all were associated with a reduced risk of death.[13] These data further support that positive results from clinical trials in advanced lung cancer do translate into benefits in clinical practice.

It is important to recall, however, that not all patients with a given diagnosis will receive the recommended treatment and

---

KEY POINTS

- Although statistical significance is easier to define, clinical significance is by and large a subjective assessment and must be interpreted in the context of the clinical question addressed by the trial.
- ASCO recently proposed more aggressive outcomes for clinical trials of advanced non–small cell lung cancer, for both squamous and non-squamous histologies.
- The applicability of clinical trial data to real-life patients requires assessment of a patient's individual circumstances, which may not have been addressed in the study. This is particularly true in older patients and patients with a poor performance status.
- Clinical pathways reduce variability and decrease costs in patients with advanced non–small cell lung cancer.
- Other measures, such as a decrease in emergency department visits and prevention of hospitalization, can reduce costs while improving the quality of care.

---

that multiple factors, including patient performance status, co-morbidity, organ function, patient preference, and treatment access, all factor into treatment decisions. In a real-world analysis of Canadian patients with advanced NSCLC who were treated in a single-payer public health care system, 70% of patients were assessed by an oncologist at some point, but only 26% received systemic therapy.[14] In those who received platinum doublet therapy and pemetrexed, outcomes were similar to or better than outcomes reported in clinical trials. However, older patients and those who had tumors with a squamous histology were significantly less likely to receive treatment for their disease. Similar data have been reported by Earle et al[15] from U.S. SEER Medicare data, in which 23% of patients with advanced lung cancer received systemic therapy.[15]

Thus, although oncologists are able to achieve excellent results in clinical practice, similar to those seen in trials, the achievement requires not only evidence-based practice but also careful patient selection and shared decision making.

Special Populations

Most clinical trials, from which practice guidelines are derived, include highly selected patients who have an Eastern Cooperative Oncology Group (ECOG) performance status (PS) of 0 or 1, few or no comorbidities, and a younger age. However, given that the median age of diagnosis in lung cancer is at least age 70 and that a majority of patients have an ECOG PS of 2 or greater, how useful are clinical trial results in the patients we actually see in practice?

In a recent review of the inclusion of older adults in advanced lung cancer trials, a third of commonly cited trials specifically excluded older patients.[16] Fortunately, there are multiple trials focused on the older patient population with lung cancer,[17,18] but, again, not all patients in routine practice are suitable for the recommended therapy. Real-world analyses of older adults with lung cancer suggest that older patients do benefit from systemic therapy.[14,19] Earle et al[20] have examined the influence of age on systemic treatment for patients with advanced NSCLC in a real-world setting, using the SEER database.[20] As age increased, the likelihood of receiving chemotherapy decreased, even though patients were still referred to medical oncologists for an opinion. Treatment rates varied inversely with the number of comorbidities.

In the case of potentially curative adjuvant chemotherapy, Cuffe et al[21] demonstrated that, although older patients are prescribed adjuvant chemotherapy, the rate of uptake is approximately half of that seen in the entire population of patients with early-stage disease (16% vs. 31% overall).[21] This population-based study confirmed that a survival benefit was seen in all age groups, and the tolerability of therapy in those patients older than age 70 selected to receive treatment appeared similar to that of younger patients.

The PS presents a similar challenge, because most patients with advanced lung cancer do not present with a PS of 0 or 1. Trials have shown that platinum-based doublet therapy is superior to single-agent treatment in patients who have a PS of 2,[22-24] whereas guidelines recommend against treatment of patients who have a PS of 3.[25] This decision is more challenging in prac-

tice, in which patients who have a PS of 2 are heterogeneous[26] and there are additional factors for or against systemic therapy, including comorbidities, young age, prognostic factors, and potential delays in system access. Many databases have not routinely included PS assessment, but this is changing and will lead to more real-world data that will be available in addition to randomized trials to better inform best practices.

Evolution in Trial Design

The treatment of lung cancer has changed dramatically over the last decade. Lung cancer trials also have changed. In a recent analysis of phase III trials of systemic therapy of advanced NSCLC, there were significant shifts over a 30-year period.[27] Although overall survival was a universal endpoint 30 years ago in these studies, there has been a perceptible increase in the use of PFS as an endpoint. This may be appropriate for studies of novel agents with major clinical benefits, which require crossover for ethical reasons. However, many trials that use PFS as the primary endpoint do not meet this criterion.

The number of agents under study in lung cancer is growing,[28] as is the sample size of randomized, phase III trials—clear evidence of progress and hope in this disease. However, it appears that the magnitude of clinical benefit that investigators deem positive is falling. In the 1980s, a median survival increment of approximately 4 months in a phase III trial was considered positive, compared with 2.5 months in this last decade. The recommendations recently put forth by ASCO are described above. Though not specifically addressed, one could infer that benefit in trials for small cell carcinoma should approximate the benchmark set for squamous carcinoma. The document will not change existing trial plans nor drug approvals for lesser benefits, but it is hoped that this effort will encourage the oncology community and patients to be more demanding of the benefits gained from new therapies.

We have more agents approved in lung cancer than ever before, and decision making about treatment options has never been more complex. Patient outcomes recorded in a real-world setting, including survival and quality of life, and an open discussion about the value of therapy to the patient and society, has never been more important.

Value in Lung Cancer Care: Use of Standardized Pathways

Over the last several years, we have seen a rapid rise in the number of new agents to treat advanced NSCLC. Examples include new cytotoxic agents (e.g., nab-paclitaxel), targeted agents (e.g., erlotinib), biologic agents (e.g., bevacizumab), and, on the immediate horizon, immunomodulatory agents (e.g., nivolumab). Some of these new agents have led to only marginal advances; others have led to more impressive ones. All, however, have added substantial cost. This makes cost, as a part of decision making, more crucial today than ever before. In fact, oncologists are being asked to discuss the costs of treatment with patients, because cost of care is not simply a payer concern.[29] Most patients bear some of the cost of their cancer care in the form of copays and coinsurance, and the prescribed treatment may be unaffordable. Patients should know what lies ahead for them,

because the harshest toxicity may be financial. High costs can be devastating to patients and their families, with up to 62% of all personal bankruptcies estimated to result from medical expenses.[30]

This situation of similar outcomes among treatment regimens associated with high variations in cost sets the stage for clinical pathways. Simply put, can there be a succinct list of regimens that highlights the ones that provide the most value? And, if a pathway is implemented, can adherence to the pathway reduce costs compared with nonadherence while upholding or even improving quality and clinical outcomes? In 2005, US Oncology instituted a set of pathways, including a pathway for NSCLC. Pathway logic was embedded in the electronic medical record to ensure that pathways were visible at the point of care. The results of this program were first published in 2010.[31] This was a retrospective study looking at two groups of patients with NSCLC over the course of an 18-month period: those who were treated entirely with on-pathway regimens and those who, at any time, were treated with an off-pathway regimen. (Because pathway adherence was not expected or meant to reach 100%, there was, indeed, a large group of patients who received at least one off-pathway regimen.) Results of the study showed a 35% reduction in outpatient costs with equivalent clinical outcomes (i.e., overall survival) for patients treated on pathway. Similar results have been shown by others. Feinberg[32] reported on a payer-sponsored pathways program in which a large Mid-Atlantic payer collaborated with community oncologists in its provider network. Patients with breast, colon, or lung cancer who started chemotherapy after the initiation of the program were compared with baseline (historic) controls using the same claims database. Chemotherapy drug savings were $2,964 per patient for lung cancer.[32]

The higher the cost of cancer treatment, the more the value is challenged. A simple equation to refer to is value = outcomes/cost. If the difference in outcome is substantial between two treatments, good value may be upheld even if the superior treatment choice costs more. However, when two regimens are marginally different in outcome, higher costs quickly diminish value. Let's look at one example: the addition of bevacizumab as a third agent in the treatment of advanced, untreated NSCLC. In the pivotal ECOG study, patients were assigned to either paclitaxel/carboplatin or paclitaxel/carboplatin with the addition of bevacizumab, and bevacizumab could be continued until disease progression occurred.[7] The median survival times were 10.3 months and 12.3 months, respectively. Of note, there was a higher incidence of bleeding and treatment-related death in the bevacizumab-treated group. The costs of these regimens, using Medicare reimbursement (average sales price + 4.3%), were $625 for six cycles of paclitaxel/carboplatin and $74,000 for paclitaxel/carboplatin/bevacizumab with bevacizumab maintenance. Indeed, the results of this study were statistically significant, but were they clinically significant? Zhu et al[33] reported on 4,168 Medicare beneficiaries older than age 65 who had advanced NSCLC and compared paclitaxel/carboplatin treatment with paclitaxel/carboplatin/bevacizumab.[33] Median survival estimates were 8.9 and 9.5 months, respectively. The 1-year survival estimates were 39% for paclitaxel/carboplatin/bevacizumab and 40% for paclitaxel/carboplatin. The authors concluded that adding bevacizumab to carboplatin and paclitaxel chemotherapy was not associated with better survival among Medicare patients with advanced NSCLC.

Chemotherapy does not represent the only cost center in cancer care; in fact, it is not even the costliest piece of the total-cost-of-care pie. In a Milliman report in which $49,000 was the average annual cancer-related cost for any cancer member, $21,000 was attributed to hospital costs and $13,800, to chemotherapy ($14,000 to other categories).[34] Therefore, reducing preventable hospitalizations resulting from chemotherapy treatment is a worthwhile goal. Hoverman et al[35] showed that, when a practice implements a formal clinical pathways program and also includes an outbound nurse call system, hospitalizations and total costs can be reduced. In a program sponsored by a payer in which clinical data and claims data were shared, patients with breast, colon, and lung cancer were enrolled in this care management program over a 2-year period.[35] Compared with baseline (i.e., preprogram) practice data, there was a 48% overall reduction in emergency room visits, a 34% reduction in hospitalizations, and a 44% reduction in hospital days (i.e., length of stay). Greater adherence to clinical pathways was one of the factors contributing to these favorable results.

The simple goal of a clinical pathways initiative should be to drive value: to maintain or improve quality and control costs. To do this, pathways should be designed to favor cost-effective drugs and to challenge or exclude treatments that are of questionable clinical benefit, particularly when they are costly. This model has been shown to improve value in NSCLC. With the continued fast pace of new drugs entering the market for lung cancer, oncologists should take an active role in designing, initiating, updating, and adhering to pathways. If we do not, others will mandate it.

The Value of Lung Cancer CT Screening: It Is All about Implementation

Bernardo H.L. Goulart, MD, MS

OVERVIEW

Hospitals have been gradually implementing new lung cancer CT screening programs following the release of the U.S. Preventive Services Task Force grade B recommendation to screen individuals at high risk for lung cancer. Policy makers have legitimately questioned whether adoption of CT screening in the community will reproduce the mortality benefits seen in the National Lung Screening Trial (NLST) and whether the benefits of screening will justify the potentially high costs. Although three annual CT screening exams proved cost-effective for the patient population enrolled in the NLST, uncertainty still exists about whether CT screening will be cost-effective in practice. The value of CT screening will depend largely on the strategies used to implement it. This manuscript reviews the current reimbursement policies for CT screening and explains the relationship between implementation strategies and screening value on the basis of the NLST cost-effectiveness analysis and other published data. A subsequent discussion ensues about the potential implementation inefficiencies that can negatively affect the value of CT screening (e.g., selection of low-risk individuals for screening, inappropriate follow-up visits for screening-detected lung nodules, failure to offer smoking cessation interventions, and overuse of medical resources for clinically irrelevant incidental findings) and the actions that can be taken to mitigate these inefficiencies and increase the value of screening.

In the past 5 years, lung cancer screening has evolved from a purely investigational intervention to a heavily debated topic in the U.S. public health agenda.[1,2] The debate has escalated rapidly to involve multiple stakeholders, including clinical experts, hospital leaders, medical associations, patient advocacy groups, insurance payers, and politicians.[3-7] Supporters endorse a national policy of coverage for lung cancer CT screening that is based on the following:

- The burden of lung cancer, which accounts for 27% of all cancer deaths in the United States.[8]
- The results of the NLST, a high-quality, randomized study that showed a 20% reduction in lung cancer mortality with the use of low-dose CT screening scans compared with chest radiographs.[9]
- The expectation that national implementation of CT screening will prevent more than 12,000 premature deaths per year.[10,11]
- Modeling studies claiming that CT screening is cost-effective in the commercially insured and Medicare populations.[12,13]

Screening opponents argue that the available data is premature to support broad CT screening coverage and express the following concerns:

- The NLST results may not be generalizable to a broad, high-risk population of older adults with a heavy smoking history and tobacco-related comorbidities.[2,14]

- The harms imposed by false-positive results and overdiagnoses may outweigh the benefits of screening in real-world settings.[15,16]
- Centers with lower expertise in lung cancer CT screening may not be able to reproduce the mortality benefits seen in the NLST.[17,18]
- Infrastructure gaps need to be addressed before screening implementation (e.g., consistent documentation of smoking history).[19,20]

Notwithstanding the opposing views, regulatory agencies have gradually taken a favorable position regarding the adoption of lung cancer CT screening. In December 2013, the U.S. Preventive Services Task Force (USPSTF) released a grade B recommendation to screen high-risk individuals, defined as those age 55 to 80 who have a minimum smoking history of 30 pack-years and who currently smoke or have quit within the past 15 years.[21] The Affordable Care Act requires that commercial insurance plans cover screening services that receive a grade B USPSTF recommendation, essentially guaranteeing coverage of CT screening to insured patients younger than age 65.[22] Likewise, the Centers for Medicare & Medicaid Services (CMS) has recently released a final decision to cover CT screening for Medicare beneficiaries who are age 55 to 77 and have the same minimum smoking history required by the USPSTF.[23] The USPSTF and CMS determi-

nations indicate that insurance coverage will no longer be a barrier to screening implementation for insured individuals. New screening programs will likely proliferate across the nation, because hospitals now realize an opportunity to increase revenues by offering lung cancer CT screening and performing downstream tests and procedures prompted by a positive screening result.[24,25]

From a pragmatic standpoint, lung cancer CT screening will gradually become routine practice. Stakeholders should focus now on developing implementation strategies to ensure that lung cancer CT screening will add value to society despite the potentially high costs.[24,26,27] The next sections will discuss how implementation can influence the value of CT screening and what measures can be taken to increase the benefits of screening per dollar spent.

VALUE AND IMPLEMENTATION

Value in health care is a concept that links the benefits of a given intervention with its costs.[28] Cost-effectiveness analysis is a type of health economic evaluation that provides a value metric, usually defined as a ratio of additional costs to additional benefits of a new intervention compared with usual care (i.e., the incremental cost-effectiveness ratio or ICER).[29]

Previous cost-effectiveness analysis failed to provide conclusive evidence about the cost-effectiveness of lung cancer CT screening in the U.S. population.[12,13,26,30-34] Most of these modeling studies were poised by multiple sources of bias, because their estimates of screening effectiveness came from nonrandomized trials, and the model assumptions often were overly optimistic. Besides methodologic limitations, the analyses achieved highly variable results; some suggested that CT screening is highly cost-effective, whereas others showed that screening was prohibitively costly.

The NLST team recently published their trial-based cost-effectiveness analysis.[35] This analysis compared the costs and outcomes of three annual CT screening exams against a no-screening strategy, assuming that screening chest radiographs result in equal outcomes compared with no screening.[36] This study probably provides the most accurate

estimate of the cost-effectiveness of CT screening, given that the analysis derived estimates of effectiveness (tumor stage shift, life expectancy, and quality-adjusted life years [QALYs]) from randomized data obtained from more than 50,000 participants. Additional strengths included the availability of quality-of-life data from a sample of 12,000 participants and detailed information about health care resource utilization in patients diagnosed with lung cancer or those who had a positive screening result.

Compared with no screening, CT screening resulted in additional U.S. $52,000 per life-year gained (95% CI, $34,000 to $106,000) and $81,000 per QALY gained (95% CI, $52,000 to $186,000), respectively. Subgroup analysis suggested that CT screening is far more cost-effective when performed in individuals with higher risks for lung cancer. For example, CT screening resulted in additional $43,000 per QALY gained in current smokers compared with $615,000 per QALY gained in former smokers. Similarly, CT screening costs an additional $169,000 per QALY gained in individuals within the lowest lung cancer risk quintile compared with $52,000 per QALY gained in those within the highest risk quintile.

The NLST cost-effectiveness analysis indicates that CT screening is cost-effective under a commonly accepted willingness-to-pay threshold of U.S. $100,000 per QALY and in the context of a randomized trial.[37,38] Despite these encouraging results, some limitations of this analysis preclude a conclusion of whether CT screening will be cost-effective in practice. Sensitivity analysis showed that the cost-effectiveness estimates highly depended on the assumptions made. For example, the authors assumed that CT screening would only affect life expectancy through early detection of lung cancer. If CT screening would have other positive effects on life expectancy, perhaps through a favorable impact on smoking cessation, the ICER would be $54,000 per QALY. Conversely, CT screening would be less cost-effective ($96,000 per QALY) if the cost of managing incidental findings was $2,500 instead of $500, as assumed by the authors. In addition, the study evaluated the cost-effectiveness of only three annual CT scans, but current guidelines recommend annual CT screening for "as long as the patients are eligible," which will consist of more than three scans for most screened patients.[4,21] The impact of subsequent CT screening scans on costs and outcomes beyond 3 years remains an area of research. Another concerning point is that screening will be less cost-effective in practice if screening programs underperform in relation to NLST centers.

The conclusion, as pointed out by the authors of the NLST cost-effectiveness analysis, is that "whether screening outside the trial will be cost-effective will depend on how screening is implemented."[35] In other words, CT screening will be a valuable intervention if an infrastructure is in place to provide patients with high-quality screening services, but policy makers have questioned whether health care institutions currently have the capacity of offering these services. This concern is of upmost importance, because CT screening will be an onerous health care investment. Large-scale screening implementation is expected to cost $1.4 to $5.5 billion per

TABLE 1. Expected Costs of Lung Cancer CT Screening

Reference	Analysis Type	Perspective	Annual Average Cost per Person Screened ($)*	Annual Average Cost in Aggregate ($ in Billions)*†	Comment
Goulart et al, 2012[27]	Budget impact model	U.S. public and private payers	816	1.4 to 2.2	Target population meets NLST inclusion criteria; screening uptake of 50% to 75%
Pyenson et al, 2012[12]	Actuarial analysis	U.S. private payer	269	4.8	Target population is age 50 to 64; uptake of 50%
Roth et al, 2014[24]	Forecast model	Medicare	NR	3.5 to 5.5	Target population is Medicare beneficiaries meeting USPSTF criteria; assumed an uptake of 100% in all 5 years or an incremental uptake of 20% per year
Pyenson et al, 2014[13]	Actuarial analysis	Medicare	241	1.7	Target population is Medicare beneficiaries meeting USPSTF criteria; uptake of 50%
Cressman et al, 2014[39]‡	Prospective cohort study	Canadian public single payer	550	NR	Target population: individuals with a 3-year lung cancer risk ≥ 2%; uptake of 100% (first scan) and 85% (second scan)

year to public and commercial health care payers, mainly depending on how many individuals will undergo screening (Table 1).[12,13,24,27,39] The number of patients screened will depend at least in part on patient's beliefs about lung cancer screening. Fear of lung cancer may motivate patients to pursue screening, while concerns for out-of-pocket costs, anxiety about CT scan results, and fear of radiation exposure may represent barriers to screening.[40] Besides the economic impact, screening will result in additional diagnostic imaging tests and procedures for lung nodules and incidental findings.

A careful implementation plan should include not only efficient management of screening-detected lung nodules but also the development of processes and delivery of smoking cessation interventions. The next section describes areas of potential implementation inefficiencies based on available data, how they can negatively affect the value of CT screening, and potential actions to mitigate these inefficiencies.

IMPLEMENTING LUNG CANCER CT SCREENING: POTENTIAL AREAS OF INEFFICIENCY

Implementation of lung cancer CT screening will require broad infrastructural developments, including building capacity with additional CT scanners and radiology staff and developing structured radiology reports.[18] A description of all necessary implementation processes is out of the scope of this manuscript. The goal of this section is to highlight the processes that are expected to influence the value of CT screening in practice. These include the selection of high-risk screening candidates, follow-up for positive screening results, provision of smoking cessation interventions, and management of screening incidental findings.

Selection of High-Risk Screening Candidates

The NLST cost-effectiveness analysis provides compelling evidence that the value of CT screening decreases substan-

tially when screening is performed in a lower-risk population, including individuals who met the NLST inclusion criteria. This negative impact on value occurs because many more additional scans need to be performed to detect one early-stage lung cancer in lower-risk screenees. The costs of CT screening will become prohibitive if new programs routinely screen individuals irrespective of their lung cancer risk (e.g., light or never smokers), potentially reaching $19 billion per year, and such practice should be strongly discouraged.[41]

The value of any screening program, and CT screening in particular, also depends on identifying and offering this intervention to high-risk individuals. Failure to offer screening to all eligible individuals will decrease the effectiveness and value of screening in any given health care system.[19]

Early evidence suggests that new screening programs are performing CT screening in lower-risk patients while at the same time potentially missing the opportunity to screen high-risk individuals (Table 2). Unawareness by primary care providers (PCPs) of the role of CT screening is one of the main reasons for inefficient selection of screening candidates. A recent survey of 212 PCPs from an academic medical center showed that only 12% of them had ordered CT screening in the prior year; 52% knew fewer than three of six guideline components of CT screening, and 24% did not know any screening guidelines.[42] Of 89 patients included in our single-center screening registry, 19 (21%) did not meet any eligibility criteria for screening; PCPs were the referral source for the majority of these ineligible individuals.[43]

Physician education should take priority in the early phases of screening implementation, because PCPs are the major source of screening referrals.[44,45] The Lahey clinic received more than 500 referrals of eligible high-risk candidates within 1 year of launching a CT screening program after conducting extensive PCP-oriented educational campaigns.[46] Most other screening programs have had lower referral num-

TABLE 2. Potential Inefficiencies That May Decrease the Value of Lung Cancer CT Screening and Potential Solutions

Screening-Related Process	Potential Inefficiency	Negative Impact on Value	Potential Solution(s)
Selection of Eligible Individuals	High-risk individuals not being screened:	↓ Screening effectiveness	• Physician educational campaigns
	• PCP's inaccurate knowledge about screening		• Patient counseling
	• Patients' views against screening		• Use of EHRs to document smoking history
	• Inconsistent documentation of smoking history in medical charts		• Use of EHR-based physician reminders
	Low-risk individuals being screened:	↓ Screening effectiveness; ↑ costs	• Patient counseling
	• Worried-well patients demanding screening		• Physician educational campaigns
	• PCP's inaccurate knowledge about screening		• Restriction of insurance coverage to high-risk individuals
Follow-up of Positive Screening Results	Lower expertise in the management of lung nodules	↑ Costs; ↓ screening effectiveness	• Adherence to guidelines
	• Overuse of diagnostic tests for false-positive results		• Multidisciplinary management
	• Delayed lung cancer diagnosis		• Referral to high-expertise center
Smoking Cessation	PCP's lack of time for counseling	↓ Screening effectiveness	• Inclusion of smoking cessation specialists in the screening program workforce
	• Current smokers continuing to smoke		
	• Former smokers going back to smoke		
Management of Incidental Findings	Overuse of resources for clinically irrelevant findings	↑ Costs	• Structured radiology report with follow-up recommendations
	• Defensive medicine		• Physician education
	• Patient anxiety		
	Overlook clinically relevant, incidental findings	↓ Screening effectiveness	

Abbreviations: PCP, primary care physician; EHR, electronic health record.

bers, mostly because of PCP unawareness and lack of insurance coverage for screening.[43,47,48]

Many low-risk individuals may demand to undergo CT screening because of a fear of developing lung cancer, despite being ineligible for screening (i.e., worried well patients).[20] Some of these patients will self-refer to a screening program, whereas others will request a referral from their PCPs who, in many cases, will order screening to honor the patient's request. Media campaigns usually target high-risk individuals, but an unintended consequence of these campaigns is that low-risk individuals feel that they need to pursue screening.

Screening programs should offer evidence-based counseling to all patients undergoing screening, particularly those who are at low risk and are ineligible by guidelines criteria.[20,21] A balanced discussion about the benefits and harms of screening based on patient's risk may ensure that screening is performed preferably in high-risk individuals. Decision-aid and risk-prediction tools may be particularly useful to inform patients about their individual risk of developing lung cancer and whether screening is more likely to be beneficial or harmful.[49] Although validated decision aids for CT screening are not available routinely, clinical trials currently are testing the effectiveness of these tools in counseling individuals.[50] To incentivize physicians to counsel patients, health insurance plans should create payment fees for CT screening counseling visits. In fact,

CMS requires documentation of a counseling visit to reimburse claims for CT screening.[23]

No evidence exists to inform whether counseling should be provided by PCPs or by screening experts. Until PCPs become more familiar with screening guidelines, the burden of counseling patients should fall on clinical experts working for screening programs (e.g., pulmonologists).[51]

At present, most clinics do not use a systematic approach to identify high-risk individuals; PCPs may order screening when they have information about smoking history and are aware of the indications for CT screening. This opportunistic approach seems unlikely to capture a large fraction of eligible screening candidates. Detailed smoking history often is not available or is not consistently reported in medical records; even when this information is available, a busy clinician may not have the time to counsel patients about screening.[19]

A potentially effective strategy to identify high-risk patients is to require that clinical staff record the elements of smoking history necessary to determine screening eligibility in electronic health records (EHRs). This process can be used to generate electronic reports that screening programs can use to contact eligible patients and offer screening. Evidence suggests that this strategy effectively captures high volumes of eligible screening candidates. The screening program at the City of Hope Medical Center implemented a similar process, in which clinical staff enters smoking history in EHRs

every 6 months in primary care clinics. In the 3 months before implementing this strategy, the program identified and screened four patients. In the 7 subsequent months, the program screened 58 eligible patients.[48]

Follow-up for Screening-Positive Results

Most positive screening results will consist of solid and non-solid lung nodules; the vast majority of these nodules will not be lung cancer and will constitute false-positive results.[9] An efficient work-up of lung nodules is crucial to maximize screening effectiveness through expedited diagnosis of lung cancer while minimizing the harms and costs of unnecessary tests and procedures for false-positive results (Table 2).

The American College of Radiology (ACR) and the National Comprehensive Cancer Network (NCCN) have developed guidelines for work-up of patients with screening-detected lung nodules.[4,52] The ACR guidelines provide a classification of lung nodules according to their risk of being lung cancer and respective recommendations for follow-up visits (Lung-RADS).[53] The NCCN guidelines represent an amalgamation of previously published guidelines for the management of incidentally detected lung nodules and expert consensus.[54] Although no formal evidence shows that these guidelines result in cost-effective management of screening-detected lung nodules, their recommendations provide a reasonable framework on which new screening programs can base their work-up algorithms until further research informs about the most cost-effective diagnostic strategies.

Because screening programs are just becoming operational, no real-world data are available to inform adherence to guideline recommendations for the work up of screening-detected nodules. Likewise, very little data exists to inform how the work up for lung nodules in practice compares with the diagnostic resources utilized in large trials such as the NLST.[47] Screening registries will play a critical role in informing adherence to guidelines as screening is implemented. Until more data from registries become available, new screening programs are encouraged to strictly follow the recommendations from current guidelines.

The management of screening-detected nodules is a potentially complex process that in most cases requires follow-up visits with additional low-dose CT scans over multiple points in time and occasionally requires invasive procedures.[16,18,20] Appropriate follow-up care requires the involvement of a multidisciplinary team of experts in lung cancer screening, including radiologists, pulmonologists, thoracic surgeons, and oncologists.[55] Excessive and often unnecessary use of diagnostic resources can occur when a multidisciplinary team is not available to guide the investigation of screening-detected lung nodules, resulting in increased costs and delays in the diagnosis of lung cancer. Clinics without this level of expertise should refer their patients to centers that can offer an integrated and multidisciplinary diagnostic approach to screening-detected lung nodules and expedited treatment for screening-detected lung cancers.[41]

As CT screening becomes routine practice, clinics can expect larger numbers of patients with early-stage lung cancer.

This may represent an opportunity for comparative-effectiveness studies of treatment modalities that potentially involve less morbidity than lobectomies, including minimally invasive surgery and stereotactic radiation techniques.[56] The role of these alternative treatments in screening-detected lung cancers remains an area of investigation; clinical trials and cost-effectiveness analyses of these approaches should receive priority as strategies offering high potential to increase the value of CT screening.

Provision of Smoking Cessation Interventions

Smoking cessation is a topic that has simultaneously incited consensus and controversies in the lung cancer CT screening debate. The consensus is that CT screening does not replace the role of smoking cessation interventions for current smokers. The main controversy surrounds the impact of CT screening on smoking behavior: some postulate that CT screening serves as a teachable moment to encourage smoking cessation, leading smokers to quit; others worry that a normal screening result provides false reassurance that smoking is safe, encouraging current smokers to continue smoking or former smokers to restart smoking.[4] Recent evidence supports the former claim, whereas no evidence confirms or contests the latter.

A subsequent analysis of the NLST showed that approximately 40% of individuals who were actively smoking at trial enrollment had quit at 7 years of follow-up and that the likelihood of quitting increased with the degree of abnormality detected by screening.[57] This quit rate is considerably higher than the 5% rate reported in the general population of adult smokers.[58,59] The analysis does not answer the question of whether this high quit rate resulted from higher motivation to quit or from higher adherence to smoking cessation interventions. Regardless, the NLST results do support the notion that positive screening results encourage smokers to quit, possibly because of fear of developing lung cancer.

Additional research is necessary to inform whether current smokers are receiving smoking cessation interventions at the time of screening. The impact of screening on smoking behavior among former smokers is also an area of investigation. These data can better inform how to engage screening with smoking cessation programs in real practice.

Meanwhile, every effort should be made to help current smokers quit. Cost-effectiveness analyses suggest that CT screening is more cost-effective if quit rates double after screening and when current smokers receive counseling and pharmacologic smoking cessation interventions.[26,34] The value of CT screening will depend, at least in part, on implementing successful smoking cessation practices.

Realistically, PCPs do not have enough time to provide comprehensive smoking cessation. Like CT screening, smoking cessation is a process that may involve multiple interactions with patients; smokers often undergo several quit attempts before achieving durable smoking cessation. To ensure appropriate longitudinal guidance on smoking cessation, screening programs should include smoking cessation specialists in their workforce (Table 2).

Less costly interventions may successfully help smokers quit and may add value to CT screening. These include the use of telephone quit lines and web-based smoking cessation resources.[60,61] Additional modeling studies should evaluate the cost-effectiveness of these interventions against traditional one-to-one or group counseling sections and pharmacologic interventions, respectively.

Management of Screening Incidental Findings

Incidental findings consist of screening abnormalities other than those suspicious for lung cancer (e.g., coronary calcifications, emphysema). The impact of these findings on the value of CT screening is unclear. The NLST cost-effectiveness analysis suggests that the value of CT screening decreases as the costs of managing incidental findings increase, but these costs were based on assumptions rather than observed costs.[35] At least in theory, the management of incidental findings can either increase or decrease the value of CT screening (Table 2). Appropriate handling of clinically relevant incidental findings may increase screening effectiveness and value[62]; work up and treatment of clinically irrelevant findings may increase costs and decrease value, respectively.

Data from the NELSON trial and NLST suggest a low prevalence of clinically relevant incidental findings (8% and 10%, respectively).[63,64] The Lahey CT screening program has reported a similar low prevalence of clinically relevant findings.[65] In practice, relevant and irrelevant incidental findings are reported frequently enough to trigger further use of medical resources in a large proportion of patients, without a clear benefit. The pan-Canadian early detection of lung cancer study revealed emphysematous changes in 1,195 patients (58%) who underwent a first CT screening exam; our registry study at the Seattle Cancer Care Alliance showed a 73% prevalence of incidental findings in the first CT screen.[39,43] Clearly, additional research is needed to determine the impact of incidental findings on the value of CT

screening. Screening registries represent an excellent research platform to address this question.

Patient anxiety and defensive medicine also can increase screening costs and decrease value. Patients may feel anxious when informed about the presence of incidental findings on screening and may request additional work up. Physicians may order unnecessary and costly evaluations for incidental findings out of concern about malpractice claims. Screening program leaders should be aware of the unintended consequences of reporting incidental findings and should develop careful language in screening reports that specifies recommendations for follow-up visits, including a statement that no further evaluations are necessary for clinically irrelevant findings. Specific recommendations, including those for no follow-up care, will provide physicians and patients with the reassurance that additional work up can be deferred safely, thus avoiding an escalation of costs.

FINAL CONSIDERATIONS

Lung cancer CT screening may save thousands of lives and add value to society if implemented in a manner that reproduces the mortality benefits seen in the NLST while minimizing harms and costs.

Screening programs should implement practices that will likely increase the value of CT screening, including counseling and selecting high-risk patients for screening, monitoring adherence to guidelines for screening-detected lung nodules, offering smoking cessation interventions, and making specific recommendations for follow-up of screening incidental findings.

Finally, value is only one angle to consider when implementing CT screening. Policy makers and clinicians also need to take into account sociodemographic disparities and other issues that can prevent equitable access to screening. Only by taking a comprehensive approach will we achieve the promise of CT screening: decrease the huge burden imposed by lung cancer.

The Latest in Surgical Management of Stage IIIA Non–Small Cell Lung Cancer: Video-Assisted Thoracic Surgery and Tumor Molecular Profiling

Gavitt A. Woodard, MD, and David M. Jablons, MD

OVERVIEW

Stage IIIA non–small cell lung cancer (NSCLC) remains a treatment challenge and requires a multidisciplinary care team to optimize survival outcomes. Thoracic surgeons play an important role in selecting operative candidates and assisting with pathologic mediastinal staging via cervical mediastinoscopy, endobronchial ultrasound, or esophageal ultrasound with fine needle aspiration. The majority of patients with stage IIIA disease will receive induction therapy followed by repeat staging before undergoing lobectomy or pneumonectomy; occasionally, a patient with an incidentally found, single-station microscopic IIIA tumor will undergo resection as the primary initial therapy. Multiple large clinical trials, including SWOG-8805, EORTC-8941, INT-0139, and ANITA, have shown 5-year overall survival rates of up to 30% to 40% using triple-modality treatments, and the best outcomes repeatedly are seen among patients who respond to induction treatment or who have tumors amenable to lobectomy instead of pneumonectomy. The need for a pneumonectomy is not a reason to deny patients an operation, because current operative mortality and morbidity rates are acceptably low at 5% and 30%, respectively. In select patients with stage IIIA disease, video-assisted thoracic surgery and open resections have been shown to have comparable rates of local recurrence and long-term survival. New developments in genetic profiling and personalized medicine are exciting areas of research, and early data suggest that molecular profiling of stage IIIA NSCLC tumors can accurately stratify patients by risk within this stage and predict survival outcomes. Future advances in treating stage IIIA disease will involve developing better systemic therapies and customizing treatment plans on the basis of an individual tumor's genetic profile.

Stage IIIA non–small cell lung cancer (NSCLC) encompasses a heterogeneous group of tumors with a wide range of sizes, degrees of local invasion, and mediastinal lymph node involvement. The variety of presentation within this stage poses an ongoing challenge to thoracic oncologists to make evidence-based treatment recommendations and accurately predict outcomes in different subgroups of patients. The features that define stage IIIA presentation suggest imminent systemic disease, and 5-year overall survival outcomes remain poor at only 24% for stage IIIA tumors and 9% for stage IIIB tumors.[1] However, certain patient populations, particularly those whose tumors are downstaged by induction therapy and those who undergo lobectomy, have decent outcomes with the appropriate multimodality regimens. Thoracic surgeons play an important role as part of an interdisciplinary care team in selecting operative candidates with stage IIIA disease for whom definitive local control offers the best chance of long-term survival.

ROLE OF THORACIC SURGEON IN PROPER STAGING AND PATIENT SELECTION

Accurate clinical staging in patients with newly diagnosed NSCLC is important to optimize the benefits from surgery and to avoid attempting curative resections in the setting of systemic disease. After a complete staging work-up that includes a PET/CT and brain MRI, staging for patients with locally advanced, stage IIIA, and select T4 disease should be discussed by a multidisciplinary care team that includes a thoracic surgeon. Initiating thoracic surgeon involvement at the time of diagnosis is particularly important in stage IIIA NSCLC, because surgeons play a critical role in determining which patients are surgical candidates and in planning mediastinal biopsies during initial staging and restaging.

Nearly half of all patients will have mediastinal disease at the time of diagnosis; therefore, any mediastinal lymph nodes suspicious for metastatic disease on PET/CT require pathologic confirmation. Cervical mediastinoscopy remains the gold-standard approach to pathologically stage the mediastinum, but other methods—including endobronchial ultrasound (EBUS) and esophageal ultrasound (EUS) with fine needle aspiration (FNA)— have the benefit of being easily repeated if restaging is necessary. This is an important consideration in stage IIIA disease; many of these patients will require pathologic mediastinal staging at the time of diagnosis and again after induction treatment before a surgical re-

section, because imaging-based mediastinal restaging after treatment is unreliable.

PET/CT for initial staging of the mediastinum has a reported sensitivity of 80% and a specificity of 70%.[2] However, it is much less accurate for restaging after chemotherapy or radiation. A meta-analysis of the accuracy of PET mediastinal restaging after neoadjuvant treatment demonstrated an overall sensitivity of 64% and a specificity of 85% in assessing mediastinal disease.[3] Given these inaccuracies, pathologic restaging with a repeat cervical mediastinoscopy or an EBUS/EUS-FNA is recommended before proceeding with surgery. Despite these recommendations, a 2010 survey of National Comprehensive Cancer Network (NCCN) member institution practice patterns showed that 60% do not pathologically restage the mediastinum after neoadjuvant therapy to make a final decision regarding surgery.[4]

For mediastinal staging, cervical mediastinoscopy remains the gold standard, with a sensitivity of 86% and a negative predicted value of 95% for detecting metastatic disease.[5] Large studies of initial mediastinoscopy have shown it to be safe, with a 0.05% procedure-related mortality rate and a 0.6% complication rate that mostly is due to vocal cord dysfunction and arrhythmia.[5,6] However, repeating a cervical mediastinoscopy is technically challenging, more dangerous, and less accurate. Fibrosis and scarring from the first attempt obliterates natural tissue planes, and interval radiation further worsens this process. For this reason, we recommend saving the first mediastinoscopy for restaging just before surgery and using EBUS and EUS-FNA during the initial staging work-up.

In situations where is it absolutely necessary, repeat mediastinoscopy is possible, and experienced institutions have

published outcomes demonstrating its safety. Marra et al[7] reported repeat mediastinoscopy in 104 patients with lung cancer after induction chemoradiotherapy. Repeat mediastinoscopy was possible in 98% of patients, with 0% mortality and 1.9% morbidity as a result of left recurrent nerve palsy. Repeat mediastinoscopy had a sensitivity of 61%, a specificity of 100%, a positive predictive value of 100%, and a negative predictive value of 85%. Successful biopsy results are dependent on the lymph node station; the best results are seen for stations 2R, 4R, 4L, and 7, with successful biopsy rates of 88% to 98% at first mediastinoscopy and 63% to 84% at repeat mediastinoscopy. Station 2L, which must be approached with caution because of its proximity to the left recurrent laryngeal nerve, was successfully biopsied during only 56% of first mediastinoscopies and 21% of repeat procedures.[7] Call et al[8] during a similar experience with 101 repeat mediastinoscopies reported a sensitivity of 74%, a specificity of 100%, a positive predictive value of 100%, and a negative predictive value of 79%.[8] These data show that repeat mediastinoscopy is feasible; however, individual surgeon experience and comfort level are of paramount importance before attempting a repeat mediastinoscopy.

EBUS- and EUS-FNA are useful and accurate alternatives for staging the mediastinum. EBUS-FNA has a reported sensitivity of 92%, a specificity of 100%, a positive predictive value of 100%, and a negative predictive value of 97% for staging mediastinal lymph nodes in NSCLC.[2] EUS-FNA is an additional technique that was first developed to stage gastric and esophageal cancer but that has gained popularity in lung cancer as well, because it provides access to the posterior mediastinum through the esophageal wall. A meta-analysis demonstrated an overall sensitivity of 83% and a specificity of 97% of EUS-FNA at detecting malignant lymph nodes in patients with NSCLC.[9] After induction treatment, Annema et al[10] reported their experience with 19 consecutive patients who had NSCLC with mediastinal disease who required restaging. Biopsy specimens were successfully obtained via EUS-FNA from at least one lymph node station in 89% of patients and from two different lymph node stations in 47% of patients.[10] Both EBUS and EUS can be performed safely and accurately after induction treatment for restaging purposes. At our institution, we preferentially use EBUS and EUS-FNA for initial mediastinal staging and reserve the first attempt at mediastinoscopy for restaging before surgery.

Patient selection for surgery in stage IIIA disease depends on the surgeon's experience and the patient's ability to tolerate a pulmonary resection. At our institution, we strongly believe in the benefits of definitive local control and have an aggressive surgical approach. We offer resection to patients who have stage IIIA tumors despite size, invasion into the main bronchus, mediastinal pleura, parietal pericardium, or resectable N2 disease as long as a complete R0 resection with clean margins is achievable. We also offer resection to select patients with T4 disease on the basis of the presence of isolated but resectable tumor nodules in a different ipsilateral lobe and tumors invading mediastinal structures, vena cava,

---

KEY POINTS

- Thoracic surgeons should be involved early in the multidisciplinary management of stage IIIA disease in patients to identify operative candidates and help guide pathologic staging of the mediastinum.
- A triple-modality treatment approach in patients with N2 mediastinal disease can achieve 5-year overall survival rates of up to 30% to 40%; good prognostic indicators are a response to induction treatment and the need for lobectomy instead of pneumonectomy.
- Pneumonectomy outcomes have improved over time, and the need for a pneumonectomy is not a reason to avoid a surgical resection in patients who can tolerate the procedure.
- Video-assisted thoracic surgery survival outcomes are comparable to those after open thoracotomy, though no randomized trials have directly compared the two approaches in stage IIIA disease.
- In the era of personalized medicine, genetic profiling of stage IIIA tumors for prognostic risk stratification is a promising area of new research that could help guide treatment decisions and better predict patient-specific outcomes within this heterogeneous stage.

atrium, or diaphragm when we believe we can perform an R0 resection. Patients with extensive T4 tumors in whom a complete resection is unlikely are generally poor surgical candidates. All of these treatment decisions are made as part of a multidisciplinary care team discussion and with the agreement of our thoracic oncologists and radiation oncologists.

MANAGEMENT OF STAGE IIIA WITH N2 MEDIASTINAL INVOLVEMENT

Patients with stage IIIA disease and N2 lymph node involvement range from those with small tumor foci in a central node to those with bulky multi-station disease who, therefore, pose the greatest treatment challenge for thoracic oncologists. The nature of mediastinal disease portends bad outcomes and possible microscopically systemic, stage IV disease. However within this group, surgery can provide definitive local control and lead to long-term survival for some patients. Randomized, controlled trials to evaluate the value of surgery in N2 disease have been continually plagued by enrollment difficulties and many have closed prematurely. In addition, they have been affected over time by changes in staging criteria, evolving induction chemotherapy and radiation trends, and the development of novel chemotherapy agents.

Early clinical trials, such as the Southwest Oncology Group (SWOG) 8805 study, demonstrated that patients with initially unresectable NSCLC could have their tumors downstaged with induction chemoradiation and ultimately undergo successful surgical resection. In this trial, patients whose tumors did not respond to induction treatment or had positive margins or nodes in the surgical specimen were given additional chemotherapy and radiation. Patients who underwent surgery had a median overall survival of 23.6 months versus 22.2 months among patients who only received chemotherapy and radiation. The 3-year overall survival with triple-modality treatment was 27% versus 20% in the chemotherapy and radiation group, respectively. Patients whose tumors were downstaged to N0 disease after induction chemoradiation had the best outcomes, with triple-modality treatment with a 3-year survival rate of 44%. Collectively, these outcomes demonstrated that a triple-modality treatment approach was not worse than chemotherapy and radiation alone and, in certain subgroups of patients, led to improved survival outcomes.

More recently, two large, randomized clinical trials have examined the benefits of surgery in patients with stage IIIA, N2 NSCLC: the European Organization for Research and Treatment of Cancer (EORTC) 8941 trial and the North American Intergroup (INT) 0139 trial. EORTC 8941 compared surgery and radiation therapy in patients with stage IIIA N2 disease who responded to induction chemotherapy. Of 579 enrolled patients, 61% responded to three cycles of platinum-based induction chemotherapy and, therefore,

were randomly assigned to either radiotherapy or surgery. A complete surgical resection was achieved in 50% of patients randomly assigned to surgery. Pneumonectomy was required in 47% of patients, and the overall operative mortality rate was 4%. Adjuvant radiotherapy was given to 40% of patients after surgery. There were no differences in survival between patients who underwent a surgical resection or radiotherapy, with a median survival of 16.4 months versus 17.5 months, respectively, and a 5-year overall survival rate of 15.7% and 14.0%, respectively.[12] This trial has been criticized for inadequate clinical staging, without PET/CT or brain MRI, which likely led to the inclusion of some patients with later-stage IIIB and IV disease. In addition, the study reported a relatively low rate of a complete R0 surgical resection and a high rate of pneumonectomy, which may reflect the advanced disease in these patients and account for the greater morbidity in the surgical arm of the study.[4]

As data emerged that concurrent neoadjuvant chemotherapy and radiation yielded better outcomes than sequential administration, new randomized, controlled trials were designed to define the role of surgical resections. INT 0139 involved 429 patients with pathologically proven stage IIIA N2 disease who were first treated with induction chemotherapy plus radiation and then randomly assigned to surgery followed by adjuvant chemotherapy or continued radiation, up to 61 Gy, followed by more chemotherapy. A complete surgical resection was achieved in 71% of patients randomly assigned to surgery. Overall there were no differences between patients who underwent a complete surgical resection versus definitive, full-dose radiation, with median overall survival times of 23.6 months versus 22.2 months, respectively, and 5-year survival rates of 27% and 20%, respectively. However, PFS was significantly improved with surgery (12.8 months vs. 10.5 months; p = 0.017). Survival outcomes also were significantly better in the subgroup of patients whose tumors were downstaged to N0 by induction chemotherapy, with a median overall survival time of 34.4 months and a 5-year survival rate of 41% (p = 0.0001).[13]

Another large trial to include patients with stage IIIA disease was the Adjuvant Navelbine International Trialist Association (ANITA) trial, which demonstrated a survival benefit with adjuvant chemotherapy in patients who had stage IB to IIIA, fully resected lung cancer. Among patients who received adjuvant cisplatin-based chemotherapy and radiation after surgery, there was a 5-year overall survival rate of 47% among patients with N2 disease.[14] Similar outcomes have been reported in single-institution, retrospective studies of tri-modal therapy in patients with stage IIIA N2 disease. Askoxylakis et al[15] reported a median survival time of 32 months and 1-, 3-, and 5-year survival rates of 85%, 50%, and 36%, respectively; 32% of patients who underwent an R0 resection remained disease free at 5 years.[15]

These clinical trials have consistently shown that certain characteristics are good prognostic indicators in stage IIIA N2 disease. A response to treatment or downstaging of the

mediastinum is predictive of more favorable outcomes after tri-modality treatment. Patients who undergo lobectomy have better overall survival times than patients who require bi-lobectomy or pneumonectomy, which may be related to both operative mortality and more advanced disease among the pneumonectomy group. Also, patients who have tumors with squamous cell histology have an overall better prognosis than those who have adenocarcinoma; one study reported a 43% 5-year overall survival rate for squamous cell histology compared with 36% for adenocarcinoma.[11,15,16] Tri-modal therapy offers the best chance of definitive local control and long-term survival for these patients with stage IIIA disease, and we recommend an aggressive approach in considering a patient for a potentially curative surgical resection.

At our institution, we typically relegate patients who have bulky N2 disease to induction chemotherapy or chemoradiation. If these patients have tumors that are downstaged on repeat imaging, and if we feel that all the node disease can be encompassed with a radical mediastinal lymphadenectomy, then we proceed with a surgical resection at that time. The default operation at our institution is a radical mediastinal node dissection, and we are aggressive in offering resection for patients with N2 disease, because we believe we can clear all of their disease. Patients who have bulky N2 disease with tumors that are not downstaged by induction therapy will continue on to definitive chemoradiation.

PNEUMONECTOMY: WORTH THE MORBIDITY AND RISK?

In the past, published outcomes after pneumonectomy were poor and often cited as reasons to avoid surgery, because the mortality from the operation itself was so high that it offset any potential survival benefits. INT 0139 trial data showed that patients with stage IIIA N2 disease who underwent pneumonectomy after induction chemoradiation had a 27% mortality rate because of postoperative complications of pneumonectomy, mainly acute respiratory distress syndrome and other respiratory causes. Performing a pneumonectomy did not improve survival outcomes, with 5-year survival rates of 22% and 36% in patients who underwent pneumonectomy and lobectomy, respectively.[13] The high perioperative mortality rate likely undercut any long-term survival benefits seen in those patients.

In addition to procedure-related mortality, retrospective studies have shown that the need for a pneumonectomy, compared with a lobectomy, is a poor prognostic indicator. Steger et al[17] reported survival outcomes with tri-modal therapy in 146 patients with stage IIIA NSCLC, 53% of whom required pneumonectomy after induction chemotherapy and radiation. Overall, approximately half of the patients experienced treatment-related comorbidity regardless of lobectomy or pneumonectomy, and the 30-day mortality was 2.7% as a result of four deaths in patients who underwent a pneumonectomy. Though none of the differences were statisti-

cally significant, the 5-year overall survival rate was 45% versus 33%, and the median survival was 55 months versus 26 months, in patients who underwent lobectomy or bi-lobectomy versus pneumonectomy, respectively. The need for a left-sided pneumonectomy was a favorable prognostic indicator, with a 5-year survival rate of 36% versus 29% in patients who underwent a right-side pneumonectomy.[17]

More recent studies from experienced and high-volume institutions have reported increasingly favorable outcomes, citing procedure-related mortality rates of less than 5% and 5-year survival rates ranging from 30% to 38% in patients with stage IIIA disease who have undergone a pneumonectomy as part of a multimodality treatment regimen.[17,18] A recent, retrospective review of 36 consecutive patients at a single institution who underwent pneumonectomy for stage IIIA lung cancer found encouraging 1-, 3-, and 5-year survival rates of 66%, 38%, and 38%, respectively. The 5-year survival rate for patients who underwent adjuvant therapy was 60% compared with only 33% in patients who received only neoadjuvant therapy and 30% in patients treated with surgery alone.[18]

In experienced centers, pneumonectomy can be safely performed as a curative resection with low operative mortality and acceptable morbidity. Contemporary pneumonectomy outcomes data from the Society for Thoracic Surgeons (STS) General Thoracic Surgery Database (GTSD) has shown a mortality rate of 5.6% and a 30.4% rate of major perioperative adverse events for all patients undergoing pneumonectomy. Analysis of the GTSD has revealed that age older than 65, male sex, congestive heart failure, forced expiratory volume in 1 second less than 60% of predicted, and receipt of neoadjuvant chemoradiotherapy are all predictors of postoperative complications.[19]

At our institution, we have developed several perioperative protocols to decrease complications and mortality from pneumonectomy. During anesthesia induction, patients receive 120 milligrams of intravenous methylprednisolone to decrease the cytokine storm and blunt the inflammatory response from a pneumonectomy. Throughout the operation, anesthesiologists aim to maintain tight volume control with sparing use of fluids, to avoid blood product transfusions, and to use acute respiratory distress syndrome (ARDS) ventilator setting that include low tidal volumes, low fraction of inspired oxygen, and minimal peak pressures. All immediate postoperative care of patients after pneumonectomy occurs in a cardiac intensive care unit with specialized intensivists, nurses, and respiratory therapists. These coordinated efforts of our experienced team have led to low post-pneumonectomy morbidity and mortality.

In experienced centers, pneumonectomy can be performed with acceptably low operative mortality and good long-term survival as part of a tri-modal treatment regimen; therefore, the need to perform a pneumonectomy is not a reason to deny patients the opportunity for definitive local control. Unfortunately, the need for a pneumonectomy also portends more advanced disease, and these patients have shorter sur-

vival times than those who can be treated with lobectomy alone.

WHEN IS VIDEO-ASSISTED THORACIC SURGERY APPROPRIATE?

There is increasing data to show that larger pulmonary resections can be safely performed with a minimally invasive video-assisted thoracic surgery (VATS) technique and that VATS is acceptable for stage IIIA disease. Initially, many characteristics that defined stage IIIA tumors—including larger tumor size, involvement of adjacent structures, any nodal involvement, centrally located tumors, and previous chemotherapy or radiation—were considered relative contradictions for VATS. However, increasing VATS experience demonstrates that even tumors with these features can be safely resected with a VATS approach.[20]

There is also concern that complete oncologic mediastinal lymph node dissections with VATS are more difficult to perform and, therefore, that patients may receive inferior oncologic resections. Merritt et al[21] performed a retrospective review of lymph nodes sampled during VATS versus open lobectomies for clinical N0 disease. They found significant differences in the mean number of lymph nodes sampled (15 nodes in open vs. 10 in VATS; p = 0.003) and in the percentage of patients whose tumors were upstaged to pathologic N1 or N2 status (25% after open vs. 10% after VATS; p = 0.05). The difference in pathologic upstaging would lead to important differences in postoperative treatment and, potentially, long-term survival outcomes for these patients.[21] Conversely, others have shown no differences in the number of total or mediastinal lymph nodes sampled and no differences in disease-free survival or 5-year overall survival rates between the two approaches.[22]

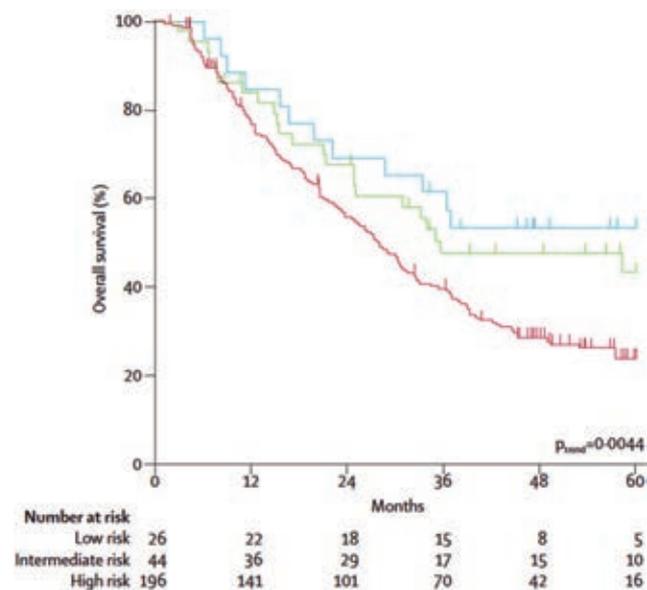
Multiple nonrandomized studies have retrospectively examined long-term survival after VATS compared with open thoracotomy and shown no survival detriment with VATS in stage IIIA disease. To examine VATS lobectomy, Yang et al[23] compared outcomes in a total of 621 patients. Of these, 67 patients has stage IIIA or greater NSCLC, and a VATS lobectomy was feasible in 13% of those patients with later-stage disease. In patients with stage IIIA disease who were undergoing VATS lobectomy, Yang et al observed a 5-year overall survival rate of 22% that was not different from the 24% 5-year overall survival rate for patients who underwent open thoracotomy.[23] However, the study was not randomized, so the patients selected by the surgeons for VATS lobectomy likely had smaller disease burdens and, therefore, more favorable prognoses.

Pneumonectomy in patients with stage IIIA disease also can be performed via VATS. Battoo et al[24] recently published a report of an 11-year, single-institution experience comparing VATS versus an open approach in 107 consecutive pneumonectomies. Among patients chosen for VATS pneumonectomy, 16% were converted to open. Patients with later-stage disease made up a large proportion of the study; the final pathology was stage III or stage IV for 27% of all patients who underwent VATS and 38% of all open pneumonectomies. The authors recognize that there was likely selection bias, because the study was not randomized and surgeons would be more prone to offer VATS to patients who had earlier-stage, less-invasive tumors. In the open operations, patients received an R1, not R0, resection 23% of the time, compared with only 10% of the time in the VATS group, which suggests that patients who had more difficult resections, closer margins, and more invasive disease were offered open thoracotomies. The 30-day mortality rate was 7.5% for VATS and was 5.0% for open, but this difference was not statistically significant. Locoregional recurrence rates were 10% for both groups of patients, and recurrence at any site was 30% in the VATS group and 38% in the open group without any statistically significant differences. Patients with clinical stages III and IV disease who underwent pneumonectomy did not have different overall survival rates; the median survival was 60 months in patients who underwent VATS versus 41 months in those who underwent VATS but converted to open and 13 months in patients in the open group. There were also no differences in overall survival based on pathologic stages III and IV disease. Rates of median survival were 18 months in the VATS group, 41 months in the VATS-converted-to-open group, and 7 months in the open group. The longer survival times in patients whose were chosen to undergo VATS and then were converted to an open operation reveal the inherent selection bias in the study, because both groups ultimately had an open thoracotomy.[24] However, it appears that, in a select group of patients with later-stage III and IV disease, complication rates and long-term survival outcomes after VATS pneumonectomy were not inferior to those of open pneumonectomy.

At our institution, we favor an open thoracotomy for patients with stage IIIA lung cancer, because these patients with stage III disease have had previous chemotherapy and radiation. We believe that, in these patients, an open approach ensures a complete lymph node dissection and optimizes the opportunity for definite local control. Without a randomized, controlled trial, it is difficult to make unbiased outcome comparisons between VATS and open resections. However, it appears that, in experienced hands, long-term survival outcomes for carefully selected patients are no worse with VATS resection than for patients who undergo an open approach.

MOLECULAR PROFILING IN LATE-STAGE DISEASE

An interesting new area of research in the management of stage IIIA NSCLC is the molecular profiling of tumors to further stratify patients by risk. Most of the current literature surrounding genetic profiling in lung cancer has focused on predicting recurrence in early-stage disease, but similar assays may have prognostic value in later lung cancer stages as well. Molecular assays of biopsy specimens could be used preoperatively to help guide patient selection for surgery

FIGURE 1. Molecular Profiling Predicts Survival in Stage III Lung Cancer


Analysis of nonsquamous stage III NSCLC tumors with a molecular assay divides patients into low, intermediate, and high risk groups on the basis of the genetic profiles of the tumors. Risk stratification by the molecular assay successfully predicts survival, with significant differences in 5-year overall survival rates (p = 0.0044). Prognostic assays such as this one may help guide future management of stage III NSCLC, but current data are limited and further investigation in this area is needed.[25]

and tumor biopsies, with high-risk profiles suggestive of ominous genetics, and imminent systemic disease could predict shorter survival times or the high likelihood for recurrence after surgery, which therefore would allow physicians to make more informed decisions about surgical candidacy.

A 14-gene expression assay was developed at our institution to stratify the mortality risk in nonsquamous NSCLC tumor specimens. This molecular assay has been internationally validated in more than 2,000 patients to predict disease recurrence and has repeatedly outperformed conventional staging criteria and high-risk NCCN clinicopathologic features.[25-28] Among a validation cohort from the China Clinical Trials Consortium that included 266 patients with stage IIIA disease who underwent an attempt at surgical resection, Kratz et al[25] demonstrated that there were significant differences in survival based on a tumor's genetic profile. Of these 266 patients, molecular profiling determined that 73% had high-risk tumors, 17% had intermediate-risk tumors, and 10% had low-risk tumors. The 5-year overall survival outcomes were significantly different between these groups, with only a 25% 5-year survival rate in high-risk patients compared with approximately a 50% 5-year survival rate in the low- and intermediate-risk groups (p = 0.0044; Fig. 1). The genetic profile of a tumor provides additional prognostic information to predict which patients within the same clinicopathologic stage are at higher risk of disease recurrence.[25]

Other studies have examined the use of markers from surgical pathology specimens to predict treatment response in later-stage disease. Shen et al[29] examined microRNA expression profiles in stages IIB and IIIA, fully resected, *EGFR*-mutant NSCLC and found that certain mRNA expression levels were predictive of disease recurrence, survival, and response to gefitinib.[29]

This is an emerging area of research, and much more work is still needed. However, preliminary studies are interesting and suggest that there is important prognostic information to be gained from genetic profiling of late-stage tumors. This information can predict recurrence or overall survival times within patients who have stage IIIA disease and also could be used to make more informed adjuvant treatment decisions. On preoperative biopsy specimens, patients with stage IIIA disease and favorable tumor genetics may be more likely to have limited local disease and, therefore, would benefit the most from local control with a surgical resection. Specific molecular assays might be developed to predict which tumors are most likely to be downstaged by induction therapy or to predict the response to certain chemotherapy or radiation regimens. As tumor mutation analysis and personalized medicine become the standard of care, patients with NSCLC will expect a more detailed tumor assessment, an individualized treatment plan, and an enhanced survival risk stratification.

CONCLUSION

Stage IIIA NSCLC includes a heterogeneous group of patients and an overall grim prognosis. Management of this stage involves separating patients who have curable local disease from those who essentially have early systemic disease. In appropriate surgical candidates, a complete a surgical resection provides optimal local control and has real survival benefits beyond chemotherapy and radiation alone. Surgical resections likely improve survival by removing the resilient and treatment-resistant cancer stem cell populations. Cancer stem cells make up a small percentage of all tumor cells and are unique in that they posses the qualities of self-renewal and pluripotency, a high proliferative capacity, and the ability to resist chemotherapy and radiation.[30] Tumor recurrence after dramatic responses to chemotherapy and radiation has been attributed to the lingering presence of isolated stem cells, which have the ability to repopulate an entire tumor after surviving treatment.[31] Eradication of this critical cell population is best achieved by removing any residual, microscopic tumor foci via a surgical resection after induction therapy.

The real future in managing stage IIIA disease lies in the development of better systemic therapies to successfully downstage tumors before obtaining definitive local control with a surgical resection. In addition, there is a need for improved prognostic molecular testing in later-stage tumors to help predict which patients will respond to induction therapy and to provide improved survival risk stratification after surgery. As these new technologies are developed, a multidisciplinary thoracic oncology team remains critical to make individualized treatment recommendations that optimize long-term survival.

Current Standards and Clinical Trials in Systemic Therapy for Stage III Lung Cancer: What Is New?

Nasser Hanna, MD

OVERVIEW

Patients with stage III non–small cell lung cancer (NSCLC) comprise a heterogeneous group, some of whom have curable disease. Although surgery plays a role for some patients, the majority of fit patients will be treated with chemotherapy and radiation alone. The optimal therapy for all patients remains undefined, but certain principles of care are widely accepted. Specifically, concurrent chemoradiation is the standard of care for patients who are able to tolerate such therapy, namely those with a good performance status, minimal or no weight loss, and adequate end-organ function, including pulmonary reserve. The most commonly used chemotherapy regimens given in combination with radiation therapy are cisplatin/etoposide or carboplatin/paclitaxel. Studies incorporating newer agents have not improved outcomes when compared to these older regimens. The merits of chemotherapy administered beyond the conclusion of radiation therapy continue to be debated, but thus far randomized phase III trials have not provided supporting evidence for this strategy. Incorporating antiangiogenics with chemoradiation has proven to be ineffective in some cases and unsafe in others. Studies with targeted agents in unselected patient populations with stage III disease have also been disappointing. Despite these recent setbacks, however, there remains a sound rationale for incorporating molecularly targeted agents into chemoradiation regimens in select patient groups or consolidating chemoradiation with immunotherapy. Studies that incorporate drugs targeting *EGFR, ALK, RAS*, programmed cell death 1 (PD-1), and programmed death ligand 1 (PD-L1) into the management of patients with stage III NSCLC will be reviewed.

Some patients with stage III NSCLC have curable disease, although the majority will die within 3 years. This variability in outcome is a result of the heterogeneity of clinical presentations, fitness of patients, and the biology of disease. Poor prognostic variables for toxicity and/or outcomes include decreased performance status, the presence of significant weight loss, N3 disease, increased number of lymph node stations involved, and the volume of lung that will receive at least 20 Gy (V_{20}) of radiation.[1-3] Challenges in treating this patient population include advanced age (median age older than 70) and the presence of multiple comorbidities which are related to chronic tobacco exposure, including compromised cardiopulmonary function. Therapeutic decisions in the advanced-stage setting are driven by tumor histology and the presence or absence of key genetic alterations. However, the integration of this knowledge into the treatment of patients with stage III disease has lagged behind.

ADVANCES IN THE TREATMENT OF PATIENTS WITH STAGE III NSCLC

Despite these obstacles, advances have been realized over the last 30 years in the treatment of patients with stage III NSCLC (Table 1).[4] For a subset of patients, surgery remains an inte-

gral part of therapy.[2,5] For the majority, radiation therapy is the backbone of treatment. Beginning in the 1980s, the integration of chemotherapy with radiation therapy prolonged survival and increased the cure rate compared with radiation therapy alone.[6,7] In the 1990s and early 2000s, the concurrent use of chemotherapy with radiation therapy proved modestly more effective than the sequential use of these modalities.[4] In addition, the routine use of PET imaging within the last 2 decades has aided in staging and radiation planning.

For fit patients with stage III unresectable or inoperable NSCLC who have adequate end-organ function including pulmonary reserve, an absence of other substantial comorbidities or weight loss, and a V_{20} less than 35%, concurrent chemoradiation is a standard of care.[4,8,9] However, the optimal choice of chemotherapy agents and the number of cycles to be given remains unsettled. Platinum-containing regimens are standard. Two cycles of cisplatin/vinblastine followed by radiation therapy proved to be superior to radiation therapy alone.[7] Subsequent studies have tested a platinum (P) agent with etoposide (E), mitomycin (M) plus vindesine (V), vinorelbine, irinotecan, paclitaxel, docetaxel, or pemetrexed.[8-13] Few trials have compared these regimens head-to-head and those that have report small therapeutic differences. The West Japan Thoracic Oncology Group (WJTOG) reported no substantial differ-

TABLE 1. Key Historic Clinical Trials in Unresectable or Inoperable Stage III NSCLC

Group	Design	Comment
CALGB[7]	Chemotherapy→ XRT versus XRT	Established the role of sequential chemotherapy followed by radiation in stage III disease
WJLCG[9]	Concurrent ChemoXRT versus Sequential ChemoXRT	Demonstrated concurrent chemoradiation may be superior to sequential therapy
RTOG[8]	Concurrent ChemoXRT versus Sequential ChemoXRT	Confirmed the superiority of concurrent chemoradiation over sequential therapy
CALGB[16]	Chemotherapy → ChemoXRT versus ChemoXRT	Induction therapy prior to concurrent chemoradiation does not prolong survival compared to concurrent chemoradiation alone
HOG/USO[17]	ChemoXRT versus ChemoXRT → Chemo	Consolidation docetaxel does not improve survival compared to concurrent chemoradiation alone
South Korea[13]	ChemoXRT versus ChemoXRT → Chemo	Consolidation therapy utilizing cisplatin and docetaxel does not improve survival when added to weekly platinum/taxane/XRT
SWOG[21]	ChemoXRT → Chemo versus ChemoXRT → Chemo → Gefitinib	The addition of gefitinib as consolidation in an unselected patient population is potentially harmful
RTOG[12]	ChemoXRT versus ChemoXRT + Cetuximab	The addition of cetuximab to concurrent chemoradiation does not improve survival compared with concurrent chemoradiation alone

Abbreviations: NSCLC, non-small cell lung cancer; CALGB, Cancer and Leukemia Group B; XRT, external beam radiation therapy; WJLCG, West Japan Lung Cancer Group; Chemo, chemotherapy; RTOG, Radiation Therapy Oncology Group; HOG, Hoosier Oncology Group; USO, US Oncology; SWOG, Southwest Oncology Group.

ences in overall survival when comparing third-generation chemotherapy with second-generation chemotherapy.[10] A randomized study of radiation therapy combined with MVP, carboplatin/irinotecan, or carboplatin/paclitaxel reported comparable survival, but higher toxicity with MVP. A second study from Japan compared radiation combined with MVP or cisplatin/docetaxel.[14] Two-year survival rates favored cisplatin/docetaxel (p = 0.059), although grade 3 or 4 esophagitis were also higher in the docetaxel arm. A phase III trial investigating cisplatin/pemetrexed and radiation therapy followed by consolidation pemetrexed compared to PE with concurrent radiation followed by consolidation chemotherapy has been completed (NCT00686959). Although efficacy endpoints have not been reported, toxicity profiles differed modestly.[15] The most commonly used regimens in the United States are PE or carboplatin plus paclitaxel. A retrospective analysis within the Veterans Health Administration data of 1,842 patients treated with either regimen suggested comparable survival outcomes, although PE was associated with increased toxicities.[16] However, to date, a prospectively conducted randomized phase III trial comparing these two regimens has not been reported.

THE ROLE OF INDUCTION OR CONSOLIDATION CHEMOTHERAPY FOLLOWING CHEMORADIATION

The initial gains in survival with the addition of chemotherapy to radiation were appreciated in phase III studies utilizing only two cycles of chemotherapy.[7] This stands in contrast to the use of three cycles of chemotherapy given in the neoadjuvant setting, four cycles in the adjuvant setting, and four to six cycles of combination therapy followed by maintenance therapy in the metastatic setting. Therefore, additional attempts to improve outcomes have focused on delivering additional chemotherapy before (induction) concurrent chemoradiation or following (consolidation) concurrent chemoradiation. Each of these strategies has been extensively studied in phase II and III studies. Unfortunately, neither approach has clearly demonstrated improved survival times compared to concurrent chemoradiation alone. For example, a phase III study from the Cancer and Leukemia Group B randomly assigned patients to receive concurrent weekly carboplatin plus paclitaxel and radiation or the same therapy preceded by two cycles of full-dose carboplatin and paclitaxel.[17] No difference in overall survival was reported. Investigators from the Hoosier Oncology Group and US Oncology evaluated the role of consolidation docetaxel.[18] In this phase III study patients were treated with concurrent PE and 59.4 Gy of radiation and then randomly assigned (if their disease had not progressed) to receive docetaxel for three cycles or observation alone. No survival difference was seen, but patients receiving docetaxel had higher rates of pneumonitis and febrile neutropenia. More recently, Huber et al treated patients with concurrent cisplatin plus oral vinorelbine and radiation and then randomly assigned them to either consolidation cisplatin plus vinorelbine or best supportive care.[19] Progression-free and overall survival times were almost identical.

KEY POINTS

- Stage III non–small cell lung cancer comprises a heterogeneous group of patients.
- Concurrent chemoradiation is the standard of care for most fit patients with stage III disease.
- The optimal chemotherapy agents and duration of therapy remain undefined.
- Early results incorporating targeted agents or antiangiogenics have proven ineffective or, in some cases, unsafe.
- Newer strategies with molecularly targeted agents, including inhibitors of *EGFR*, *ALK*, *RAS*, and PD-1, are under investigation.

At the 2014 ASCO Annual Meeting, Park et al reported the results from their phase III trial testing consolidation therapy utilizing a platinum agent and a taxane.[13] All patients initially received weekly cisplatin and docetaxel with concurrent radiation followed by consolidation cisplatin and docetaxel versus observation alone. Although no survival difference was reported, patients receiving consolidation therapy experienced substantially more toxicity. A similar study design evaluating the role of consolidation carboplatin plus paclitaxel (versus observation) following weekly carboplatin and paclitaxel given concurrently with radiation has not been conducted. A pooled analysis of the literature which included 41 phase II or III studies indicated no improvement in survival (hazard ratio [HR] 0.94 for median survival time; p = 0.4) with any consolidation strategy, including using the same drugs in consolidation as were given with concurrent radiation, switching chemotherapy agents, or incorporating novel or molecularly targeted agents.[20]

Regardless of the drugs used, doses of radiation, or duration of chemotherapy, it appears we have reached a plateau in survival with current strategies in stage III NSCLC. Although the median survival time has improved in contemporary studies, the 3-year survival rates (a surrogate for long-term survival or even cure) are only 15% to 25%. Improvements in median survival may be attributed to better patient selection, stage migration, improved radiation techniques and supportive care, and greater experience by clinicians in treating this population of patients with concurrent chemoradiation.[21]

INITIAL ATTEMPTS AT INCORPORATING NOVEL AGENTS INTO CHEMORADIATION REGIMENS

Initial attempts to incorporate molecularly targeted therapies into chemoradiation have been disappointing thus far. A phase III study from the Southwest Oncology Group treated patients (irrespective of EGFR status) with PE plus radiation followed by consolidation docetaxel. Patients without progressive disease were randomly assigned to receive further therapy with gefitinib or placebo.[22] Overall survival favored placebo. More recently, a study led by the Radiation Therapy Oncology Group randomly assigned patients with stage III NSCLC to receive chemoradiation (60 Gy vs. 74 Gy; MST 28.7 vs. 20.3 months, HR 1.38, p = 0.004). with or without cetuximab. Survival times favored 60 Gy, and the addition of cetuximab provided no additional benefit.[12] Furthermore, attempts at incorporating antiangiogenic agents have proven to be ineffective or unsafe.[23-26]

NEWER STRATEGIES INCORPORATING MOLECULARLY TARGETED AGENTS INTO STAGE III NSCLC

Despite these early failures incorporating molecularly targeted agents into chemoradiation regimens, the scientific rationale to do so remains sound (Table 2). The initial trials evaluating EGFR targeting agents did not require patient se-

TABLE 2. Key Ongoing or Planned Clinical Trials in the United States in Unresectable or Inoperable Stage III NSCLC

Study Design	Schema	NCT Registry Number
Randomized phase II	Arm 1: Erlotinib→ ChemoXRT	01822496
	Arm 2: ChemoXRT (EGFR mut cohort)	
	Arm 3: Crizotinib→ ChemoXRT

lection based on the tumor molecular profile. Continued efforts to target the EGFR in stage III disease are underway. Radiation is known to increase the expression of EGFR, resulting in radiation resistance.[27] Proposed mechanisms for this include EGFR interaction with DNA repair enzymes; EGFR activation of PI3K/AKT signaling which suppresses DNA damage-induced apoptosis; and activation of downstream signaling through the RAS and STAT pathways to promote cancer cell repopulation. Furthermore, tumors with activating EGFR mutations appear to be more sensitive to radiation than their EGFR wild-type counterparts.[27,28] This may be because mutated EGFR fails to bind to a key enzyme in DNA repair. Similarly, in vitro studies suggest that cell lines that harbor ALK fusion proteins may be more sensitive to ALK inhibition combined with radiation.[29] In one experiment, the combination of crizotinib with radiation resulted in greater tumor growth inhibition than either treatment alone in a cell line with an ALK fusion protein. Similar effects were not seen in a cell line without the ALK fusion protein.

Based on this preclinical data, a study of erlotinib or crizotinib as induction therapy in patients with stage III NSCLC is ongoing (NCT 01822496). Approximately 234 patients with nonsquamous NSCLC will be stratified based on *EGFR* mutation and *ALK* gene-rearrangement status and randomly assigned to one of four arms. Patients on arm 1 and 3 receive erlotinib or crizotinib, respectively, as induction therapy for up to 12 weeks. Those who have no disease response after 6 weeks will undergo immediate chemoradiation. After 2 weeks of completion of induction therapy, patients receive concurrent chemoradiation with cisplatin and etoposide or carboplatin and paclitaxel. Patients on arm 2 (*EGFR* mutation cohort) or arm 4 (*ALK* gene-rearranged cohort) receive concurrent chemoradiation beginning on day 1. The primary objective is to assess whether patients treated with targeted agents based on molecular characteristics have a longer progression-free survival than those treated with chemoradiation alone.

The *RAS* oncogene has also been proposed to play a role in radiation resistance.[30] Although targeting *RAS* activation directly has yielded disappointing results, downstream targets of *RAS*, including *MEK*, may be feasible. In vitro studies demonstrate an increased radiosensitization when such downstream pathways are inhibited. It has also been proposed that PI3K is a mediator of *RAS*-induced radiation resistance. Efforts are underway within the National Cancer Institute to incorporate trametinib (NCT 01912625), a *MEK* inhibitor, into chemoradiation in patients with *KRAS* mutations. Approximately 30 patients with any histology NSCLC with a *KRAS* mutation in exons G12, G13, or Q61 will receive daily oral trametinib with concurrent carboplatin, paclitaxel, and radiation for 6 weeks followed by two cycles of consolidation carboplatin and paclitaxel alone. The primary objective is to determine the maximum tolerated dose of trametinib when combined with chemoradiation. Future efforts with PI3K inhibitors may also be worth testing.

IMMUNOTHERAPY IN STAGE III NSCLC

Targeting immune regulatory pathways has proven to be a successful strategy in NSCLC. A phase III study comparing nivolumab with docetaxel in patients with NSCLC was recently closed based on the recommendations of a Data and Safety Monitoring Board citing evidence of superior overall survival favoring nivolumab (CheckMate-017 trial, Bristol Myers Squibb press release January 11, 2015). Consolidating chemoradiation with an immunotherapy has been studied in stage III NSCLC. Tecemotide (L-bLP25), a MUC1-antigen–specific cancer immunotherapy, was evaluated as consolidation therapy after chemoradiation in a phase III randomized trial.[31] In this trial, patients were allowed to receive either concurrent or sequential chemoradiation. Although overall survival did not statistically differ between the two groups (HR 0.88, 0.75–1.03; p = 0.123), a subset analysis of 829 patients treated with concurrent chemoradiation favored the tecemotide arm (median survival, 30.8 vs. 20.6 months, HR 0.78; p = 0.016). Another trial

from the Eastern Cooperative Oncology Group, combining tecemotide with bevacizumab after chemoradiation, has recently completed accrual (NCT 00828009). Patients with stage III nonsquamous NSCLC received concurrent chemoradiation using weekly carboplatin and paclitaxel for 6.5 weeks. Patients with nonprogression receive two additional cycles of consolidation chemotherapy. On completion of consolidation chemotherapy, patients receive a single dose of cyclophosphamide 3 days before the first tecemotide and bevacizumab treatment. Patients then receive bevacizumab on day 1 and tecemotide subcutaneously on days 1, 8, and 15 for cycles 1 and 2 then every other cycle beginning in course 4. Treatment continues every 21 days for up to 34 cycles. The primary endpoint is to determine the safety of bevacizumab plus tecemotide as maintenance therapy in this setting.

Evidence indicates radiation therapy induces tumor antigen release from the dying tumor cells that can be recognized by the immune system.[32,33] Therefore, radiation is an immune stimulator that enhances T-cell activation and infiltration. Furthermore, radiation has been shown to increase the expression of PD-L1, an immune checkpoint. Combining radiation with checkpoint inhibitors, such as PD-1 or PD-L1 inhibitors, including MED14736, pembrolizumab, and nivolumab, are being investigated. MED14736, an antibody to PD-L1, will be tested in a phase III industry-sponsored trial (PACIFIC) involving 702 patients across 100 sites around the globe (NCT 02125461). Patients with unresectable stage III NSCLC will be treated with concurrent chemoradiation utilizing at least two cycles of platinum-based chemotherapy. If no evidence of progression is seen, patients will then be treated with MED14736 or placebo (2:1 randomization) for up to 1 year. The primary endpoint is overall survival. A phase II single-arm study evaluating pembrolizumab as consolidation therapy after concurrent chemoradiotherapy will be conducted by the Hoosier Cancer Research Network (NCT 02343952). In this trial, approximately 83 patients will receive either weekly carboplatin/paclitaxel or cisplatin/etoposide with 59.4 to 66 Gy radiation. Patients with nonprogressive disease will then receive pembrolizumab every 3 weeks for up to 1 year. A safety analysis will take place after the initial 10 patients have been treated and received at least three cycles of pembrolizumab. Given the possibility of pneumonitis after chemoradiation and the expected activation of T cells with pembrolizumab, the incidence of delayed or severe pneumonitis and/or recurrent esophagitis in the radiated field will be of special importance. The primary endpoint is to assess the time to distant relapse. Secondary analyses will evaluate the effect of PDL-1 status on outcomes. In addition, a randomized trial with nivolumab after chemoradiation is under development (personal communication, Jeffrey Bradley, February 2015).

CONCLUSION

Therapeutic advances in the treatment of stage III NSCLC are difficult to achieve. Many factors contribute to the diffi-

culty of this task. Valuable lessons have been learned from research over the last 3 decades. Namely, further manipulations of existing chemotherapy drugs are unlikely to provide substantial survival gains. The path forward will follow new science and new drugs. The recent success with targeted agents and immunotherapy in the metastatic setting provides encouragement that similar success is possible in the stage III setting, where cures are still possible.

ABC, GCB, and Double-Hit Diffuse Large B-Cell Lymphoma: Does Subtype Make a Difference in Therapy Selection?

Grzegorz S. Nowakowski, MD, and Myron S. Czuczman, MD

OVERVIEW

Personalized therapy for the treatment of patients with cancer is rapidly approaching and is an achievable goal in the near future. A substantial number of novel targets have been developed into therapeutic agents. There is a substantial variability to antitumor activity by novel therapeutics because of the unique heterogeneity and biology that exists both between and within lymphoma subtypes. Diffuse large B-cell lymphoma (DLBCL) is the most common subtype of non-Hodgkin lymphoma (NHL). Approximately 40% of patients have refractory disease or disease that will relapse after an initial response, and the majority of patients with relapsed DLBCL will succumb to the disease. There are two major biologically distinct molecular subtypes of DLBCL: germinal center B-cell (GCB) and activated B-cell (ABC). ABC DLBCL is associated with substantially worse outcomes when treated with standard chemoimmunotherapy. In addition to GCB and ABC subtypes, double-hit lymphomas (approximately 5% to 10% of patients) and double-expressor lymphomas, which overexpress *MYC* and BCL2 protein, are aggressive DLBCLs and are also associated with a poor prognosis. Double-hit lymphomas have concurrent chromosomal rearrangements of *MYC* plus *BCL2* (or less likely, *BCL6*). Advances in molecular characterization techniques and the development of novel agents targeting specific subtypes of DLBCL have provided a foundation for personalized therapy of DLBCL based on molecular subtype. A number of early clinical trials evaluating combinations of novel targeted agents with standard chemotherapy (R-CHOP) have been completed and have demonstrated the feasibility of this approach with encouraging efficacy. As such, molecular classification of DLBCL is not only important for prognostication, but moves to center stage for personalization of therapy for DLBCL.

The addition of the anti-CD20 monoclonal antibody rituximab (R) to the standard CHOP regimen consisting of cyclophosphamide, doxorubicin, vincristine, and prednisone (R-CHOP) was a major breakthrough in the front-line treatment for patients with DLBCL, resulting in dramatic improvements in progression-free survival (PFS) and overall survival (OS).[1-3] However, despite these improvements approximately 40% of patients with DLBCL who are treated with R-CHOP or R-CHOP–like chemotherapy will relapse or develop refractory disease,[4,5] and the majority of patients with relapsed or refractory DLBCL will succumb to the disease.[1-3] Various strategies have been implemented to improve the outcome of DLBCL, including intensification of chemotherapy and use of maintenance therapy. Regardless of molecular subtype, standard front-line treatment for DLBCL is a combination of R-CHOP or CHOP-like chemotherapy.

Additional regimens and immunochemotherapy combinations are under investigation as alternatives to front-line R-CHOP, including dose-dense R-CHOP14, dose-adjusted R-EPOCH (rituximab plus etoposide, prednisone, vincristine, cyclophosphamide, doxorubicin), and R-CEOP90 (rituximab, cyclophosphamide, etoposide, vincristine, prednisone).[6-8] In a

phase III trial including 1,080 patients with previously untreated DLBCL, no additional clinical benefit was observed in patients treated with R-CHOP every 14 days (R-CHOP14) versus every 21 days (R-CHOP21).[6] Although evaluation of some of these intensification strategies is still ongoing, recent insight into the biology of DLBCL allowed the development of strategies based on the addition of novel agents (X) to R-CHOP in so-called XR-CHOP combinations[9] that target specific oncogenic pathways (Fig. 1). In the development of these strategies, molecular characterization of DLBCL and the development of biomarkers is a critical step to identify patients who might benefit from the addition of novel agent(s). Indeed, because of the molecular heterogeneity of DLBCL, addition of a novel agent may benefit only a subgroup of patients with DLBCL. In this regard, preclinical and clinical studies of novel agents as monotherapies in relapsed and refractory DLBCL often provide important initial indications regarding the subtype of DLBCL that might benefit from specific targeted therapy.

Gene expression profiling (GEP) of DLBCL resulted in the identification of two major and clinically distinct subtypes that are classified based on cell of origin (COO) and are as-

sociated with differences in clinical outcome: GCB and non-GCB, which is further comprised of ABC and primary mediastinal B-cell types.[10,11] DLBCL subtypes have striking differences in clinical outcome, with the ABC DLBCL subtype being associated with poor outcome. Until recently, COO classification of DLBCL had little influence on clinical practice. However, COO classifications have become more clinically relevant as a result of two major factors: (1) the development of new real-time COO assessment methods, including immunohistochemistry (IHC) and Nanostrings technology and (2) the identification of novel agents with activity in a specific DLBCL subtype (particularly ABC DLBCL).

CLASSES OF AGENTS WITH MOLECULAR SUBTYPE-SPECIFIC ACTIVITY CURRENTLY IN DEVELOPMENT FOR THE TREATMENT OF DLBCL
Agents Predominantly Active in Non-GCB (ABC) DLBCL

The majority of novel agents in development as front-line treatment for DLBCL appear to specifically target the ABC subtype of DLBCL, through either the B-cell receptor (BCR) pathway or pathway(s) downstream of the BCR pathway. This review will include only agents that are already in advanced clinical trials.

Proteasome inhibitors. Proteasome inhibitors play a key role in suppression of the transcription factor nuclear factor kappa B (NFκB), a critical pathway downstream of the BCR

pathway that is constitutively activated in ABC DLBCL.[12] Use of the first-generation proteasome inhibitor bortezomib as monotherapy generated no responses in patients with relapsed/refractory DLBCL despite good preclinical evidence of possible activity. Bortezomib combined with DA-EPOCH (dose-adjusted etoposide, vincristine, doxorubicin, with cyclophosphamide and prednisone) chemotherapy yielded a complete response (CR) of 18% and a partial response (PR) of 16%,[13] and demonstrated a significantly higher response (83% vs. 13%; p < 0.001) and median OS (10.8 vs. 3.4 months; p = 0.003) in ABC DLBCL compared to GCB DLBCL, respectively.

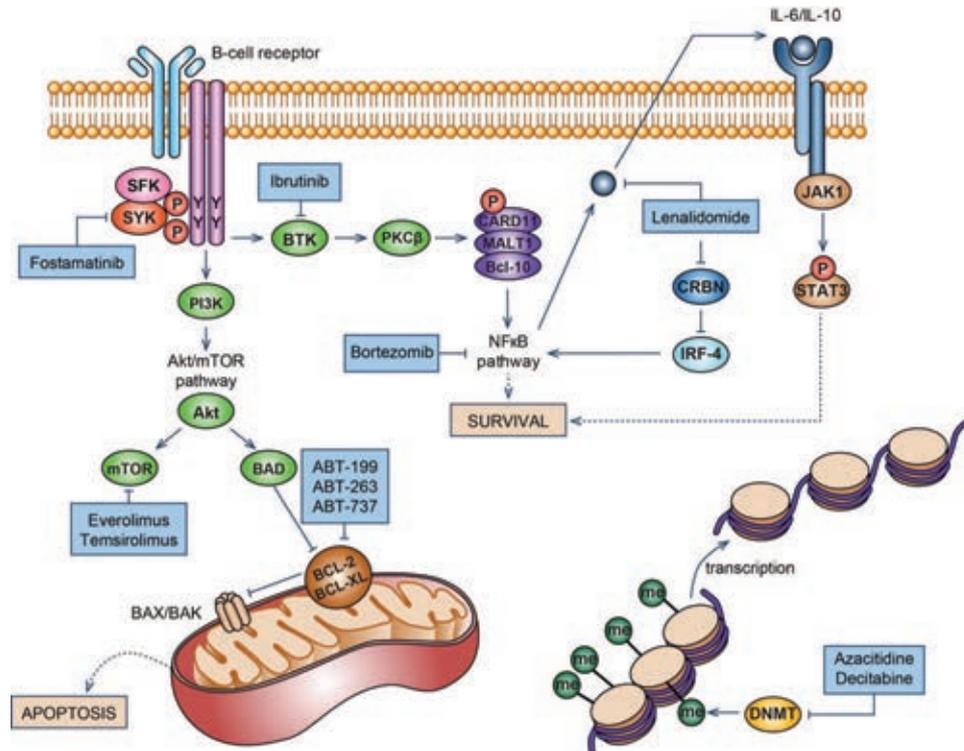
Immunomodulatory agents. Immunomodulatory drugs (IMiDs) are structural and functional analogs of thalidomide that have immunomodulatory, antiangiogenic, and antitumor functions.[14] Preclinical studies show that IMiDs modulate antibody synthesis; regulate the production of certain subsets of T cells (T-helper cells); inhibit the production of cytokines, including tumor necrosis factor alpha (TNFα); induce G_0/G_1 cell cycle arrest; and decrease angiogenesis through the suppression of vascular endothelial growth factor (VEGF) and fibroblast growth factor (FGF).[15] In vivo and in vitro experiments have shown that the IMiD lenalidomide functions in DLBCL through multiple mechanisms, for example by enhancing antibody-dependent cell-mediated cytotoxicity (ADCC), inhibiting the production of proinflammatory cytokines such as TNFα, decreasing NFκB activity, and arresting DNA synthesis.[16-18] The effect of single-agent lenalidomide was investigated in 217 patients with aggressive relapsed/refractory NHL as part of an international phase II study. Median PFS and response duration in the DLBCL subpopulation were 2.7 months and 4.6 months, respectively.[19] In a retrospective analysis of two phase II trials (NHL-002 and NHL-003), patients with aggressive relapsed/refractory NHL who received single-agent lenalidomide and prior autologous stem cell transplantation (ASCT) were compared with those who did not receive ASCT. Thirty-four patients (39%) with relapsed or refractory NHL and prior ASCT therapy responded to lenalidomide (objective response rate [ORR] 39%), including patients with DLBCL (ORR 29%).[20] In an ongoing, randomized, phase II/III clinical trial, the safety and efficacy of lenalidomide in relapsed/refractory DLBCL is being compared to the Investigator's choice (gemcitabine, oxaliplatin, rituximab, or etoposide) (NCT01197560).[21]

B-cell receptor signaling pathway inhibitors. The BCR complex and associated protein tyrosine kinases are important for normal B-cell function and antibody production. Constitutively activated BCR signaling is linked to the initiation and maintenance of B-cell malignancies, including involvement in the pathogenesis of the ABC subtype of DLBCL.[22] The BTK inhibitor ibrutinib was investigated in 70 patients with relapsed/refractory DLBCL as part of a multicenter, open-label, phase II trial. Among 60 patients who were evaluable for response, the ORR was 22% (5% CR) and PFS was 1.6 months.[23] In a phase II study, 23 patients treated with the

---

KEY POINTS

- The activated B-cell (ABC) subset of diffuse large B-cell lymphoma (DLBCL) is biologically distinct, characterized by clonic B-cell receptor signaling, and associated with poor outcomes when treated with a standard therapy. Activation of the clonic B-cell receptor pathway allows for therapeutic targeting.
- Targeted agents in relapsed DLBCL can be combined with R-CHOP in front-line therapy of DLBCL. Since most of these agents are active in ABC DLBCL, many ongoing studies select patients who have this subset.
- The germinal center B-cell (GCB) subset of DLBCL is associated with better outcomes and may require different therapeutic approaches.
- Double-hit lymphoma (DHL) is responsible for a substantial number of relapses in GCB DLBCL (DHL is usually a GCB phenotype). All newly diagnosed DLBCL biopsy samples should be tested for DHL by fluorescent in situ hybridization and by immunohistochemistry for double-expressor DLBCL and, whenever possible, patients should be referred to participation in clinical trials.
- Off-study treatment of DHL should be dose-intense whenever feasible, with current data supporting the use of dose-adjusted R-EPOCH plus central nervous system prophylaxis until more effective novel targeted agents for this lymphoma subtype are developed.

FIGURE 1. Pathways Targeted By Treatments Currently in Development for Patients with DLBCL


Abbreviations: AKT, protein kinase B; BAD, BCL2-associated death promoter; BAK, BCL2 antagonist killer; BAX, BCL2-associated X protein; BCL, B-cell lymphoma; BTK, Bruton's tyrosine kinase; CARD11, caspase recruitment domain family, member 11; CRBN, cereblon; DLBCL, diffuse large B-cell lymphoma; Me, methylation; DNMT, DNA methyltransferase; JAK1, Janus kinase 1; IL, interleukin; IRF-4, interferon regulatory factor 4; MALT1, mucosa-associated lymphoid tissue lymphoma translocation protein 1; MTOR, mammalian target of rapamycin; P, phosphorylation; NFκB, nuclear factor kappa B; PI3K, phosphoinositide 3-kinase; PKC-beta, protein kinase C beta; SFK, Src family kinase; STAT3, signal transducer and activator of transcription 3; SYK, spleen tyrosine kinase.

spleen tyrosine kinase (SYK) inhibitor fostamatinib demonstrated a median PFS of 2.7 months and achieved an ORR of 22%.[24]

AGENTS WITH POTENTIAL ACTIVITY IN GCB DLBCL

Although patients with GCB DLBCL have better outcomes than patients with the ABC subtype, approximately 20% of patients with the GCB subtype of DLBCL relapse following R-CHOP or R-CHOP—like chemotherapy and DLBCL relapse is associated with poor outcomes regardless of molecular subtype. Several agents show potential activity in the GCB subtype of DLBCL, among which BCL2 inhibitors are the best studied to date. Importantly, DLBCL with concurrent *MYC* and *BCL2* or *BCL6* translocation, known as double-hit DLBCL,[25] is associated with very poor outcomes and is usually the GCB subtype by molecular profiling. Double-hit DLBCL represents approximately 5% of de novo cases of DLBCL, and is responsible for approximately a quarter of all relapses in GCB DLBCL. Treatment of this particularly high-risk lymphoma is discussed later.

BCL2 inhibitors. Prevention of apoptosis is one mechanism through which cancer cells continue to survive. Unlike most oncogenes that promote proliferation, members of the antiapoptotic B-cell lymphoma-2 (BCL-2) family of proteins (BCL-2, BCL-XL, BCL-w, MCL-1, BFL1/A-1, and BCL-B)

suppress apoptosis through interaction with, and inactivation of, proapoptotic proteins such as BH3.[26] In contrast to most agents active in ABC DLBCL, which appear to have low activity in the GCB subtype, BCL2 inhibitors might be active in both ABC and GCB DLBCL. Whereas in the GCB subtype BCL2 is often overexpressed as a result of translocation, some patients with the ABC subtype appear to overexpress BCL2 at the protein level.[27] ABT-737 and its oral equivalent ABT-263 target multiple antiapoptotic members of the BCL-2 family, including BCL-2, BCL-XL, and BCL-w, whereas ABT-199 potently and selectively inhibits BCL-2, thereby sequestering the proapoptotic proteins and facilitating death of malignant cells.[26,28,29]

FRONT-LINE TREATMENT: XR-CHOP
Bor-RCHOP

A combination of the proteasome inhibitor bortezomib and R-CHOP (VR-CHOP or Bor-RCHOP) was evaluated in patients with previously untreated DLBCL or mantle cell lymphoma. The evaluable ORR was 100%; 86% of patients exhibited CR or CR unconfirmed (CRu). In the intent-to-treat (ITT) population of 40 patients, ORR was 88%, and 75% had CR/CRu. The 2-year PFS was 64% and 2-year OS was 70%.[30] A current randomized phase II trial is designed to compare the effect of VR-CHOP versus R-CHOP on PFS (NCT00931918),[31] and an ongoing randomized phase III

trial is investigating the efficacy of CHOP versus RV-CHOP in patients with DLBCL (REMoDL-B; NCT01324596).[32]

R2-CHOP

Patients treated with the immunomodulatory agent lenalidomide (R) in combination with R-CHOP (R2-CHOP) achieved ORRs and CRs of 90% to 100% and 77% to 86%, respectively, in phase I and phase II trials.[33-36] In one phase II trial, the most frequent grade 3/4 hematologic adverse events (AEs) included neutropenia (31%), leukocytopenia (28%), and thrombocytopenia (13%); no grade 4 nonhematologic AEs were reported.[36] Response to R2-CHOP in patients with GCB versus non-GCB DLBCL was similar in a phase II trial (32 tissue samples available), and the 2-year PFS was 71% and 81%, respectively.[36] Interestingly, in a separate phase II trial involving patients with newly diagnosed DLBCL who were treated with R2-CHOP, the 2-year OS was 75% for patients with GCB DLBCL compared with 83% for non-GCB subtypes. In patients treated with R-CHOP alone, a 2-year OS of 78% and 46% was achieved in GCB and non-GCB subgroups, respectively, suggesting that the addition of lenalidomide can improve the poor prognosis usually reported in the non-GCB population in response to standard R-CHOP therapy (Fig. 2).[37]

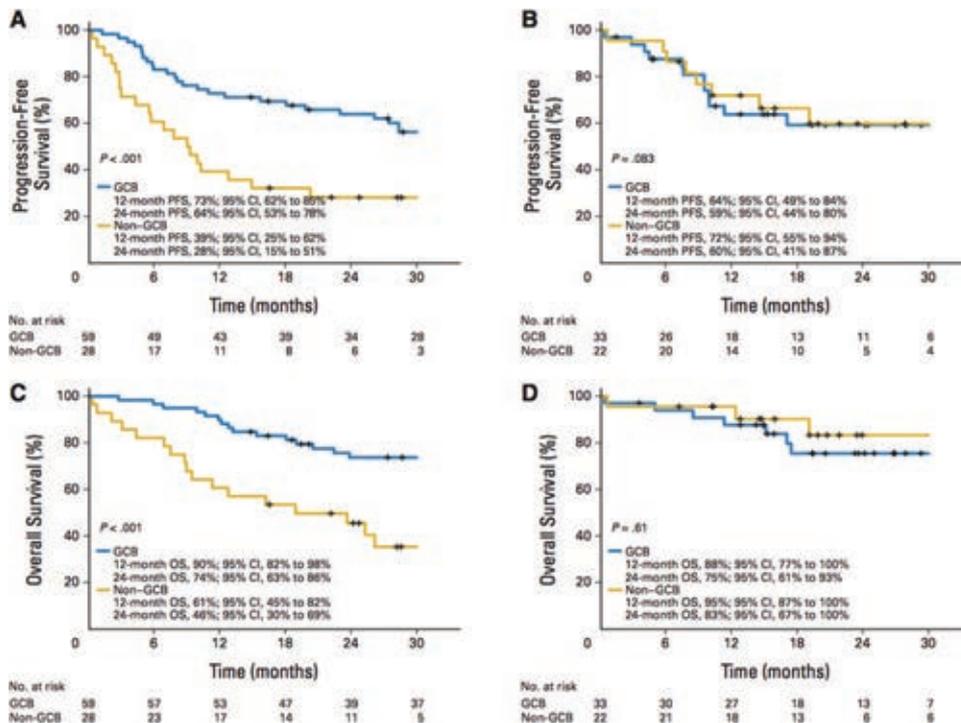
A randomized phase II trial designed to evaluate the effect of R-CHOP versus R2-CHOP in patients with newly diagnosed DLBCL (NCT01856192) is ongoing.[38] A separate phase III study (ROBUST) evaluating R2-CHOP versus R-CHOP in patients with ABC DLBCL as defined by GEP is currently open. Real-time GEP with a turnaround time of 5 business days or less is used to assess patient eligibility for this trial.

IR-CHOP

The Bruton's tyrosine kinase (BTK) inhibitor ibrutinib has been investigated in combination with R-CHOP (IR-CHOP) in a phase Ib, nonrandomized, open-label trial in 33 patients with newly diagnosed DLBCL, mantle cell lymphoma, or follicular lymphoma. At the interim evaluation, the ORR was 100% (CR 64% and PR 36%) in 22 patients with DLBCL. The most common all-grade AEs reported in all patients were neutropenia (67%), nausea (67%), thrombocytopenia (61%), vomiting (48%), and anemia (36%).[39] Additionally, a randomized, double-blind, phase III study is currently comparing event-free survival in patients treated with IR-CHOP versus R-CHOP (NCT01855750).[34]

TREATMENT FOR RELAPSED/REFRACTORY DLBCL

In the Collaborative Trial in Relapsed Aggressive Lymphoma (CORAL) study, 396 patients with relapsed/refractory CD20+ DLBCL were randomly selected to receive either rituximab, ifosfamide, etoposide, and carboplatin (R-ICE),

FIGURE 2. Outcomes of Patients Treated with R-CHOP or R2-CHOP according to GCB versus Non-GCB DLBCL Subtype


Outcomes are shown for historic control patients treated with R-CHOP and study patients treated with R2CHOP based on germinal center B-cell (GCB) versus non-GCB diffuse large B-cell lymphoma (DLBCL) subtype. (A) Progression-free survival in patients treated with R-CHOP for non-GCB versus GCB DLBCL. (B) Progression-free survival in patients treated with R2CHOP for non-GCB versus GCB DLBCL. (C) Overall survival in patients treated with R2CHOP for non-GCB versus GCB DLBCL. (D) Overall survival in patients treated with R2CHOP for non-GCB versus GCB DLBCL.

TABLE 1. Agents with Differential Single Agent and in Combination of XR-CHOP Activity in DLBCL Subtypes

Agent	Combination	No. of Patients	Phase	ORR (%)		CR (%)		PFS (%)		OS (%)	
				GCB	ABC/NGCB	GCB	ABC/NGCB	GCB	ABC/NGCB	GCB	ABC/NGCB
Front-Line

Lenalidomide [42]	–	40	II	9	53	4	24	1.7	6.2	13.5	14
Ibrutinib [23]	–	70	II	5	40	0	8	1.3	2.5	–	–

Abbreviations: ABC, activated B-cell typeCR, complete response; DA-EPOCH, dose-adjusted etoposide, vincristine, doxorubicin, with cyclophosphamide and prednisone; DLBCL, diffuse large B-cell lymphoma; GCB, germinal center B-cell type; NGCB, non-GCB type; mo, month; ORR, overall response rate; OS, overall survival; PFS, progression-free survival; R-CHOP, rituximab with cyclophosphamide, doxorubicin, vincristine, prednisone; XR, addition of novel agents to R-CHOP.
*R-CHOP without lenalidomide.

or rituximab, dexamethasone, high-dose cytarabine, and cisplatin (R-DHAP). Patients whose disease relapsed early (< 1 year) following front-line rituximab chemotherapy had a very poor prognosis, with a 3-year PFS of 20% compared with 45% for patients whose disesase relapsed after 1 year.[40]

MYC-POSITIVE AND DOUBLE-HIT DLBCL

MYC is a transcription factor associated with a number of cellular functions (e.g., cell growth and proliferation, angiogenesis, protein synthesis, metabolism, and DNA replication) with a strong oncogeneic potential.[42] In human B-cell neoplasms, *MYC* rearrangements involving the t(8;14) is a hallmark in Burkitt lymphoma and present in the majority of cases. Typically, it is a primary genetic event and presents as a simple karyotype and the sole chromosomal abnormality in this aggressive subtype of B-cell lymphoma. *MYC* gene rearrangements have also been identified in other lymphoid neoplasms, including: DLBCL (7% to 14%), unclassifiable B-cell lymphoma (35%), plasmablastic lymphoma (50%), plasma cell myeloma (15% to 50%), and mantle cell lymphoma (26 patients). Of interest, in non-Burkitt lymphoma histologies, *MYC* rearrangements are found as part of a complex karyotype and typically represent secondary genetic events.[42-43] *MYC* gene activation in DLBCL can occur via translocation (5% to 14%), copy gain (19% to 38%), amplication (2%), or mutation (32%).[44-47] In general, *MYC* rearrangement predicts an inferior outcome in DLBCL, but it is not clear whether it is because of *MYC* rearrangement itself or because 58% to 83% of MYC-translocated DLBCL also have concurrent dual or triple translocation with *BCL2* and/or *BCL6* (less likely) identified as double-hit or triple-hit DLBCL.[42,48-49] These patients often have 12 months or less OS when treated with R-CHOP.[50]

Of note, high MYC-protein expression (28% to 41%) of DLBCL without *MYC* gene abnormalities has been identified (suggesting alternate mechanisms of MYC induction). Patients with DLBCL with a high percentage of both MYC and BCL2 protein (20% to 44%) expression by IHC staining carry a poor prognosis; treatment with standard R-CHOP or CHOP-like immunochemotherapy results in inferior PFS and OS on retrospective

analyses.[51-54] Many studies have defined these patients as having double-expressor DLBCL, and most studies require that tumor cells express at least 40% MYC and at least 50% to 70% BCL2 positivity. Although patients with double-expressor DLBCL (DEL) have a worse prognosis than those without double expression of MYC plus BCL2, it should be noted that different studies utilize variable cutoff points to define positivity. Unlike the reproducibility of the fluorescent in situ hybridization (FISH) technique, the IHC technique is less robust and has more variability associated with it. Interestingly, the majority of double-hit DLBCL (DHL) (defined here as having *MYC* + *BCL2* rearrangements) is primarily GCB-like, whereas DEL is primarily ABC-like. This unique observation leads us to question whether a successful therapeutic approach in DHL will be equally successful in DEL based on differences inherent within the COO and likely differences in cellular/molecular pathways, genetics, and variable-resistance pathways. Only large prospective clinical trials utilizing central path review of FISH, as well has IHC, and well-defined inclusion definitions of positivity will be able to answer this question.

CURRENT TREATMENT APPROACH: OVERVIEW

As mentioned previously, R-CHOP is an inadequate induction therapy for DHL (i.e., most patients die within 2 years of diagnosis). The malignant DHL neoplastic cell attains an amazing survival advantage. Concurrent *MYC* + *BCL2* translocations confer increased cell growth, cell cycle transit, and metabolism and/angiogenesis via MYC, but at the same time increased antiapoptosis (i.e., drug resistance) via BCL2. In general, DHL patients often present with several poor prognostic characteristics: median age in the seventh decade (many unable to tolerate dose-intensive therapeutic approaches); stage III/IV disease; high-intermediate/high (HI/H) IPI; elevated LDH; high frequency of extranodal sites (including the central nervous system).[55-56] Various multidrug therapy regimens with or without rituximab have been utilized to treat DHL, including dose-intensive therapies that have curative potential in BL, although published data from retrospective reviews do not indicate any single optimal induction therapy approach (Table 2). Patients achieving a

TABLE 2. DHL Induction Therapy and Outcome

Reference	No. of Patients	Treatment	Outcome (Median)	Comments
Petrich et al[50]	311	R-CHOP (32%)	PFS: 10.9; OS: 21.9 mo	Median follow-up: 23 mo
		R-Hyper CVAD/MA (21%)	PFS (R-CHOP): 7.8 mo versus 26.6 mo (for any "intensive" regimen; p = 0.001)	No difference between intensive regimens
		R-EPOCH (21%)		Consolidative SCT: no improvement in OS in CR patients (p = 0.14)
		R-CoDox-M/IVAC (14%)		
Oki et al[60]	129 (93 with both MYC and BCL2 translocation)	R-CHOP	2-yr EFS	Increased OS with R-EPOCH c/w R-CHOP (p = 0.057)*
		R-Hyper CVAD/MA	Overall: 33% (overall)	
		R-EPOCH	R-CHOP: 25%	
			R-Hyper CVAD/MA: 32%	CNS involvement: 13% at 3 yrs
			R-EPOCH: 67%	
			CR	
			R-CHOP: 20%	
			R-EPOCH: 68%	
			R-Hyper CVAD/MA: 70%	
Johnson et al[61]	54	CHOP-like (43%)	OS	BCL2 protein–negative cases (more favorable)
	BCL-U (36 patients)	R-CHOP (20%)	R-CHOP: 1.4 yr	
	DLBCL (17 patients)	HDT (11%)	CHOP: 5 mo	
		Palliative (26%)		
Li et al[62]	BCL-U (33 patients)	R-CHOP (39%)	OS: 18.6 mo	Median age: 55
	DLBCL (23 patients)	R-Hyper CVAD/MA (57%)		Aggressive chemotherapy nor SCT associated with increased PFS/OS

Abbreviations: BCL-U, B-cell lymphoma, unclassifiable with features intermediate between DLBCL and BL; R, rituximab; CHOP, cyclophosphamide, doxorubicin, vincristine, prednisone; Hyper CVAD/MA, hyper-fractionated cyclophosphamide, doxorubicin, vincristine, dexamethasone/methotrexate, cytarabine; EPOCH, etoposide, prednisone, doxorubicin, cyclophosphamide, doxorubicin; CoDox-M/IVAC, cyclophosphamide, vincristine, doxorubicin, methotrexate, ifosfamide, etoposide, cytarabine; PFS, progression-free survival; OS, overall survival; SCT, stem cell transplant.
*Consolidative SCT in 50% R-EPOCH versus 4% R-CHOP group.

complete remission with regimens more intensive than R-CHOP had better PFS, but consolidative SCT did not seem to improve OS in these patients. Of the regimens utilized, R-EPOCH: (1) has curative potential in BL, (2) is better tolerated than more dose-intensive (DI) regimens, and (3) appears to have at least similar efficacy compared to DI therapies. In addition to the data from Oki et al (Table 2), a meta-analysis of 401 DHL patients by Howlett et al[57] presented at the 2014 American Society of Hematology (ASH) Annual Meeting demonstrated R-EPOCH (and more DI regimens) were associated with improvement in PFS (but not OS) compared to R-CHOP. Another presentation at ASH 2014 by Dunleavy et al[58] utilizing R-EPOCH in a multicenter phase II study, which included DHL, demonstrated a promising early PFS (87% at 14 months).

Currently consolidative autologous SCT in chemotherapy-sensitive patients (especially CRs) does not appear to signifi-

TABLE 3. Novel Future Therapeutic Considerations

Agent	Comment	Reference
ABT-199	Platelet-sparing BCL2 inhibitor (BH$_3$-mimetic)	28, 63
BET bromodomain inhibitors (JQ1, I-BET 151, OTX015)	Down-regulation of MYC-associated transcription: Decreased cell proliferation and inhibition of MYC-driven neoplasms	64–66
CAR-T cells	Autologous T-cell-mediated killing of CD19-positive lymphoid neoplasms	67, 68
Aurora kinase inhibitors (alisertib)	Aurora kinase function is required for tumor maintenance of MYC-driven lymphoma	69, 70
mTor inhibition	mTOR may plan an important role in tumor maintenance by MYC in B lymphocytes	71, 72
MLN9708/Ixazomib (second generation proteasome inhibitor)	Preclinical model: Degraded MYC and can induce lymphoma cell death at nanomolar concentrations	73
PI3K inhibition	High percent GCB-DLBCL cases: loss of PTEN → activation of PI3K/AKT pathway → MYC upregulation	74
Inhibition of human mitochondrial peptide deformylase	Causes apoptosis in MYC-overexpressing hematopoietic neoplasms	75
SIRT4 protein	Suppresses tumor formation in MYC-induced B-cell lymphoma models	76

Abbreviations: mTOR, mammalian target of rapamycin; GCB, germinal B cell; DLBCL, diffuse large B-cell lymphoma.

cantly change clinical outcomes. This may likely be a result of the inherent rapid tumor cell growth and inherent drug-resistant DHL cells that remain after induction therapy (i.e., minimal residual disease) that would likely not be cured with a high-dose, chemotherapy-based conditioning regimen typically utilized during autologous stem cell transplantation. Of interest, review of the literature identified two abstracts, which included a total of approximately 50 patients, that concluded that patients with DHL who undergo allogeneic SCT following dose-intensive induction therapy have prolonged OS.[57,59] Unfortunately, several reasons make it unlikely that allogeneic SCT will make a major effect in the future treatment of a significant percentage of DHL patients: (1) limited data from a small number of selected patients, (2) the risk of relapsed disease while awaiting graft-versus-lymphoma to occur, (3) the need for a suitable HLA-compatible donor, and (4) the risk of chronic graft-versus-host disease.

The future holds promise that novel targeted agents, which either directly or indirectly inhibit MYC and BCL2, will lead to improved overall survival in patients with DHL (Table 3). Many agents have demonstrated in vitro and in vivo animal antitumor activity, and a limited number are in early human clinical trials. It is quite likely that DHL will require a rational combination of MYC/BCL2 inhibitors in combination with effective chemotherapeutic agents (e.g., BH_3-mimetics will resensitize cells to drug toxicity, etc.) to optimize the killing of these highly resistant lymphoma cells and change DHL from one of the worst subtypes of DLBCL into a therapeutically responsive subtype (with a significant improvement in clinical outcomes). Based on the information provided above, all newly diagnosed DLBCL tumor biopsies should undergo FISH and IHC evaluation to identify DHL and DEL, respectively. These patients, whenever possible, should be referred to participation on clinical trials. Off study, the use of R-EPOCH induction (including central nervous system prophylaxis) is a reasonable approach while we await further testing and validation of effective novel targeted agents to be added to our current therapeutic armamentarium against DHL.

Cell-of-Origin in Diffuse Large B-Cell Lymphoma: Are the Assays Ready for the Clinic?

David W. Scott, MBChB, PhD

OVERVIEW

Diffuse large B-cell lymphoma (DLBCL) is the most common lymphoma worldwide and consists of a heterogeneous group of cancers classified together on the basis of shared morphology, immunophenotype, and aggressive clinical behavior. It is now recognized that this malignancy comprises at least two distinct molecular subtypes identified by gene expression profiling: the activated B-cell-like (ABC) and the germinal center B-cell-like (GCB) groups—the cell-of-origin (COO) classification. These two groups have different genetic mutation landscapes, pathobiology, and outcomes following treatment. Evidence is accumulating that novel agents have selective activity in one or the other COO group, making COO a predictive biomarker. Thus, there is now a pressing need for accurate and robust methods to assign COO, to support clinical trials, and ultimately guide treatment decisions for patients. The "gold standard" methods for COO are based on gene expression profiling (GEP) of RNA from fresh frozen tissue using microarray technology, which is an impractical solution when formalin-fixed paraffin-embedded tissue (FFPET) biopsies are the standard diagnostic material. This review outlines the history of the COO classification before examining the practical implementation of COO assays applicable to FFPET biopsies. The immunohistochemistry (IHC)-based algorithms and gene expression–based assays suitable for the highly degraded RNA from FFPET are discussed. Finally, the technical and practical challenges that still need to be addressed are outlined before robust gene expression–based assays are used in the routine management of patients with DLBCL.

Diffuse large B-cell lymphoma is the most frequent non-Hodgkin lymphoma (NHL), making up about 30% to 40% of diagnoses of NHL worldwide.[1] It is increasingly recognized that DLBCL represents a heterogeneous group of malignancies that have previously been grouped together on the basis of a shared morphology, immunophenotype, and aggressive clinical behavior.[1] The standard of care for patients with DLBCL, established over a decade ago, is rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone (R-CHOP) immunochemotherapy. This "one-size fits-all" approach results in cure for 50% to 60% of patients.[2,3] However, the outcomes for those that experience disease progression or relapse are poor, making identification of this clinical subgroup and improving their up-front treatment a major priority for the field.

A major step toward precision medicine in DLBCL was taken 15 years ago, when examination of the gene expression of DLBCL tumors revealed previously unrecognized molecular heterogeneity in this malignancy.[4] The resulting COO classification divided tumors into those with gene expression reminiscent of germinal center B cells (the GCB group) and those with gene expression similar to activated B cells (the ABC group). The division of DLBCL tumors into these two groups has provided a scaffold on which a substantial amount of

our current understanding of the DLBCL pathobiology is now organized. Additionally, DLBCL COO is a strong prognostic biomarker[4-6] identifying patient groups with substantially different outcomes following treatment. Finally, over the last decade, clinical observations and our evolving knowledge of the biology of the disease has led to the realization that the COO subtypes respond differentially to therapeutic agents.[7] Thus, COO is potentially a predictive biomarker that will soon be used to guide clinical management. This has cast the spotlight on our ability to accurately and reliably assign COO to patients' tumors. This review will focus on the assays that have been developed to determine COO, focusing on those applicable to routinely produced FFPET biopsies, addressing a central question: are these assays ready to guide clinical management?

FROM DEFINING DLBCL COO TO A PREDICTIVE BIOMARKER
Discovery of the Molecular Subtypes of DLBCL
In 2000, Alizadeh et al used gene expression profiling to explore the notion that unrecognized molecular heterogeneity in DLBCL underlies the heterogeneity in clinical behavior.[4] They used "Lymphochip" complementary DNA (cDNA) mi-

croarrays, covering a broad range of genes expressed by lymphoid cells and others suspected of being involved in cancer and immunology, to compare the gene expression profiles of lymphoid tumors against profiles from normal lymphoid cells.[4] Using hierarchical clustering (a method of grouping tumors together based on similarity of gene expression), it was shown that there were at least two distinct groups within DLBCL. The first group, which was designated as GCB, was characterized by high expression of genes expressed in normal B cells from the germinal center. The second group showed very low expression of these germinal center B cell genes, but high expression of genes normally expressed by activated B cells and was thus named ABC DLBCL. Importantly, these groupings explained some of the clinical heterogeneity in DLBCL, as patients with ABC DLBCL experienced substantially worse outcomes compared with patients with GCB DLBCL.

This work was expanded by the Leukemia Lymphoma Molecular Profiling Project (LLMPP), by applying the same microarray technology to a larger cohort of patients.[5] Hierarchical clustering, using the 100 genes that were most highly differentially expressed between GCB and ABC, identified three clusters within DLBCL: the aforementioned GCB and ABC, and a third group of cases that had gene expression that fell between these two groups, which they named "type 3." With cyclophosphamide/doxorubicin/vincristine/prednisone (CHOP) chemotherapy (the standard at that time), this group of patients had outcomes similar to those with ABC DLBCL. This type 3 nomenclature gave the impression that this was a biologically distinct third group of tumors. In hind-

sight, it is possible this group contained some cases that had low tumor content and some cases that were later identified as primary mediastinal B cell lymphoma.[8] What is clear is that when, in further studies, such cases were carefully removed, about 10% to 15% of DLBCL tumors remained that did not convincingly fall into either ABC or GCB categories––these cases are now labeled "unclassified."

The COO Algorithm

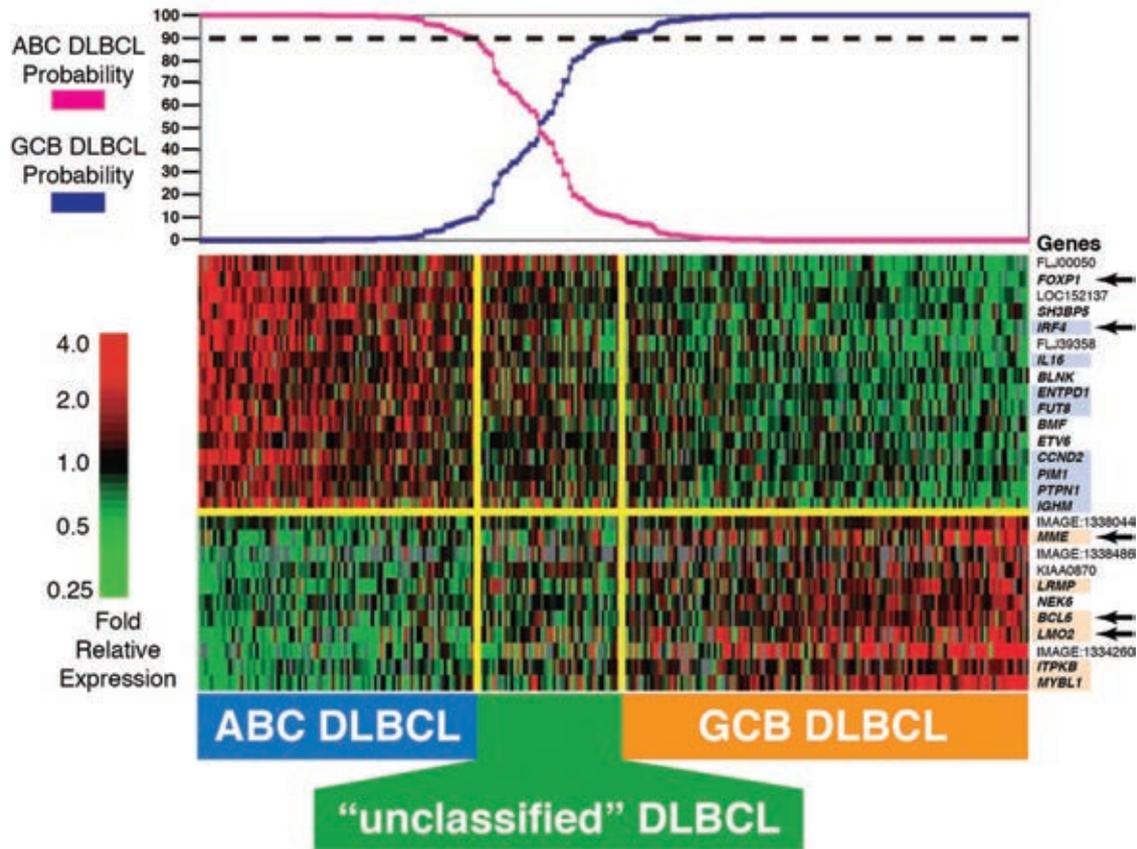
The LLMPP rapidly realized that in order for COO to be accurately assigned by other groups, there needed to be shift away from both the vagaries of hierarchical clustering and a microarray chip that was not commercially available. In 2003, Wright et al defined an algorithm that allowed classification of individual cases.[9] This algorithm was based on 27 genes on the Lymphochip microarray that were the most discriminatory between GCB and ABC, with these genes having both high fold-change differences between the two groups and also high variance in expression over the DLBCL population. These characteristics underlie the robustness of this algorithm even when other technology platforms are used to determine gene expression.

The algorithm produces a linear predictor score (LPS) using an equation that sums the gene expression of each gene multiplied by individual gene coefficients. Normal distributions of LPS scores were constructed for the ABC and GCB groups and then, for a given LPS score, a probability is assigned indicating whether that individual case is best allocated to the ABC or GCB group (Fig. 1). If the probability of the case being an ABC is over 90% it is designated ABC, and if the probability of being an ABC is less than 10% (i.e., greater than 90% chance of being a GCB) the case is called a GCB. This approach produces an "unclassified" group (roughly 10% to 15% of the tumors), in which the tumor cannot be assigned to either GCB or ABC with sufficient confidence. Although this would appear to be an undesirable feature of the algorithm, it has a distinct advantage when producing robust assays for COO. In a binary system, where there is no unclassified group, small shifts in the LPS, which could occur on retesting a tumor or testing it with a different technology, would lead to a shift from ABC to GCB, or vice versa. The unclassified group, by producing a buffer zone between ABC and GCB, minimizes the chances of a tumor being frankly misclassified (e.g., an ABC tumor labeled a GCB).

Fourteen of the initially selected 27 genes are present on commercially available Affymetrix microarray chips (Fig. 1) and an adjusted algorithm including just those 14 genes provides very similar results to the full algorithm.[9] The LLMPP have subsequently further refined the algorithm to include approximately 180 genes present on Affymetrix microarrays,[6] although the increase in accuracy over the 14-gene model is incrementally small. GEP on fresh frozen tissue with COO assignment using these algorithms is now widely considered to be the "gold standard" and, because of the robustness of the algorithm, is likely producing acceptable consistency of COO assignment across research groups. The caveat to this is that the accurate deployment of the

KEY POINTS

- Diffuse large B-cell lymphoma comprises at least two distinct molecular subtypes, defined by gene expression profiling, with different mutation landscapes, outcomes following treatment, and responses to novel targeted agents: the activated B-cell–like and germinal center B-cell–like cell-of-origin groups.
- Accurate and robust cell-of-origin assignment applicable to routinely produced formalin-fixed paraffin-embedded tissue biopsies is critically needed to support clinical trials and, ultimately, to guide disease management.
- The immunohistochemistry-based algorithms cannot currently be deployed with sufficient reproducibility or accuracy to support their use to guide clinical decision-making.
- A number of gene expression–based assays applicable to formalin-fixed paraffin-embedded tissue biopsies have been described with two of these assays now supporting patient selection in phase III randomized controlled trials of targeted agents.
- It is anticipated that a robust, accurate gene expression–based assay will be widely available by the time substantive evidence is produced that cell-of-origin should be used to guide initial treatment decisions in the clinic.

FIGURE 1. The Original Algorithm for Assigning COO


The model is shown in the form of a heatmap of gene expression data from 274 fresh frozen tissue biopsies using the Lymphochip microarray. Each column represents the relative gene expression of a tumor. The rows are the 27 genes that contribute to the model's linear predictor score (LPS). The 14 genes that were also present on the commercially available Affymetrix microarrays are highlighted in blue (overexpressed in ABC DLBCL) and orange (overexpressed in GCB DLBCL). Arrows designate genes, where antibodies against their corresponding protein have been used in immunohistochemistry-based COO assays. For an individual LPS score, a probability is determined as to whether the tumor is likely to be part of the ABC group or the GCB group (shown at top). Tumors with a probability of being ABC greater than 90% are considered ABC, whereas those with a probability of less than 10% are considered GCB.

This research was originally published in *Proceedings of the National Academy of Sciences*, Volume 100, Issue 17, G Wright et al, "A gene expression-based method to diagnose clinically distinct subgroups of diffuse large B cell lymphoma." Pages 9991-9996, Copyright 2003.

Wright algorithm requires that gene expression data are normalized back to that of the original cohort used to define the algorithm, which is a process that requires a large number of tumors that have a similar proportion of ABC and GCB as the original cohort. This error-prone process means that the position of the unclassified group is likely differently located across research groups, producing (subtly) different proportions of ABC, unclassified, and GCB DLBCL.

COO Defines Biologically Distinct Groups

Since the observation that gene expression could separate tumors into the two COO groups, ample evidence has emerged that these are, indeed, distinct biologic groups (recently reviewed by Shaffer et al[10]) classified together based on shared morphology. Targeted genetic examination[11-15] and subsequent genome-wide studies[16-20] have revealed an array of genetic aberrations that are heavily enriched, or exclusive to either ABC or GCB DLBCL. It has emerged that ABC DLBLC is characterized by constitutive activation of NF-κB, through chronic active B cell receptor signaling and/or aberrant Toll-

like receptor signaling, in concert with a differentiation block preventing maturation beyond the plasmablast stage. Although a straightforward schema is yet to emerge in GCB DLBCL, mechanisms providing a similar block to differentiation are present preventing maturation beyond the germinal center B cell.[21] The GCB and ABC gene expression signatures largely reflect the presence of these differentiation blocks, with the tumor cells continuing to express remnants of the gene expression program of normal germinal center B cells or plasmablasts, respectively.

The separation of DLBCL into ABC and GCB groups explains a substantial proportion of the heterogeneity seen in the genetic mutation landscape of DLBCL. However, it should be appreciated that there is still marked heterogeneity even when ABC and GCB are considered as separate diseases.[16-18] This is reflected when considering COO as a prognostic biomarker. As a group, patients with GCB DLBCL have superior outcomes following R-CHOP immunochemotherapy.[6] Hidden heterogeneity is implied by the observation that those patients known to have the poorest prognosis, being those with translocations involving *MYC* and *BCL2* (so-

called double-hit lymphoma) are almost exclusively GCB DLBCL. Correlation between genetic aberrations and outcomes after R-CHOP treatment within ABC and GCB groups is the subject of ongoing research.

COO as a Predictive Biomarker

From the clinical perspective, the observations and research linking COO with response to therapeutics are particularly exciting, holding the promise of improved patient outcomes. In some cases, this linkage is based on determining COO retrospectively in clinical trials searching for previously unsuspected differential efficacy across the COO groups,[22,23] in which the mechanism for these observations are yet to be explained. At the other end of the spectrum are therapeutic agents that are highly likely to only have efficacy in one or other of the COO groups based on their established mechanism of action.[7]

Accurate and reliable assays for COO are critically needed to allow patient selection for clinical trials of these agents, enriching for patients likely to truly benefit. Ultimately these assays will be needed to guide treatment decisions in the standard clinical management of patients with DLBCL. In order for an assay to be suitable for this task, it needs to be applicable to the FFPET biopsies routinely produced in the diagnostic process and have a rapid turnaround time.

TRANSLATION TO PRACTICAL TECHNOLOGY PLATFORMS

The gold standard methods originally described to assign COO rely on fresh frozen material and microarray technology. These methods are impractical for routine use in clinical trials, let alone standard clinical practice. Reflecting the importance of reliably assigning COO in the clinic, considerable efforts have been made to approximate the results of the gold standard method using practical technology platforms including IHC and methods for gene expression quantitation using RNA derived from FFPET.

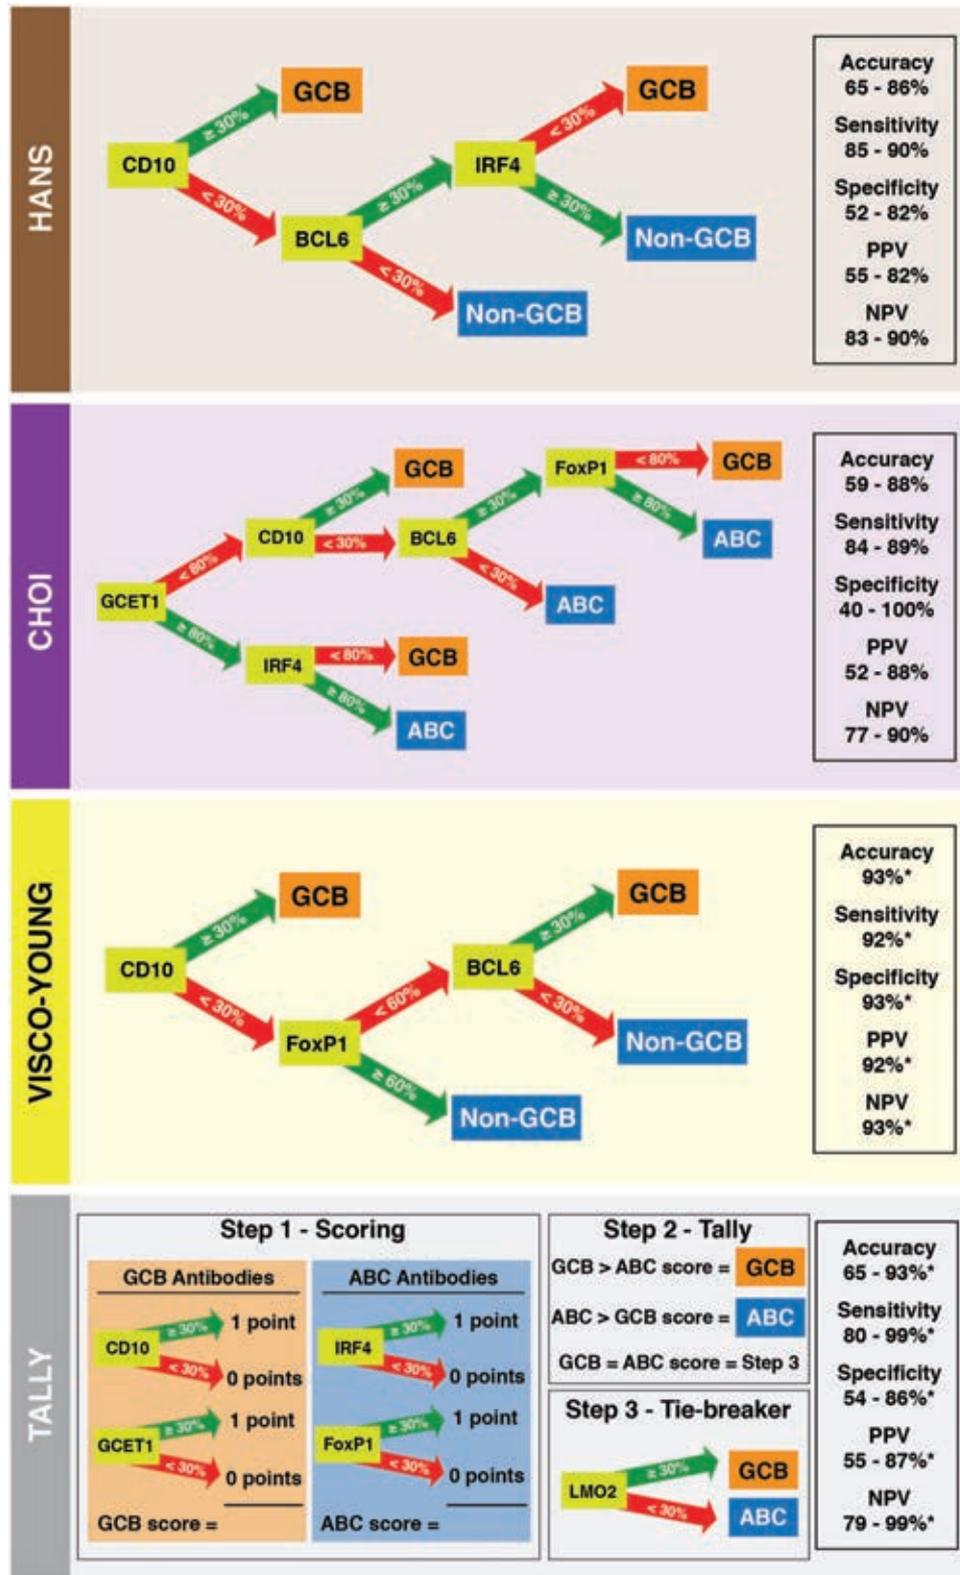
IHC-Based Assays

The wide availability and familiarity of pathologists with IHC makes assays based on this technology highly desirable. In 2004, Hans et al developed an IHC-based algorithm applicable to FFPET biopsies that aimed to replicate the COO assignments made using GEP on fresh frozen tissue with the Lymphochip microarray.[5,24] A tissue microarray (TMA) was produced comprising FFPET from 152 de novo DLBCL tumor, with 142 of these having matching GEP results. IHC was performed with antibodies against CD10 (HUGO designation MME), BCL6, MUM1 (HUGO designation IRF4), CCND2, and FOXP1—five proteins that are highly differentially expressed between ABC and GCB (Fig. 1). No one single IHC stain was sufficient to accurately assign COO and a sequential algorithm was developed using CD10, BCL6, and MUM1 (Fig. 2) to separate GCB DLBCL from non-GCB DLBCL, with the latter group including both ABC DLBCL

and unclassified cases. Against the GEP gold standard, the Hans classifier correctly assigned 112 of the 142 tumors, a concordance of 79%. The authors emphasized that the groupings identified showed similar separation of outcomes after chemotherapy as the GEP-based groupings.

Since then, a number of other IHC-based algorithms have been described.[25-30] Choi et al[25] incorporated an additional newly developed antibody against GCET1 (HUGO designation SERPINA9), which is a protein highly expressed in germinal center B cells. They trained a sequential IHC algorithm (Fig. 2) using FFPET biopsies on TMAs against COO assignments that had been made on matching fresh frozen tissue using the Lymphochip microarray.[5] The assay was then validated using an independent group of 63 tumors that had matching GEP COO assignment with Affymetrix arrays. The reported concordance between the IHC-based assay and GEP in the validation cohort was 88%. Meyer et al[26] recognized that the sequential nature of these algorithms may be discarding important information that could be captured if the results of the stains were tallied up, thus producing the "Tally" algorithm (Fig. 2). A tie-breaker—if the scores supporting ABC were equal to those supporting GCB—was provided by staining for an antibody to LMO2, which is a protein that is highly expressed in germinal center B cells. Trained against COO assigned by GEP using Affymetrix microarrays on matched fresh frozen tissue, they reported a concordance of 93% in the training cohort. Finally, Visco et al[27] trained an IHC-based algorithm using 431 FFPET tumor biopsies on TMA using GEP on FFPET, rather than fresh frozen material, as the gold standard. They also reported a 93% concordance with COO by GEP and, similar to the Tally algorithm, this awaits confirmation in an independent validation cohort. A perceived weakness of these three studies is that they up-front excluded cases that were unclassified by GEP in both the training of the algorithms and calculations of performance. Three other studies have used antibodies that stain proteins that are differentially expressed between ABC and GCB DLBCL to produce assays that are prognostic in DLBCL.[28-30] It is important that these assays not be considered as COO assays as they were trained against outcome to treatment and not against a COO gold standard.

The described performance of these assays (Fig. 2) appeared very promising. However, a number of studies have highlighted issues regarding reproducibility and accuracy of IHC-based assays for COO. The Lunenburg Lymphoma Biomarker Consortium examined the reproducibility and reporting of a number of IHC stains, including for CD10, BCL6, and MUM1.[31] TMAs were distributed to eight laboratories for IHC staining and reporting. The level of agreement across the laboratories was poor, with agreement between laboratories for COO being 57% with a κ statistic (which corrects for agreement due to chance) of 0.36. Although CD10 staining and scoring was quite robust, there was poor agreement for both BCL6 and MUM1. The BCL6 stain appears to be very sensitive to different laboratory techniques, especially antibody detection. When a single laboratory performed the stains optimally, the pairwise agreement between reporting

FIGURE 2. Immunohistochemistry-Based Assays for COO Assignment


The four immunohistochemistry-based algorithms that were trained against gold standard gene expression profiling are shown. Accuracy is defined as the concordance with the gold standard. Sensitivity and specificity are shown for the ABC subtype—as they are binary assays, the specificity for ABC is the sensitivity for GCB, whereas the sensitivity for ABC is the specificity for GCB. The positive predictive value (PPV) and negative predictive value (NPV) are for the ABC subtype. The performance values are determined from independent validation cohorts, except where marked with an *, where they are from the training cohort and thus may overestimate the performance of the assay.

pathologist improved. However, the level of agreement with regards to COO was still suboptimal at 77% (κ statistic of 0.62). This level of agreement was improved if stains were excluded if no positive internal control was seen, but this resulted in a substantial rise in the failure rate of the assays. In response to the technical issues identified with BCL6, it has been suggested that the Hans and Choi classifiers be modified to exclude the BCL6 antibody.[26] More recently, Coutinho et al[32] examined the level of agreement across the IHC-based assays showing that the concordance between the assays was generally low. The study of Gutiérrez-Garcia et al directly addressed the accuracy of the IHC-based assays comparing the COO assignments by the Hans, Choi, and Tally algorithms with those from GEP on matched fresh frozen tissue using Affymetrix microarrays.[33] The results were disappointing, with concordance rates between 59% and 65% for the three IHC-based assays compared with the gold standard. The issues with reproducibility and the variable agreement with the gold standard COO likely play major roles in the observation that, although COO by GEP is prognostic in the R-CHOP era, the literature is highly discordant when COO is assigned by IHC-based assays. A meta-analysis of the IHC-based studies and the GEP-based studies has recently been published illustrating this point.[34]

In aggregate, despite the careful studies that defined the assays and the wide availability of IHC, the accumulated evidence indicates that IHC-based methods are not ready to guide clinical care at this time. If IHC-based assays are to be used to make management decisions, there will have to be a shift away from individual laboratory–developed tests and toward defined kits, where standardized antibodies, laboratory techniques, and agreement on scoring may improve reproducibility and accuracy, with reproducible observer scoring representing the most formidable obstacle to standardize. This approach is currently being used with the Hans algorithm providing the patient selection for a phase III, randomized, controlled trial assessing the efficacy of adding ibrutinib to R-CHOP in non-GCB DLBCL (ClinicalTrials.gov Identifier NCT01855750).

Gene Expression–Based Assays

Over the last decade, technologies have been developed that allow GEP employing the highly degraded RNA that is extracted from FFPET. Since 2010, a number of GEP-based assays have been described capitalizing on these advances. The generally high degree of accuracy of these assays is a testament to the very distinct gene expression patterns between ABC and GCB, and the robustness of the COO algorithm on which most of these assays are based.

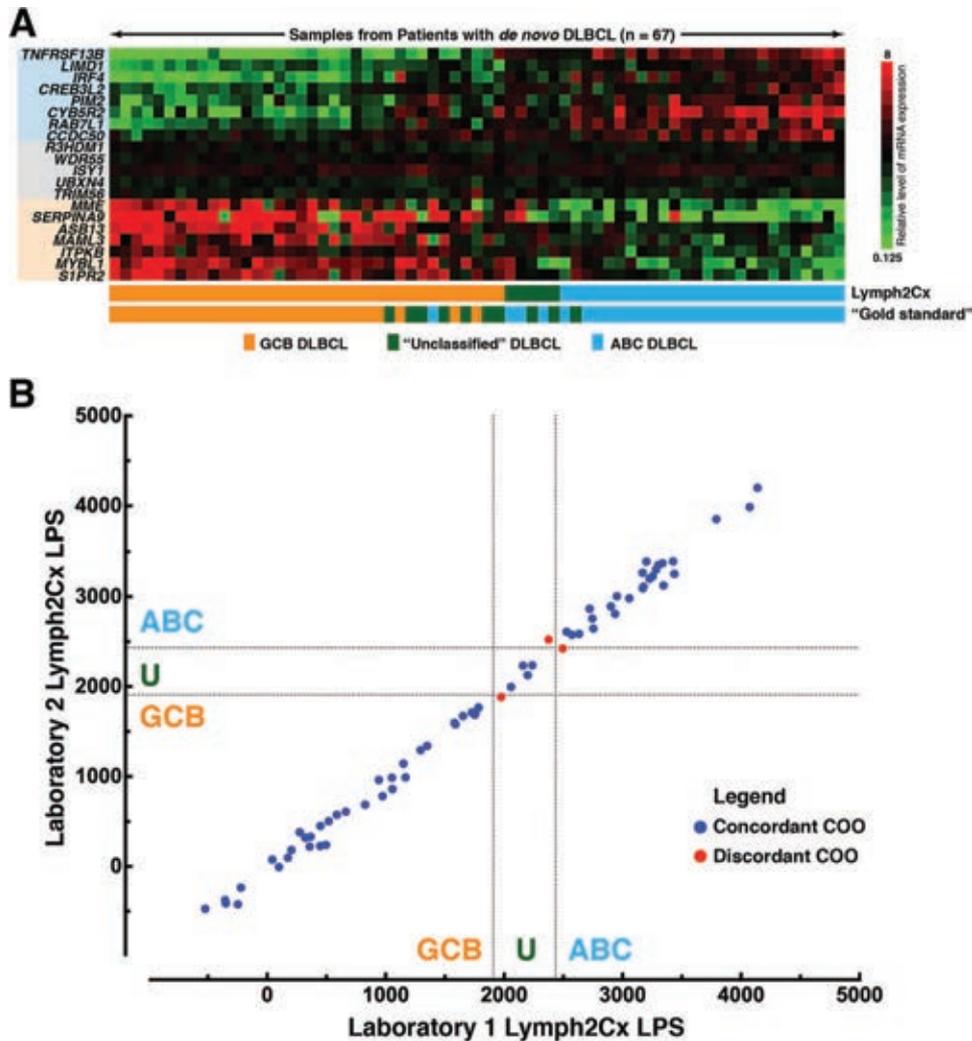
The first demonstration of robust COO assignment using GEP on RNA from FFPET came from techniques that make this degraded RNA suitable for GEP using standard microarray technology. Williams et al compared the results of applying the Wright algorithm to GEP using RNA from FFPET compared with that of matched fresh frozen tissue.[35] When unclassifiable cases were excluded, there was one frank misclassification out of 44 cases, giving a concordance of 98%.

This approach has subsequently been used to assign COO in a large cohort of patients with de novo DLBCL treated with R-CHOP,[27] with the expected survival difference observed between the GCB and ABC groups.

A range of other technology platforms have subsequently been used as the basis of COO assays, including quantitative nuclease protection assay,[36] multiplex reverse transcription (RT)–polymerase chain reaction (PCR),[37-39] DASL,[40] and NanoString.[41-43] In studies in which the comparator was the gold standard of GEP in fresh frozen tissue, concordance was typically high at approximately 95%, when unclassified cases are removed.[36,37,41,43] Two studies will be discussed in more detail below as these assays are now supporting phase III randomized controlled trials.

Barrans et al have developed an assay for DLBCL COO based on the cDNA-mediated Annealing, Selection, extension, and Ligation (DASL) platform (Illumina, San Diego, CA), which provides genome-wide GEP in degraded RNA samples.[40] This technology, in combination with a new tool for COO assignment based on balanced voting between four machine-learning tools,[44] was used to assign COO in a population-based cohort of 172 patients with DLBCL.[40] The COO assignments in this population were 48% GCB, 31% ABC, and 21% type 3 (presumably equivalent to unclassified). Although there was no comparison with the gold standard COO assignment from fresh frozen material, the characteristics of the ABC and GCB groups were consistent with previous reports, with inferior outcomes following treatment in the ABC group. This assay is currently being used to stratify patients for a phase III, randomized, controlled trial assessing the efficacy of adding bortezomib to R-CHOP in patients with DLBCL (ClinicalTrials.gov Identifier NCT01324596). The randomization to the treatment arms, stratified by COO to ensure equal proportions of patients with ABC and GCB in each arm, occurs after one cycle of R-CHOP to allow patients to commence treatment in a timely fashion while awaiting the GEP results.

The LLMPP used the NanoString platform to develop a parsimonious gene expression–based COO assay for RNA from FFPET.[43] We took advantage of the ability of this platform to quantitate up to 800 RNA species in multiplex to build a model that most accurately replicated the larger GEP model described in Lenz et al.[6] In brief, 93 genes that were most differentially expressed between ABC and GCB on Affymetrix microarray data from fresh frozen tissue were quantified in RNA extracted from matched FFPET biopsies on the NanoString platform. Genes were then selected based on the degree of correlation of the expression between the two platforms (and across the sources of RNA). In total, 15 genes (Fig. 3A) were sufficient to accurately replicate the model from Lenz et al[6] with the addition of further genes resulting in negligible increase in assay accuracy. The low-density assay, comprising only these 15 genes and five house-keeping genes, was applied to samples that contributed to the training of the Lenz et al model, the final model was built and then "locked." This assay, named the Lymph2Cx, was then tested

FIGURE 3. The Lymph2Cx Assay: A Gene Expression-Based Assay for COO


Panel A: The assay in the form of a heatmap from the independent validation cohort. The rows represent the 20 genes in the assay, with those highlighted in blue being overexpressed in the ABC group and those in orange being overexpressed in the GCB group. Genes in the middle are the house-keeping genes used to normalize for the number of quantifiable RNA species present. The columns are the relative gene expression of the 67 patients, arrayed from left to right based on ascending values of the assay's linear predictor score (LPS). Below the heatmap is the assignment according to the Lymph2Cx assay, with the gold standard assignments, from gene expression profiling from matched fresh frozen tissue using microarrays, at the bottom.

Panel B: Comparison of the LPSs from the Lymph2Cx assay between two independent laboratories. As indicated, lower LPS values indicates an assignment of GCB, whereas higher scores indicate an assignment of ABC. The concordance between the two sites was 95% (63 out of 66 cases) with no case being frankly misclassified (i.e., an ABC assigned GCB, or vice versa).

This research was originally published in *Blood*, Volume 123, Issue 8, DW Scott et al, "Determining cell-of-origin subtypes of diffuse large B-cell lymphoma using gene expression in formalin-fixed paraffin-embedded tissue." Pages 1214-1217, Copyright 2014.

in an independent cohort of 68 FFPET biopsies from the validation cohort of Lenz et al cases that have never contributed to COO model building. Compared with the gold standard, only one case was frankly misclassified (ABC to GCB) and the assay had a similar rate of unclassified cases to the gold standard. The Lymph2Cx was tested across two independent laboratories and showed 95% agreement of COO assignment, with discordant cases having shifted from a definitive assignment to unclassified, or vice versa (Fig. 3B). To the author's knowledge, this is the only published data addressing interlaboratory performance of the gene expression–based COO assays. The Lymph2Cx has subsequently been applied to FFPET biopsies from a population-based cohort of patients with de novo DLBCL, displaying a low failure rate of 1%, an unclassified rate of 11%, and substantial separation of

outcomes following R-CHOP between the ABC and GCB groups.[45] The assay has now been developed into a companion diagnostic by NanoString and is used to select patients for inclusion in a phase III, randomized, controlled trial assessing the efficacy of adding lenalidomide to R-CHOP in patients with ABC DLBCL (ClinicalTrials.gov Identifier NCT02285062). The rapid turnaround time of the assay is allowing randomization before starting treatment.

The unclassified category identifies tumors in which COO cannot be assigned with sufficient confidence. It is anticipated that clinical trials testing novel agents will be designed to include or exclude these patients by weighing the potential, albeit uncertain, benefits against the expected toxicities of the therapeutic. However, it is possible that patients with unclassified DLBCL will be left in a therapeutic wasteland,

where no agents have been specifically trialed in this group. This will particularly be an issue with assays that assign larger proportion of tumors in this category. It is hoped that the use of assays that provide more uniform and consistent COO assignment that we will be able to determine the genetic mutation landscape of unclassified cases and ascertain whether they represent a unique biologic group.

Ongoing Challenges for Gene Expression–Based Assays

In order for gene expression–based assays to be broadly and reliably deployed, a number of challenges need to be addressed. The first is the interlaboratory performance of the assays, which has only been demonstrated for the Lymph2Cx assay.[43] The second is the provision of adequate tissue for these assays. With the growing trend toward core needle biopsies for diagnosis of lymphoma, in many cases the biopsy material is exhausted in the routine diagnostic work-up. For these assays to be applicable to all patients, there will need to be a move back toward excisional biopsies and/or dedicated cores taken for molecular studies. Finally, most of these assays require the purchase and standardization of specialized equipment. It is anticipated that substantive evidence demonstrating the clinical and financial benefit of accurately determining DLBCL COO will be needed for the widespread adoption of these technologies.

ENVISAGING THE NEAR FUTURE

Although there is an expectation that eventually treatment of DLCBL will be guided by a comprehensive analysis of the genetic aberrations found in the tumor cells, the huge complexity that has been uncovered by genome-wide studies indicates that this will not be realized in the short-term or maybe even the medium-term. The first step toward precision medicine in DLBCL is the recognition that it comprises at least two distinct entities, as identified 15 years ago. The accurate and reliable ascertainment of COO in this disease will provide important enrichment for patients that will benefit from targeted therapeutics. It is anticipated that further genetic analyses will be performed on patients that do not respond to these agents to identify determinants of drug resistance.

At this point in time, there are no assays for COO assignment that can reliably inform treatment decisions outside of clinical trials. However, I firmly believe that by the time there is substantive evidence that new targeted agents improve patient outcomes, robust gene expression–based assays will be in place to identify the patients that will benefit.

Novel Treatments for T-Cell Lymphoma

Chan Yoon Cheah, MBBS, DMedSc, Yasuhiro Oki, MD, and Michelle A. Fanale, MD

OVERVIEW

T-cell lymphomas are a biologically and clinically diverse collection of diseases that collectively account for 10% to 15% of non-Hodgkin lymphomas. Unlike B-cell lymphomas, the response of T-cell lymphomas to standard anthracycline-containing chemotherapy regimens is suboptimal and the prognosis of patients is accordingly poor. To address these shortcomings, there has been a proliferation in biologic agents with novel mechanisms of action that target surface antigens, signaling pathways, or cellular processes. Given the large number of candidate molecules showing preclinical promise and the rarity of these diseases, drug development for peripheral T-cell lymphoma is challenging. We provide an overview of agents that have recently been approved for relapsed/refractory T-cell lymphoma and highlight efforts to introduce these agents into front-line treatment protocols in combination with chemotherapy. We discuss biologic doublets currently being evaluated as "chemotherapy-free" salvage regimens and highlight some of the most promising investigational agents in early clinical development.

Peripheral T-cell lymphomas (PTCLs) are a heterogeneous group of diseases that account for 10 to 15% of non-Hodgkin lymphomas (NHLs) in most Western countries. Although the WHO 2008 classification system includes 22 distinct mature T-cell and natural killer (NK) cell neoplasms,[1] they can be functionally grouped according to typical presentation as nodal, extranodal, leukemic, and cutaneous (Fig. 1). Three entities account for approximately 60% of T-cell lymphomas: PTCL not otherwise specified (PTCL-NOS), angioimmunoblastic T-cell lymphoma (AITL), and systemic anaplastic large cell lymphoma (ALCL), which may be positive or negative for anaplastic lymphoma kinase (ALK).[2] For the purpose of this review, we will focus primarily on these most common subtypes.

CURRENT TREATMENT OUTCOMES

Unfortunately, the majority of patients with PTCL do not experience durable remissions following multiagent chemotherapy. The exception is patients with ALK$^+$ ALCL, in whom outcomes can be favorable even when they are treated with cyclophosphamide/doxorubicin/vincristine/prednisone (CHOP).[2] The International T-cell Lymphoma Project described outcomes for 340 patients with PTCL-NOS: 5-year overall survival (OS) and failure-free survival (FFS) were 32% and 20% respectively, with no clear benefit for patients treated with anthracyclines.[3] Despite these data, CHOP remains the most common induction therapy used. Attempts to improve on CHOP with intensive induction such as VIP/ABVD (etoposide/ifosfamide/cisplatin–doxorubicin/bleomycin/ vinblastine/dacarbazine) and other high-

dose sequential chemotherapy regimens have been mostly unsuccessful.[4-6] In one retrospective study, Hyper-CVAD/MA (hyper-fractionated cyclophosphamide/doxorubicin/vincristine/dexamethasone alternating with methotrexate/cytarabine) showed higher overall response rate (ORR) and progression-free survival (PFS), but not higher OS, than CHOP,[7] although this finding has not been replicated in other retrospective studies.[5] Given the substantially greater toxicity associated with this regimen, we recommend that Hyper-CVAD be used with caution.

The German High-Grade Lymphoma Study Group (DSHNHL) retrospectively analyzed the outcomes of patients with PTCL who were treated in prospective studies using CHOP-like regimens to address whether (1) shortening the interval from 21 to 14 days, or (2) adding etoposide to CHOP (CHOEP) affected outcomes.[8] In a subgroup analysis, patients age 60 or older with normal serum lactate dehydrogenase (LDH) levels achieved superior event-free survival (EFS) when treated with etoposide-containing regimens; this was largely the result of a significant benefit in patients with ALK$^+$ ALCL (3-year EFS 92% for CHOEP vs. 57% for CHOP; p = 0.012) whereas those with other histologies displayed a nonsignificant trend toward improvement (3-year EFS 61% for CHOEP vs. 48% for CHOP; p = 0.057).[8] The benefit of etoposide in younger patients was supported by a recent large Swedish registry analysis, which found that use of CHOEP (vs. CHOP) was associated with improved PFS in patients younger than 60.[9]

UP-FRONT TRANSPLANTATION IN PTCL

Because of the poor outcomes described using chemotherapy alone, up-front consolidation using high-dose chemotherapy

and autologous stem cell transplantation (ASCT) in patients who achieve a response has been explored. The ORR following induction ranged from 66% to 82%, 41% to 72% of patients received ASCT, and the median OS was 3 to 5 years.[6,10-14] Reimer et al treated 83 patients (32 with PTCL-NOS) with CHOP induction followed by cyclophosphamide-total body irradiation conditioning and ASCT. At a median follow-up of 33 months, the 3-year PFS and OS were 36% and 48% respectively.[13] The Nordic Lymphoma Group treated 160 patients with PTCL (excluding ALK$^+$ ALCL) with bi-weekly CHOP with etoposide (CHOEP-14).[11] At a median follow-up of 60.5 months, the 5-year PFS and OS were 44% and 51% respectively, with marginal improvement in PFS (p = 0.04) and OS (p = 0.03) among patients with ALK$^-$ ALCL compared with other PTCL subtypes. In both studies, patients who had transplants had markedly superior outcomes compared with those who did not; however, the latter group consisted mostly of patients whose disease did not re-

spond to induction therapy or had comorbidities precluding SCT. The U.S. multicenter consortium reported that outside of clinical trials, only 33/341 patients (10%) treated at large academic centers received ASCT in first remission; this was associated with improvement in both PFS (hazard ratio [HR] 0.48; 95% CI, 0.27 to 0.84, p = 0.01) and OS (HR 0.48, 95% CI, 0.24 to 0.98, p = 0.04), although the typical limitations of a retrospective study apply.[7] Smith et al analyzed data collected by the Center for International Blood and Bone Marrow Transplant Research (CIBMTR) for 241 patients with mature T-cell lymphomas who underwent transplantation.[15] Patients in complete response (CR)1 had favorable outcomes (3-year PFS and OS of 58% and 70% respectively), indicating a major role for ASCT in patients with PTCL (other than those with primary cutaneous or ALK$^+$ ALCL) who are in first remission. However, it should be noted that no prospective randomized data demonstrating a clear advantage for transplant over induction chemotherapy alone currently exist.

Up-front allogeneic stem cell transplantation (alloSCT) has been explored in a prospective phase II study in which Corradini et al randomly assigned patients age 60 or older whose disease responded to induction therapy to either ASCT (14 patients) or alloSCT (23 patients) based on donor availability.[10] The reported 4-year OS (92% vs. 69%, p = 0.10) and PFS (70% vs. 69%, p = 0.92) were not significantly different; however, the study was neither designed nor powered for this comparison. The CIBMTR multicenter retrospective study attempted to compare outcomes for 115 patients who received ASCT and 126 who received alloSCT; patients in the alloSCT group were younger, but had more unfavorable features. The 3-year PFS for ASCT versus alloSCT in this analysis was 47% versus 33%, but only 17% of the patients who received ASCT and 14% of those with alloSCT had received just one prior line of treatment.[15] Thus, whether alloSCT as front-line consolidation offers additional disease control over ASCT remains controversial and is being addressed by

KEY POINTS

- Outcomes for patients with peripheral T-cell lymphoma treated with cyclophosphamide/doxorubicin/vincristine/prednisone (CHOP)-like induction regimens with and without front-line consolidative stem cell transplantation will be summarized.
- Clinical data supporting the regulatory approval of pralatrexate, romidepsin, brentuximab vedotin, and belinostat for patients with relapsed/refractory disease will be reviewed.
- Trials combining these novel agents in combination with CHOP-like chemotherapy in previously untreated patients will be outlined.
- Studies using combinations of new agents in biologic doublets as salvage regimens will be described.
- Emerging clinical data on agents with promising clinical efficacy in phase I studies will be highlighted.

an ongoing German cooperative group study (EudraCT number: 2007-001052-39).

NEW AGENTS FOR RELAPSED AND REFRACTORY DISEASE

When treated using conventional chemotherapy alone, the outcome of patients with relapsed or refractory PTCL is particularly poor—a population-based registry study from the British Columbia Cancer Agency found that the median OS of patients with PTCL was only 5.5 months.[16] When used as a single agent in pretreated patients, bendamustine results in an ORR of approximately 50% with a median duration of response (DOR) of 3.5 months.[17] Gemcitabine has a similar ORR and the responses appear more durable.[18,19] However, there is a substantial unmet need for more options for patients whose disease does not respond to these therapies. Fortunately, several agents with novel mechanisms of action have been approved for this setting in the last 5 years, with several others undergoing evaluation in trials for potential future approval (Table 1).

Pralatrexate

Folates are critical for DNA synthesis and folate antagonism was one of the earliest successful chemotherapeutic pathways.[20] Pralatrexate is an inhibitor of dihydrofolate reductase that was designed to have increased affinity for the reduced folate carrier and therefore accumulates within cells and exhibits increased potency compared with methotrexate.[21] A phase I study demonstrated promising activity in T-cell lymphomas,[22] prompting an international phase II study (PROPEL). In this trial, 111 patients with relapsed or refractory aggressive PTCL were treated with single-agent pralatrexate (30 mg/m² administered intravenously once weekly),

achieving an ORR of 29% (CR 11%) with median DOR of 10.1 months.[23] The major toxicities seen with this agent are cytopenias (particularly thrombocytopenia, which may be dose limiting) and mucositis (any grade, 70%; grade ≥3, 22%), although there are data suggesting that prophylactic use of leucovorin may ameliorate the latter without compromising efficacy.[24] On the basis of this study, in 2009 pralatrexate gained U.S. Food and Drug Administration (FDA) approval for patients with PTCL who have received one or more systemic therapies.

Histone Deacetylase Inhibitors

Epigenetic therapies are useful for a range of hematologic malignancies, particularly PTCL. Recent publications have shown that histone deacetylase (HDAC) inhibitors have pleiotropic downstream effects including apoptosis, senescence, immune suppression, and angiogenesis.[25] HDACs are a group of enzymes with both histone and nonhistone targets that together govern chromatin conformation and gene expression.[26] Several agents in this class are effective in PTCL.

Romidepsin. Romidepsin is a cyclic, class 1-selective HDAC inhibitor that has been used as monotherapy for relapsed or refractory PTCL in two phase II studies.[27,28] Coiffier et al reported the larger study, in which 130 patients (53% PTCL-NOS) with a median of two prior treatments received 14 mg/m² romidepsin intravenously once weekly for 3 of 4 weeks.[28] Responses occurred at a median of 1.8 months; the ORR of 25% (CR 15%) was comparable across major histologic subtypes. Responses were durable, and a recent update of this study reported a median DOR of 28 months.[29] The most common toxicities included fatigue, thrombocytopenia, and gastrointestinal (GI) disturbance. Early reports suggesting prolongation of corrected QT interval were sub-

TABLE 1. Summary of Selected Novel Agents Currently Being Evaluated for Efficacy in Peripheral T-Cell Lymphoma

Agent	Mechanism	Phase	n	Grade ≥3 Toxicities	ORR	CRR	DOR
FDA-approved agents for PTCL							
Pralatrexate[23]	Folate antagonist	II	111	Mucositis	29%	11%	10.3 mo
Romidepsin[27,28]	HDAC inhibitor	II	47	Nausea, fatigue, thrombocytopenia	38%	17%	8.9 mo
		II	130	Thrombocytopenia, neutropenia, infection	25%	15%	28 mo*
Brentuximab vedotin[38]	Antibody-drug conjugate	II	35	Neutropenia, peripheral neuropathy	41%	24%	7.6 mo
Belinostat[31]	HDAC inhibitor	II	129	Hematologic	26%	10%	13.6 mo
Agents under investigation in PTCL							
Mogamulizumab[43]	Anti-CCR4 mAb	II	37	Neutropenia, rash	34%	17%	8.2 mo**
Alisertib (MLN8237)[54]	Aurora A kinase inhibitor	II	37	Hematologic, febrile neutropenia	24%	5%	NR
Duvelisib (IPI145)[69]	PI3Kγδ inhibitor	I	33	Transaminitis, rash, neutropenia	47%	12%	NR
Crizotinib[89]	ALK inhibitor	II	14	Diarrhea, vomiting, visual impairment	60%	36%	8.3 mo
Nivolumab[88]	Anti-PD1 mAb	I	5	Pneumonitis, rash, sepsis	40%	0%	NR

Abbreviations: ORR, objective response rate; CRR, complete response rate; DOR, duration of response; PI3K, phosphoinositide-3-kinase; CCR4, chemokine receptor-4; HDAC, histone deacetylase; ALK, anaplastic lymphoma kinase; NR, not reported; PD-1, programmed cell death-1; mAb, monoclonal antibody.
Response rates refer to patients with nodal PTCL subtypes where information available.
*Duration of response reported from updated report.[29]
**Median progression-free survival of patients with PTCL achieving response.

sequently attributed to antiemetic therapy and clinically significant dysrhythmias were not seen. Romidepsin gained FDA approval in 2011 for patients with PTCL who have at least one prior systemic therapy. Chihara et al reported a single-center phase I study to determine the safety profile of romidepsin administered on days 1 and 4 with ifosfamide/carboplatin/etoposide (ICE), with the hope that this combination would improve the CR rate over ICE alone and thus facilitate a greater proportion of patients receiving SCT.[30] The main toxicities were hematologic, with reversible grade 3 or greater thrombocytopenia in 87% of patients, and 5/7 (71%) response-evaluable patients achieved CR. This encouraging preliminary observation requires further confirmation in an expanded cohort and enrollment is ongoing.

Belinostat. Belinostat is a pan-HDAC inhibitor derived from hydroxamic acid that was evaluated in a single-arm phase II study with a dosing schedule of 1,000 mg/m^2 for days 1 through 5 in a 3-week cycle until progression or unacceptable toxicity.[31] Among 120 patients with PTCL confirmed by central pathology review, the ORR was 26% (CR 10%). As with romidepsin, responses were rapid (median time to response 5.6 weeks) and the median DOR was 8.3 months at the time of initial reporting. The major toxicities were hematologic (grade ≥3 anemia, neutropenia, and thrombocytopenia in 10, 13, and 13%, respectively).[31] Of note, belinostat appears to induce grade 3 or greater thrombocytopenia less frequently than romidepsin. On the basis of this study, in 2014 belinostat received accelerated FDA approval for patients with relapsed/refractory PTCL.

Brentuximab Vedotin

Although "naked" monoclonal antibodies (mAbs) against CD30 showed preclinical promise, clinical activity in patients with CD30$^+$ lymphomas was disappointing.[32] Brentuximab vedotin (BV) was designed to improve efficacy by conjugating the anti-CD30 mAb to the antimicrotubule agent monomethylauristatin E (MMAE). Binding to CD30 on the cell surface results in proteolytic release, internalization, and lysosomal uptake of MMAE, and tubule disruption, cell cycle arrest, and apoptosis.[33] ALCL has uniform strong CD30 expression, and on the basis of positive data from BV phase I trials,[34,35] a multicenter phase II study in patients with relapsed/refractory systemic ALCL (ALK-positive and -negative) was conducted.[36] Fifty-eight patients with a median number of two prior treatments were treated with 1.8 mg/kg BV intravenously every 3 weeks for up to 16 doses. The ORR was 86% (CR 57%) with 97% of patients having a reduction in tumor volume; responses occurred after a median of 6 weeks and the median DOR was 12.3 months. The most common toxicities were nausea, fatigue, GI disturbance, rash, and neutropenia (mostly grade 1 to 2). Peripheral sensory neuropathy was mainly grade 1 (all grades, 41%; grade 3, 12%) and was manageable with dose reductions and delays. Rare but potentially fatal adverse events reported include posterior multifocal leukoencephalopathy and pancreatitis.[37] Horwitz et al treated 35 patients with non-ALCL

PTCL subtypes (which have variable CD30 expression) using a similar study design.[38] The patients included in this study had either AITL (13 patients) or PTCL-NOS (22 patients); among these two histologic subtypes the ORR was 54% and 33% and the CR was 38% and 14%, respectively. Interestingly, CD30 expression by immunohistochemistry did not correlate with clinical outcomes, thus it could be hypothesized that MMAE diffuses out of the apoptotic tumor cell and exerts local effects on the tumor microenvironment. BV was approved by the FDA in 2011 for patients with systemic ALCL having failed at least one prior systemic therapy, and at the time of writing has National Comprehensive Cancer Network compendium class 2A listing for the treatment of patients with relapsed non-ALCL CD30$^+$ PTCL.

Alemtuzumab

CD52 is a pan-lymphoid antigen with variable expression in PTCL.[39] The anti-CD52 mAb alemtuzumab was used as a single agent in two small European studies in patients with pretreated PTCL.[40,41] Enblad et al treated 14 patients with 30 mg alemtuzumab administered intravenously three times weekly for up to 12 weeks.[40] Despite chemoprophylaxis with trimethoprim/sulfamethoxazole and valaciclovir, fatal opportunistic infections occurred in 5/14 (35%) patients, resulting in early study termination. The observed ORR was 36%. Interestingly, Zinzani et al showed that a reduced dose (10 mg) and a shorter schedule was better tolerated and effective, with an ORR of 50% in six patients with PTCL.[41] However, the toxic deaths that occurred in the first study have dampened enthusiasm for further development in patients with pretreated PTCL.

Mogamulizumab

Mogamulizumab, a defucoslyated mAb against chemokine receptor-4 (CCR4), was found to have single-agent activity in patients with relapsed/refractory T-cell lymphomas in a phase I study.[42] Ogura et al performed a phase II study in Japanese patients with relapsed/refractory T-cell lymphoma with 1.0 mg/kg mogamulizumab administered intravenously weekly for 8 weeks.[43] Among 37 patients treated, the median number of prior therapies was two and the main histologic subtypes were PTCL-NOS (16 patients), AITL (12 patients), and CTCL (8 patients). The ORR was 35% (CR 13%), with a median PFS of 3.0 months. The main toxicities reported were neutropenia (any grade, 38%; grade ≥3, 19%), fever (grade 1–2, 30%), infusion reaction (grade 1–2, 24%), and skin disorders (any grade, 51%; grade ≥3, 11%). Although CCR4 expression by immunohistochemistry was required for study entry, there was little correlation between expression of target antigen and response, similar to the data for BV and CD30. The authors hypothesized depletion of CCR4$^+$ regulatory T (T$_{reg}$) cells, resulting in an increase in the number of CD8$^+$ cytotoxic T-cells, as a mechanism of tumor control, and on the basis of these data mogamulizumab gained approval for the treatment of relapsed PTCL in Japan in 2014. Zinzani et al performed a multicenter European phase II study with 38 patients and reported a lower ORR of 11% with

a similar median PFS of 2 months,[44] although the limited DOR suggests that mogamulizumab might be best suited for combination studies. However, one possible exception may be the highly aggressive and chemorefractory disease adult T-cell lymphoma/leukemia. Ishida et al performed a phase II study of mogamulizumab in 28 patients with relapsed/refractory disease, in which the ORR was 50% with median PFS and OS of 5.2 and 13.7 months respectively.[45]

Lenalidomide

The immunomodulatory drug lenalidomide has substantial activity in myeloma and B-cell lymphomas.[46,47] Three small studies have explored lenalidomide (25 mg administered orally for days 1 to 21 of a 28-day cycle) in patients with relapsed/refractory PTCL, with a reported ORR of 22% to 39% (CR 8% to 30%).[48-50] Although the median DOR in the largest study of 54 patients was only 3.6 months, there was a nonsignificant trend toward higher response rates among the subset of patients with AITL.[48]

Alisertib

Aurora A kinase regulates mitotic entry and spindle formation; it is overexpressed in aggressive lymphomas and has a potential role in oncogenesis.[51] The orally available, small-molecule competitive inhibitor alisertib induces cytotoxicity in a range of solid and hematologic tumors.[52] Friedberg et al performed a multicenter phase II study of alisertib in 48 patients with heavily pretreated aggressive lymphomas.[53] Although the ORR was 27% overall, it was 4/8 (50%) among patients with T-cell lymphoma, with 3/4 (75%) maintaining a response for more than 1 year at the time of reporting. Subsequently, the SWOG1108 phase II study extended this observation in an additional 37 heavily pretreated patients with a range of PTCL subtypes.[54] Alisertib was administered at a dosage of 50 mg twice daily for 7 days in a 21-day cycle. The most common adverse events (AEs) of grade 3 or greater

were hematologic, observed in approximately one-third of patients; febrile neutropenia was seen in 14%. The ORR was 24% overall and 31% in patients with PTCL-NOS. As a pathway to potential approval, an ongoing international phase III registration study is comparing alisertib to investigators choice (gemcitabine, pralatrexate, or romidepsin) in patients with PCTL (NCT01482962).

MOVING NOVEL AGENTS INTO THE FRONT LINE

With many drugs demonstrating efficacy in relapsed/refractory PTCL, integrating agents into front-line therapy is a major focus of drug development efforts. The conventional approach has been to be combine novel agents with chemotherapy in an attempt to discover an "R-CHOP" equivalent for PTCL; a summary of these studies is provided in Table 2.

CHOP/CHP Plus Brentuximab Vedotin

Because of the promising single-agent activity of brentuximab, a phase I study of CHOP without vincristine (CHP) and with brentuximab was designed to minimize the overlapping toxicity of peripheral sensory neuropathy. This study enrolled 39 patients with CD30$^+$ PTCL, although most (32 patients) had ALCL.[55] Two schedules of administration were used: BV×2 followed by CHOP×6 (sequential, 13 patients) or BV given concurrently with CHP (combination, 26 patients). The sequential arm was closed by the sponsor after two patients who responded to BV progressed during CHOP. Toxicity was similar between the schedules and manageable; the most common AE overall was peripheral neuropathy (31% with grade ≥3 in the combination group), followed by hematologic febrile neutropenia (21% in the combination group), fatigue, nausea, and GI disturbance. The combination was highly active, with an ORR of 85% and 100% (CR, 62% and 88%) and 1-year PFS of 77% and 71% in the sequential and combination groups, respectively, and none of these

TABLE 2. Summary of Selected Chemotherapy/Novel Agent Combinations for Untreated Peripheral T-Cell Lymphoma

Combination	Study Group	Major Histologies	Phase	n	ORR	CRR	PFS	OS
CHOP + romidepsin[57]	LYSARC	NR	Ib/II	35	68%	51%	18 mo 57%	18 mo 76%

patients underwent front-line consolidative ASCT.[55] The combination schedule is currently being compared with CHOP for patients with CD30$^+$ PTCL in the phase III ECHELON-2 study (NCT01777152).

CEOP Plus Pralatrexate

Advani et al reported preliminary results from the T-cell consortium trial of CEOP (cyclophosphamide/etoposide/vincristine/prednisone) alternating with pralatrexate in newly diagnosed patients with PTCL.[56] Etoposide was substituted for doxorubicin because of data suggesting improved efficacy (discussed above) and the lack of proven benefit for anthracyclines. CEOP was administered in the standard fashion, with pralatrexate administered at 30 mg/m^2 intravenously on days 15, 22, 29; up to 6 cycles in total were planned and growth factor support was mandatory. The goal was to improve the CR rate to facilitate optional ASCT, which was allowed at the investigator's discretion. The ORR was 70% (CR 45%) and the 1-year EFS was 48%. Observed toxicities of grade 3 or greater included hematologic events, sepsis, and mucositis.

CHOEP Plus HDAC Inhibitors

The French cooperative group LYSARC (Lymphoma Academic Research Organization) performed a phase Ib/II study of CHOP with romidepsin in 35 patients with treatment-naive PTCL. CHOP21×8 was given at standard doses, with the dose of romidepsin escalated (phase II dose 12 mg/m^2 on days 1 and 8 in a 21-day cycle). The major adverse events were, predictably, hematologic: grade 3 or greater neutropenia (38%), thrombocytopenia (19%), and anemia (9%). The ORR was 68% (CR 51%) and the estimated PFS at 18 months was 57%.[57] This combination is being tested in a randomized phase III study (NCT01796002). The Italian Cooperative Group is performing an ongoing phase I/II study of romidepsin in combination with CHOEP followed by ASCT (NCT02223208). Because of its activity in cutaneous T-cell lymphoma,[58,59] Oki et al. tested the combination of the orally available pan-HDAC inhibitor vorinostat with CHOP in a small phase I study of 14 newly diagnosed patients with PTCL.[60] Toxicities were comparable to those expected from standard CHOP, with the exception of mild diarrhea in approximately half of all patients treated. All 12 patients who completed therapy achieved a CR (93% of total population) suggesting that this promising combination warrants further evaluation. A multicenter phase I study evaluating the combination of CHOP with belinostat is in progress (NCT01839097).

CHOP Plus Alemtuzumab

Alemtuzumab has also been explored in combination with CHOP-like therapy in three separate phase II multicenter European studies with markedly different treatment schedules.[61-63] The Italian study used 8 doses of CHOP-14 with 30 mg alemtuzumab given intravenously at 2-week intervals (total 240 mg)[62]; the HOVON (Dutch-Belgian Hemato-Oncology Group) study also used CHOP-14, but intensified alemtuzumab with three 30-mg doses per cycle (total 720 mg)[63]; the DSHNHL study used alemtuzumab (133 mg over 4 weeks) as consolidation following CHOP induction (with etoposide for patients older than 60) in 41 patients with newly diagnosed PTCL.[61] In all three studies, serious opportunistic infectious complications such as CMV reactivation, disseminated zoster and tuberculosis JC virus encephalitis, invasive fungal infections, and EBV-associated lymphoproliferative disease were observed despite aggressive chemoprophylaxis. Although comparisons between small phase II studies in heterogeneous disease groups are difficult, it appeared that both the ORR and rate of infection of grade 3 or greater were proportional to the cumulative dose of alemtuzumab administered. The ongoing ACT-1 (NCT00646854) and ACT-2 (EudraCT 2007-000821-23) phase III studies are randomized comparisons of CHOP ± alemtuzumab in PTCL in younger (with ASCT consolidation) and older patients respectively.

BIOLOGIC DOUBLETS IN THE RELAPSED SETTING

Moving beyond the traditional "CHOP+X" development pathway are a plethora of studies testing combinations of novel agents and eschewing chemotherapy altogether. At present, these biologic doublets are mostly being tested in the relapsed/refractory setting. A selection of such studies is presented in Table 3. We anticipate that the most promising combinations will be investigated in chemotherapy-free front-line protocols, as is currently underway in B-cell lymphoma. At the present time, results from most of these protocols are not mature. Hopfinger et al explored the combination of lenalidomide, vorinostat (400 mg daily, fixed dose), and dexamethasone in a phase I/II study and found that the maximum tolerated dose (MTD) of lenalidomide in the combination was only 5 mg daily.[64] Planned dose escalation was aborted because of grade 3 thrombocytopenia and stroke at the 10-mg dose of lenalidomide. Probably because of the low tolerated dose of lenalidomide, activity was modest (ORR 25%, median PFS 2.2 months). Tan et al recently reported on a phase II study of the HDAC inhibitor panobinostat with the proteasome inhibitor bortezomib in patients with pretreated PTCL.[65] The main toxicities were hematologic, diarrhea, fatigue, and peripheral sensory neuropathy; among 23 evaluable patients, the ORR was 43% (CR 22%) with five patients successfully bridged to allogeneic stem cell transplantation.

Several combination studies are underway using romidepsin in combination with other biologic agents. There are preclinical data suggesting potent synergism between romidepsin and alisertib in T-cell lymphomas,[66] an observation supported by preliminary results from a phase I study of the combination being performed at The University of Texas MD Anderson Cancer Center.[67] Among the included histologies, activity seems most promising in PTCL, with a CR observed at the lowest dose level and ORR of 1/3 (33%). This study is ongoing and the expansion cohort will be restricted to patients with PTCL. Romidepsin is also being explored in combination with several other nonchemotherapic agents, including lenalidomide, 5-azacitidine, and pralatrexate, with promising early results. Preliminary results from a phase I/II

TABLE 3. Selected Ongoing Studies Testing Biologic Doublets in Peripheral T-Cell Lymphoma

Agents	Phase	Population	Sponsor/Site	ClinicalTrials.gov
Romidepsin + lenalidomide	I	Untreated PTCL	Northwestern University	NCT02232516
	I	RR lymphoma/myeloma	Yale/Peter MacCallum Cancer Centre	NCT01742793

Abbreviations: PTCL, peripheral T-cell lymphoma; NHL, non-Hodgkin lymphoma; RR, relapsed/refractory.

combination of romidepsin/lenalidomide suggested that the combination is active, with ORR in relapsed PTCL of 58% but only 1 of 12 patients entering into CR.[68] Phase II studies are planned and Petrich et al will be conducting a front-line PTCL phase II trial of romidepsin plus lenalidomide. As these biologic doublets move into the front-line setting further information will be gained in terms of their efficacy, although challenges remain with respect to which components of efficacy (ORR, CR, or PFS) are most important to determine which biologic regimens should be selected for front-line randomized comparative trials against standard chemotherapy regimens such as CHOP or CHOEP.

AGENTS IN EARLY CLINICAL DEVELOPMENT
PI3K Inhibitors
The orally administered phosphoinositide-3-kinase (PI3K) gamma/delta inhibitor duvelisib (IPI-145) was assessed in a phase I study of 33 heavily pretreated patients with T-cell lymphoma (CTCL 17, PTCL 16).[69] Most patients were treated at the MTD of 75 mg twice daily; among patients with PTCL the ORR was 47% (CR 12%) with a favorable toxicity profile (the most common AEs were transaminitis, rash, and neutropenia). These highly promising results warrant further evaluation. Based on preclinical data,[70] another PI3K gamma/delta inhibitor, RP-6530, is currently being evaluated in a phase I study of patients with relapsed/refractory lymphomas and appears to be well tolerated, although no patients with PTCL were included in the preliminary report.[71] Another interesting approach to improve the efficacy of novel therapeutics is the design of bifunctional molecules through medicinal chemistry. One such agent, CUDC-907, is both a pan-HDAC and PI3K inhibitor and has shown greater preclinical activity than single-agent HDAC or PI3K inhibitors.[72] The compound is currently in a phase I clinical trial of refractory lymphoid malignancies (NCT01742988).

Proteasome Inhibitors
The first agent in this class, bortezomib, had moderate activity as a single agent in CTCL[73] and in combination with

CHOP in untreated patients with PTCL.[74] The second-generation proteasome inhibitor carfilzomib is being investigated in an ongoing phase I study (NCT01336920).

IDH2 Inhibitors
Gain-of-function mutations in the genes encoding the metabolic enzymes isocitrate dehydrogenase 1 and 2 (IDH1 and IDH2) result in accumulation of R-2-hydroxyglutarate, a metabolite that induces epigenetic changes that drive oncogenesis.[75] Mutations in *IDH1* and *IDH2* have been reported in a range of hematologic and solid tumors, including 45% of cases of AITL.[76,77] AG-221 is a first-in-class, oral selective inhibitor of mutant IDH2 enzyme that appears to be well tolerated, with promising activity and durable responses in a preliminary report of a phase I study in advanced IDH2-positive hematologic malignancies.[78] It is being evaluated in a phase I/II study including patients with IDH2-positive AITL (NCT02273739).

Retinoids
Vitamin A derivatives have demonstrated a range of anticancer functions including antiangiogenesis activity and induction of apoptosis and differentiation.[79] With the exception of acute promyelocytic leukemia, their clinical development has been limited by their toxicity profile. The synthetic retinoic acid (fenretinide) appears to be better tolerated than all-trans retinoic acid, and a phase I study using a pharmacologically optimized emulsion formulation resulted in a clinical benefit rate (CR+PR+SD) of 64% among 11 patients with relapsed T-cell lymphomas.[80]

Selective Inhibitors of Nuclear Export
Selinexor (KPT-330) is a first-in-class, selective, reversible inhibitor of nuclear export that binds to the nuclear export protein XPO1, forcing its nuclear retention and activation of tumor suppressor proteins.[81] It has shown preclinical activity in a range of malignancies.[82-84] Preliminary data from a phase I study in patients with relapsed/refractory hematologic malignancies suggest that it is well tolerated and has potential efficacy in T-cell lymphoma with one outcome of CR and two

of stable disease (SD) among three evaluable patients.[85] A phase II study in PTCL (and other histologies) is planned.

Immune Checkpoint Inhibitors

PD-1 is an immune checkpoint receptor that inhibits T-cell activation upon binding to its ligand PD-L1, which is over-expressed in many lymphoid malignancies. Antibodies specific for PD-1, such as nivolumab, thus induce antitumor T-cell activation and are highly active in Hodgkin lymphoma.[86] PD-L1 is known to play an important role in the tumor microenvironment in PTCL, providing a preclinical rationale for PD-1 inhibitors in these conditions.[87] A phase I study in heavily pretreated patients with NHL including 23 patients with T-cell lymphoma recently reported a favorable toxicity profile and ORR of 17%. However, among patients with PTCL, the ORR was 2/5 (40%).[88]

ALK Inhibitors

For patients with ALK$^+$ ALCL, the *EML4-ALK* fusion onco-gene provides an attractive target. Crizotinib, the first-generation ALK inhibitor, was used in a phase Ib study of 15 patients with ALK$^+$ lymphomas (14 with ALK$^+$ ALCL).[89] The main toxicities were diarrhea, vomiting, and visual impairment; the ORR was 60%. This agent is being tested in a phase I/II study in combination with chemotherapy in untreated patients (NCT01979536) and in a study of relapsed/refractory ALK$^+$ ALCL (NCT00939770). As with many tyrosine kinase inhibitors, secondary resistance has been reported and second-generation agents such as ceritinib (LDK378) will undoubtedly be explored in patients who experience treatment failure.[90-93] A phase I study that includes an arm enrolling patients with ALK$^+$ malignancies other than lung cancer is in progress (NCT01283516).

TOWARD MOLECULAR STRATIFICATION IN PTCL

Gene expression profiling (GEP) has advanced our understanding of the classification,[92] prognostic stratification, and molecular pathogenesis of T-cell lymphomas. The Mayo group recently described two genetic subsets of ALK$^-$ ALCL with disparate clinical outcomes: patients with rearrangements in *DUSP22* (at the 6p25.3 locus, found in 30% of cases) had excellent outcomes, comparable to those of ALK$^+$ ALCL, whereas those with *TP63* rearrangement (on 3q28, seen in 8% cases) had dismal prognosis.[93] Several recurrent somatic mutations in genes such as *TET2*,[94] *IDH2*,[77] and *RHOA*[95,96] have been described, although their clinical relevance requires further investigation. In PTCL-NOS, a recurrent t(5;9)(q33;q22) translocation resulting in a *ITK-SYK* fusion gene and SYK overexpression was described in a subset of patients with follicular histology.[97] Finally, small nucleolar RNA (snoRNAs) have been shown to have potential diagnostic and prognostic significance in PTCL.[98] Further development and more widespread utilization of these technologies are clearly needed to deliver on the promise of true precision medicine for patients with T-cell lymphomas.

CONCLUSION

Cooperative studies in the last 5 years have successfully enabled the rapid completion of phase I/II studies and brought four new drugs for patients with T-cell lymphoma to the clinic. Continuing efforts are needed to complete confirmatory randomized phase III studies in combination with chemotherapy. The development of chemotherapy-free regimens using the most active biologic agents in PTCL will be a critical focus of research efforts in the future. Additional efforts to develop molecular targeted approaches are also clearly needed in order to rationally select a treatment plan that would be predicted to have the highest efficacy for a particular patient.

Novel Agents in the Therapy of Hodgkin Lymphoma

Stephen Ansell, MD, PhD

OVERVIEW

Hodgkin lymphoma (HL) is a B-cell malignancy that typically has a favorable prognosis when treated with chemotherapy, often in combination with radiation therapy. The prognosis for patients whose disease relapses or is refractory, however, is far less favorable and novel therapies are needed for these patients. The unique cellular composition of HL provides a number of opportunities to target either the malignant Reed-Sternberg cell or the inflammatory tumor microenvironment. Antibody-drug conjugates targeting CD30, small molecule inhibitors of cell signaling, and antibodies that inhibit immune checkpoints, have all demonstrated activity in HL. Current and future trials are exploring the use of these agents in combination with each other and with standard chemotherapy.

Hodgkin lymphoma is an uncommon B-cell malignancy affecting approximately 9,000 new patients each year and representing approximately 12% of all lymphomas seen in the United States.[1] HL is composed of two distinct disease entities, namely classical HL and nodular lymphocyte predominant HL. Classical HL is further subcategorized as nodular sclerosis, mix cellularity lymphocyte depletion, and lymphocyte rich HL.[2] Although HL commonly responds well to initial therapy and a substantial percentage of patients have durable remissions and many are cured, a subset of patients continue to experience relapsed disease, and patients progressing after intensive treatments, such as autologous stem cell transplantation, have a very poor outcome. In the recent past, particularly effective novel therapies have been identified to treat these patients, and these novel agents are now being integrated into earlier lines of treatment.

THERAPEUTIC TARGETS IN HODGKIN LYMPHOMA

HL has a unique histologic pattern in that a small fraction of the nodal infiltrate is attributable to malignant Reed-Sternberg cells.[3] A vast majority of the cells seen in the tumor tissue are reactive inflammatory cells, including a dense infiltrate of T cells, histiocytes, eosinophils, and plasma cells.[4] Furthermore, the tumor microenvironment is unique in that the activated cells secrete multiple chemokines and cytokines, which attract many of these cells to the tumor environment. These cytokines and immunologically active molecules include thymus- and activation-regulated chemokine (TARC/CCL17), interleukin (IL)-6, IL-13, and soluble IL-2 receptor.[5,6] The immune cells attracted to the tumor microenvironment appear to support the growth of Reed-Sternberg cells by secreting additional survival factors. The

immune effector cells present in the tumor, however, appear unable to mount an effective antitumor immune response. Initially, this was attributed to the fact that the T cells present in the tumor were predominantly T helper 2 (TH2) cells. Recent data, however, have suggested they may well be TH1 cells in view of the fact that TH1-associated *TBET* is abundant in classical HL and TH2-associated *GATA3* is expressed in substantially lower levels.[7]

An effective immunologic response, however, may be considerably suppressed as a result of signaling through programmed death (PD)-1. PD-1 is expressed on activated T cells, and signaling through PD-1 suppresses T-cell function. Malignant Reed-Sternberg cells express high levels of PD-1 ligands, namely PD-L1 and PD-L2. Expression of the PD-1 ligands on Reed-Sternberg cells is related to chromosomal translocations that result in amplification of the PD-L1 and PD-L2 loci on chromosome 9p24.1 and result in suppression of the antitumor immune response. Epstein-Barr virus infection, which is often seen in patients with HL, may also induce the expression of PD-1 ligands.[8] These mechanisms are responsible for upregulation of Janus kinases and signal transducers and activators of transcription (JAK-STAT) signaling; activation of JAK-STAT signaling and overexpression of PD-L1 appear to be higher among patients with multiple relapsed HL.

Other intratumoral factors associated with disease progression and a poorer outcome in HL include the presence of other intratumoral immune cells, as well as immune mechanisms in the peripheral blood. Tumor-associated macrophages, particularly increased numbers of CD163+ macrophages, have been associated with a poorer outcome and decreased overall survival.[9] Factors in the peripheral blood (including increased serum cytokines and the absolute lymphocyte to monocyte count ratio, which may reflect a patient's immune status) are

associated with patient prognosis.[6,10] These features of an active tumor microenvironment and immune response represent a potential target for novel therapies.

Furthermore, the malignant Reed-Sternberg cells represent a therapeutic target in that they express CD30, a member of the tumor necrosis factor receptor family.[11,12] CD30 is not typically expressed on most human tissue under normal physiologic conditions. CD30 can, however, be expressed on thymocytes during thymus development, on pancreatic exocrine cells, and on cells in the uterus and endometrium during pregnancy. Activated T cells can also transiently up-regulate CD30. The limited expression of CD30 and the substantial expression of CD30 on Reed-Sternberg cells make CD30 a useful target for treatment in HL.

NOVEL AGENTS IN HODGKIN LYMPHOMA

Based on the unique composition of the tumor, new agents have been developed that either specifically target Reed-Sternberg cells, target the inflammatory infiltrate, or reverse the suppressed immune microenvironment. Many of these agents have demonstrated substantial clinical activity in patients with HL who have failed multiple previous lines of treatment.

Brentuximab Vedotin

Brentuximab vedotin, although not strictly a new agent, demonstrates the benefit of specifically targeting the Reed-Sternberg cell. Initial clinical trials utilizing this CD30-directed antibody-drug conjugate included large numbers of patients with HL. In an initial phase I trial, patients received brentuximab every 3 weeks. The trial confirmed that 17 patients with HL had objective responses (ORs) (11 patients had complete responses).[13] Of the 12 patients with HL who received treatment at the maximum tolerated dose, an OR rate of 50% was seen. These results were confirmed in a pivotal phase II trial using brentuximab vedotin in patients with relapsed and refractory HL, all of whom had previously been treated with an autologous stem cell transplant.[14] In a cohort of 102 patients, all of whom received brentuximab vedotin at a dose of 1.8 mg/kg every 3 weeks, the overall response rate (ORR) was 75%, with a complete response rate (CRR) of 34%. The median progression-free survival (PFS) for all patients in the study was 5.6 months; however, the median duration of response for patients obtaining a complete remission was 20.5 months. Long-term follow-up of this trial confirmed the durability of the responses.[15] Of the 34 patients who obtained complete remission, 16 (47%) remained progression free at a median of 53.3 months.

Based on these promising results, brentuximab vedotin subsequently has been incorporated into combination therapy. A clinical trial utilizing brentuximab vedotin in combination with ABVD (doxorubicin, bleomycin, vinblastine, dacarbazine) or AVD (bleomycin omitted) chemotherapy found that the maximum tolerated dose of brentuximab vedotin in combination with the chemotherapy was defined as 1.2 mg/kg.[16] Importantly, however, the study found that when brentuximab vedotin was given with the bleomycin-containing regimen, it resulted in significant pulmonary toxicity. A subsequent cohort of patients treated with AVD chemotherapy tolerated the treatment far better with no additional pulmonary toxicity; the combination was highly effective, with CRs seen in 96% of the patients. Based on these promising results, a front-line randomized control trial of AVD chemotherapy plus brentuximab vedotin compared to standard ABVD chemotherapy is currently ongoing.

Everolimus

The phosphatidylinositide 3-kinase/mammalian target of rapamycin (PI3K/mTOR) signaling pathway has been shown to be activated in patients with HL. Everolimus is an oral antineoplastic agent that targets this pathway, specifically the mTOR complex 1 (mTORC1). Everolimus not only may target the signaling pathways within the Reed-Sternberg cells but may also suppress signaling within the immune infiltrate and production of cytokines present in the tumor microenvironment. A clinical trial of everolimus administered at a dose of 10 mg orally every day, was performed among 19 patients with relapsed and refractory HL.[17] The majority of patients had received multiple previous lines of therapy and 84% of the patients had undergone a previous autologous stem cell transplant. In this small cohort of patients the ORR was 47%, with one patient experiencing a complete remission and eight patients achieving partial remissions. The median time to disease progression was 7.2 months. Overall, the treatment was well tolerated and four of the responding patients remain progression free at 12 months. This study confirmed that everolimus has single-agent activity in patients with relapsed and refractory HL and confirmed that targeting the mTOR pathway in HL is clinically warranted.

Panobinostat and Mocetinostat

Agents that target acetylases may regulate several oncogenic pathways including cell cycle progression, cell survival, angiogenesis, and antitumor immunity. Panobinostat and mocetinostat target histone deacetylase, and these agents may be effective in patients with HL by modulating serum cytokine

levels and the expression of PD1 on intratumoral T cells. In one study, 129 patients with relapsed and refractory HL received 40 mg of panobinostat orally three times per week.[18] Treatment with panobinostat was effective as tumor reductions were seen in 74% of the patients, and ORs were achieved by 35 patients (27%). Thirty patients (23%) had partial responses to treatment and five patients (4%) had CRs. The median duration of response was 6.9 months, and the median PFS was 6.1 month. The agent was reasonably well tolerated, and serum testing for TARC showed reduction in TARC levels for patients responding to treatment.

Mocetinostat has also been tested in patients with relapsed and refractory classical HL.[19] In a clinical trial, 51 patients were treated at a dose level of either 110 mg or 85 mg. The group who received 110 mg had increased toxicity; 85 mg was felt to be a more optimal dose level. Among the 51 patients, two had CRs and 12 had PRs. Serum cytokines were also tested in each of the patients, and levels of multiple cytokines significantly decreased after treatment was initiated. TARC levels decreased by more than 40% between baseline and day 8 of treatment and correlated with clinical benefit.

JAK Inhibitors

JAKs are a family of intracellular non-receptor tyrosine kinases that transduce signals from cell surface receptors activated by cytokines and growth factors. After phosphorylation, JAKs lead to recruitment of STAT proteins. The STAT proteins subsequently translocate to the nucleus and trigger transcription of target genes involved in cell proliferation, cell survival, and immune response.

Aberrant activation of the JAK-STAT pathway has been linked to a variety of malignancies, including HL. SB1518 is a small molecule inhibitor of JAK2 kinase with preclinical activity in lymphoid malignancies. This JAK inhibitor has been tested in a phase I clinical trial of a variety of lymphomas, including refractory HL.[20] Doses of 100 to 600 mg/day were tested, and the drug was found to be well tolerated. Among the study's 34 patients, the ORR was 14%, including three partial remissions. In the group of patients with HL, however, none of the 14 patients had a partial remission or better. However, at least five of the patients with HL did benefit from the treatment, with a decrease in the sites of active disease.

Lenalidomide

Lenalidomide has a diverse set of possible mechanisms of action. It is proposed to directly induce cell death in malignant B cells and to indirectly regulate the tumor microenvironment. Lenalidomide has immunomodulatory and antiangiogenic properties and may specifically modulate many of the changes in the microenvironment, including the skewing of the cytokine profile, the altered immune cell infiltrate, and the recruitment of macrophages to the tumor microenvironment.

In view of the potential benefits to modulating the microenvironment by using lenalidomide, this agent has been tested in a clinical trial of relapsed and refractory classical HL.[21] In a study of 38 patients with classical HL, most of whom had previously been treated with an autologous stem cell transplant, patients received a standard dose of 25 mg daily for 3 out of every 4 weeks. Overall, the treatment was well tolerated, and of 36 evaluable patients, the study confirmed one complete remission and six partial remissions, resulting in an ORR of 19%. When patients who clinically benefited were included, a third of the patients benefited from treatment. Serum levels of cytokines were tested and plasma levels of CCL17 and CCL22 were associated with subsequent response. Lenalidomide was potentially beneficial in patients with refractory HL.

Anti-PD-1 Antibodies

The PD-1 pathway serves as an immune checkpoint to dampen immune responses. As outlined above, the tumor microenvironment in classical HL overexpresses the PD-1 ligands, resulting in a successful mechanism of tumor immune escape. Blocking PD-1 interactions with its ligands is therefore a promising treatment approach, particularly as genetic alterations result in PD-L1 and PD-L2 copy gain and thus overexpression of PD-1 ligands. As mentioned above, Epstein-Barr virus infection is a further mechanism that upregulates PD-1 ligand expression. Two recent clinical trials targeting PD-1/PD-1-ligand interactions have been reported, both with remarkable clinical results. In a clinical trial utilizing nivolumab, 23 patients with relapsed or refractory HL were treated every 2 weeks with 3 mg/kg of the antibody.[22] The majority of these patients had previously received an autologous stem cell transplant, and most had received previous brentuximab vedotin. In this group of patients, an ORR of 87% (20 out of 23) patients was seen, with a CRR of 17% and a PR rate of 70%. The PFS at 24 weeks was 86% and 11 of the patients continued on therapy, suggesting that the responses were durable.

In a second clinical trial utilizing the anti-PD-1 monoclonal antibody pembrolizumab (MK-3475), patients received the drug at a dose of 10 mg/kg administered every 2 weeks.[23] In this group of very heavily previously treated patients, pembrolizumab was well tolerated and similar dramatic clinical responses were seen. The ORR was 53%, with three patients (20%) having a complete remission and five additional patients (33%) having a partial remission. Virtually all patients appeared to have benefitted from therapy and the responses also appeared durable.

CONCLUSIONS AND FUTURE DIRECTIONS

The results presented above show that multiple agents have substantial activity in relapsed and refractory HL. These agents have all been tested as single agents, and therefore an important future approach will be to combine these agents with each other as well as with standard chemotherapy approaches. These future studies will specifically need to exclude the possibility of overlapping toxicities. However, provided the treatments can be safely given together, the future of patients with HL may be markedly improved as these agents move into earlier lines of treatment.

Smoldering Multiple Myeloma: When to Observe and When to Treat?

María-Victoria Mateos, MD, PhD, and Jesús-F San Miguel, MD, PhD

OVERVIEW

Smoldering multiple myeloma (SMM) is an asymptomatic disorder characterized by the presence of at least 3 g/dL of serum M-protein and/or 10% to 60% bone marrow plasma cell infiltration with no myeloma-defining event. The risk of progression to active multiple myeloma (MM) is not uniform and several markers are useful for identifying patients at high risk of progression. The definition of the disease has recently been revisited and patients with asymptomatic MM at 80% to 90% of progression risk at 2 years are now considered to have MM. Although the current standard of care is not to treat, a randomized trial in patients with high-risk SMM that compared early treatment versus observation demonstrated that early intervention resulted in substantial benefits in terms of time to progression and overall survival (OS). These findings highlight the need to follow a correct diagnosis by an accurate risk stratification to plan an optimized follow-up according to the risk of disease progression.

Smoldering multiple myeloma is an asymptomatic plasma cell disorder defined in 1980 by Kyle and Greipp on the basis of a series of six patients who met the criteria for MM but whose disease did not have an aggressive course.[1]

At the end of 2014, the International Myeloma Working Group (IMWG) updated the definition of SMM as a plasma cell disorder characterized by a minimum of 3 g/dL of serum M-protein and/or 10% to 60% bone marrow plasma cells (BMPCs), but with no evidence of myeloma-related symptomatology (hypercalcemia, renal insufficiency, anemia, or bone lesions [CRAB]) or any other myeloma-defining event (MDE).[2] According to this recent update, the definition of SMM excludes asymptomatic patients with BMPCs of 60% or more, serum free-light chain (FLC) levels of 100 or greater, and those with two or more focal lesions of the skeleton as revealed by MRI. The new criteria were introduced because independent studies showed that patients with these features have an ultra-high risk of progression to MM (80% to 90% at 2 years), and that they should therefore be considered as patients with MM.

The incidence of SMM differs from one series to another, and the median age of the patients at diagnosis, as with other plasma cell disorders, ranges from 65 to 70 years.[3] Kristinsson et al, through the Swedish Myeloma Registry, recently reported that 14% of patients diagnosed with myeloma had SMM and, taking the world population as a reference, that the age-standardized incidence of SMM was 0.44 cases per 100,000 people.[4]

In this article, we focus on SMM, evaluate the prognostic factors that predict progression to symptomatic MM, and ex-

amine how patients may be managed, particularly with respect to the possibility of early treatment.

DIFFERENTIAL DIAGNOSIS WITH OTHER ENTITIES

SMM must be distinguished from other plasma cell disorders, such as monoclonal gammopathy of undetermined significance (MGUS) and symptomatic MM (Table 1). The MGUS entity is characterized by a level of serum M-protein of less than 3 g/dL plus less than 10% of plasma cell infiltration in the bone marrow, with no CRAB and no MDE. Symptomatic MM must always have CRAB symptomatology or MDE, in conjunction with a minimum of 10% clonal BMPC infiltration or biopsy-proven bony or extramedullary plasacytoma.[2]

End-organ damage often needs to be correctly evaluated to distinguish myeloma-related symptomatology from some signs or symptoms that could otherwise be attributed to comorbidities or concomitant diseases,[3] such as anemia due to iron, vitamin B12 or folic acid deficiency, or to the presence of autoimmune or chronic diseases, or myelodysplastic syndromes. In the case of moderate or severe renal impairment, patients with hypertension or diabetes should be carefully assessed. In patients who have isolated hypercalcemia without bone lesions, the presence of hyperparathyroidism should be considered, and diffuse osteoporosis should always be carefully evaluated, especially in women, to determine whether it is related to myeloma. If osteoporosis starts suddenly or is more extensive than expected for someone of the patient's

TABLE 1. Differential Diagnosis of MGUS, SMM, and Symptomatic MM

Feature	MGUS	SMM	MM
Serum-M protein	< 3 g/dL and	≥ 3 g/dL and/or	
Clonal BMPC infiltration	< 10%	10-60%	≥ 10% or biopsy-proven plasmacytoma
Symptomatology	Absence of CRAB*	Absence of MDE** or amyloidosis	Presence of MDE**

Abbreviations: MGUS, monoclonal gammopathy of undetermined significance; SMM, smoldering multiple myeloma; MM, multiple myeloma; BMPC, bone marrow plasma cell; CRAB, hypercalcemia, renal failure, anemia, and bone; MDE, myeloma-defining event. *CRAB includes (1) hypercalcemia: serum calcium > 0.25 mmol/L (> 1 mg/dL) higher than the upper limit of normal or > 2.75 mmol/L (> 11 mg/dL); (2) renal insufficiency: serum creatinine > 177 μmol/L (2 mg/dL) or creatinine clearance < 40 mL/minute; (3) anemia: hemoglobin value of > 2 g/dL below the lower normal limit, or a hemoglobin value < 10 g/dL; (4) bone lesions: one or more osteolytic lesion revealed by skeletal radiography, CT, or PET-CT. **MDE: Myeloma-defining events include CRAB symptoms (above) or any one or more of the following biomarkers of malignancy: clonal bone marrow plasma cell percentage ≥ 60%; involved/uninvolved serum free light-chain ratio ≥ 100; > 1 focal lesions revealed by MRI studies.

age, then myeloma-related symptomatology should be considered. Finally, if there is a single bone lesion present with no other symptoms, it is essential to rule out the presence of a benign bone cyst.

DIAGNOSTIC EVALUATION

Initial investigation of a patient with suspected SMM should include the tests shown in Sidebar 1, which are coincidental

KEY POINTS

- Smoldering multiple myeloma is not a homogeneous plasma cell disorder and includes patients at low, intermediate, and high risk of progression to symptomatic multiple myeloma.
- All newly diagnosed SMM patients should be stratified according to their risk.
- It is essential to identify asymptomatic patients at high risk of progression to symptomatic disease, in which the progression risk is 50% at 2 years following diagnosis, because they require close follow-up and, if possible, inclusion in clinical trials.
- Although the standard of care has been not to administer treatment until symptoms arise, early treatment with lenalidomide plus dexamethasone has helped change the treatment paradigm for patients with high-risk SMM.
- The updated International Myeloma Working Group criteria allow us to initiate therapy in patients who would previously have been considered asymptomatic on the basis of the absence of calcium, renal insufficiency, anemia, or bone lesions (CRAB) features, but who possess a specific biomarker predicting ultra-high risk of progression.
- In the future, novel therapeutic approaches will determine whether early treatment of patients with asymptomatic high-risk disease can definitively prevent the development of myeloma-related symptoms.

SIDEBAR 1. Evaluation of Patients Newly Diagnosed With SMM

- Medical history and physical examination
- Hemogram
- Biochemical studies, including of creatinine and calcium levels; beta 2-microglobulin, LDH, and albumin
- Protein studies
  - Total serum protein and serum electrophoresis (serum M-protein)
  - 24-hour urine sample protein electrophoresis (urine M-protein)
  - Serum and urine immunofixation
- Serum free light-chain measurement (FLC ratio)
- Bone marrow aspirate with or without biopsy: infiltration by clonal plasma cells, flow cytometry, and fluorescence in situ hybridization analysis
- Skeletal survey, CT, or PET-CT
- MRI of thoracic and lumbar spine and pelvis; ideally whole-body MRI

Abbreviations: SMM, smoldering multiple myeloma; LDH, lactate dehydrogenase; PET-CT, ^{18}F-fluorodeoxyglucose (FDG) PET/CT.

with those used for a correct diagnosis of symptomatic MM.[5] However, as result of the updated IMWG criteria for the diagnosis of MM, there are some specific assessments to be aware of in order to make a correct diagnosis of SMM.[2]

First, the IMWG recommends that bone disease be evaluated by x-ray, [18F]fluorodeoxyglucose (FDG) PET/CT or low-dose whole-body CT in all patients with suspected SMM, with the exact modality determined by availability and resources. The aim is to exclude the presence of osteolytic bone lesions, currently defined by the presence of at least one lesion (≥ 5 mm) revealed by x-ray, CT, or PET-CT. In addition, a whole-body MRI of the spine and pelvis is a necessary component of the initial evaluation. It provides detailed information about not only bone marrow involvement, but also the presence of focal lesions that predict more rapid progression to symptomatic myeloma. Hillengass et al reported in 2010 that the presence of more than one focal lesion in whole-body MRI was associated with a substantially shorter median time to progression (TTP) to active disease (13 months) compared with the period when no focal lesions were present.[6] Kastritis et al reported similar results after the analysis of a subgroup of patients who underwent spinal MRI and were followed for a minimum of 2.5 years. The median TTP to symptomatic disease was 14 months when more than one focal lesion was present.[7] Therefore, if more than one focal lesion in MRI is present in patients with SMM, the disease should no longer be considered as SMM but as MM, according to the current IMWG criteria.

Second, with respect to bone marrow infiltration, the Mayo Clinic group evaluated BMPC infiltration in a cohort of 651 patients and found that 21 (3.2%) had extreme infiltration (≥ 60%).[8] This group of patients had a median TTP to active disease of 7.7 months, with a 95% risk of progression at 2

years. This finding was subsequently validated in a study of 96 patients with SMM, in whom a median TTP of 15 months was reported for the group of patients with extreme infiltration.[9] In a third study, six of 121 patients (5%) with SMM were found to have 60% or greater BMPC, and all progressed to MM within 2 years.[10] Therefore, if 60% or greater of clonal plasma cell infiltration is present either in bone marrow aspirate or biopsy, the diagnosis of SMM should be replaced by MM. Additional assessments, for example, by flow cytometry or by identifying cytogenetic abnormalities in SMM patients, are not obligatory but can help estimate the risk of progression to active disease.

Third, with respect to the FLC assay, Larsen et al studied 586 patients with SMM to determine whether there was a threshold FLC ratio that predicted 85% of progression risk at 2 years. They found a serum involved/uninvolved FLC ratio of at least 100 in 15% of patients and a risk of progression to symptomatic disease of 72%.[11] Similar results were obtained in a study by Kastritis et al from the Greek Myeloma Group. In their study of 96 SMM patients, 7% had an involved/uninvolved FLC ratio of at least 100 and almost all progressed within 18 months.[9] In a third study, the risk of progression within 2 years was 64%. Therefore, physicians must consider the FLC assay at the moment SMM is first suspected and if the involved/uninvolved ratio is 100 or higher, the diagnosis of MM is correct under these circumstances.

Once SMM has been diagnosed, considering the specific assessments mentioned above, the serum and urine M-component, hemoglobin, calcium, and creatinine levels should be re-evaluated 2 to 3 months later to confirm the stability of these parameters. The subsequent follow-up involves the same evaluation, but the frequency should be adapted on the basis of risk factors for progression to symptomatic MM.

RISK FACTORS PREDICTING PROGRESSION TO ACTIVE MM

Most patients diagnosed with SMM will progress to symptomatic MM and will need to start treatment. However, SMM is not a uniform disorder and once the diagnosis has been confirmed, the doctor should evaluate the risk of progression to symptomatic disease to plan an appropriate, risk-based follow-up, and to optimize the management of patients with SMM. This approach is different from that taken when MGUS is diagnosed. MGUS is a homogeneous disease in which the risk of progression to symptomatic disease is substantially lower than that of SMM (1% per year) and uniform over time. Therefore, the recommended follow-up would be once per year.

In the first and largest systematic study of SMM, the Mayo Clinic group retrospectively evaluated the prognosis of patients with SMM in a large cohort of 276 patients for whom long-term follow-up data were available and whose disease was defined homogeneously according to the conventional IMWG criteria ($\geq$ 3 g/dL serum M-protein and/or $\geq$ 10% BMPCs with no CRAB symptoms). The annual risk of progression from SMM to symptomatic MM was 10% per year

for the first 5 years, 5% per year during the following 5 years, and only 1% per year after 10 years.[12]

Several studies have reported possible predictors of progression to symptomatic MM, and this information is useful for physicians and could also be used to help explain to patients their risk of progression to active MM (Sidebar 2).

SIZE OF SERUM M-PROTEIN AND THE EXTENT OF MARROW INVOLVEMENT

The aforementioned Mayo Clinic study[12] defined three SMM subgroups according to BMPC infiltration and the size of the serum M-protein. Group 1 was characterized by a minimum of 3 g/dL of M-protein and 10% or more of plasma cells in bone marrow, with a median TTP to symptomatic MM of 2 years. Group 2 featured 3 g/dL or less of M-protein and 10% or higher of BMPCs M-protein with a median TTP of 8 years. Group 3 had a minimum of 3 g/dL of M-protein but less than 10% BMPC infiltration, resulting in a median TTP of 19 years.

IMMUNOPHENOTYPING AND IMMUNOPARESIS

Multiparameter flow cytometry (MFC) used to identify the immunophenotypic profile of plasma cells in SMM has been evaluated by the Spanish Myeloma Group. The presence of an aberrant BMPC phenotype (minimum of 95% phenotypically abnormal plasma cells, determined by MFC and defined as the overexpression of CD56 and CD19, CD45-negative and/or decreased reactivity for CD38) was reported to be the most important predictor of early progression from SMM to active MM.[13] The presence of immunoparesis (i.e., a decrease in one or two of the uninvolved immunoglobulins to 25% below the lowest normal value) also emerged as an important independent prognostic characteristic. Based on these two parameters, our group proposed a scoring system for patients with SMM that prognostically stratified patients with SMM into three groups with a median TTP of 23 months when the two risk factors were present, 73 months when only one was present, and TTP not reached when neither was present.[14]

SERUM FREE-LIGHT CHAIN RATIO

The Mayo Clinic group also evaluated the previously described patient population to identify the risk of progression to symptomatic myeloma on the basis of a FLC assay. A kappa/lambda FLC ratio of 0.125 or less or 8 or more was associated with an increased of progression to symptomatic MM. This parameter was added to their previous score, which considered the size of serum M-protein and BMPC infiltration, to refine the Mayo risk stratification model. This yielded three groups, with a median TTP of 1.9 years for the high-risk group, whose members exhibited all three defined risk factors.[15]

SIDEBAR 2. Smoldering MM: Markers Predicting Progression to Symptomatic MM

Features for Identifying High-Risk SMM: 50% at 2 Years
· Tumor Burden
  - ≥ 10% clonal plasma cell bone marrow infiltration plus
  - ≥ 3 g/dL of serum M-protein and
  - Serum free light-chain ratio of 0.125 or less or 8 or more
  - Bence Jones proteinuria positive from 24-h urine sample
  - Peripheral blood circulating plasma cells > 5 × 106/L
· Immunophenotyping Characterization and Immunoparesis
  - ≥ 95% of aberrant plasma cells by flow within the plasma cell bone marrow compartment plus
  - Immunoparesis (> 25% decrease in one or both uninvolved immunoglobulins relative to the lowest normal value)
· Cytogenetic Abnormalities
  - Presence of t(4;14)
  - Presence of del17p
  - Gains of 1q24
  - Hyperdiploidy
  - Gene Expression Profiling risk score > -0.26
· Pattern of serum M-Component Evolution
  - Evolving type: if M-protein ≥ 3 g/dL, increase of at least 10% within the first 6 months. If M-protein < 3 g/dL, annual increase of M-protein for 3 years
  - Increase in the M-protein to ≥ 3 g/dL over the three months since the previous determination
· Imaging Assessments
  - MRI: Radiologic progressive disease (MRI-PD) was defined as newly detected focal lesions (FLs) or increase in diameter of existing FL and a novel or progressive diffuse infiltration.
  - Positive PET/CT with no underlying osteolytic lesion

Abbreviations: MM, multiple myeloma; SMM, smoldering multiple myeloma; PET-CT, ^{18}F-fluorodeoxyglucose (FDG) PET/CT.

PERIPHERAL BLOOD CIRCULATING PLASMA CELLS

The Mayo Clinic group also evaluated the role of peripheral blood circulating plasma cells in 171 SMM patients and in those (15%) who had high levels of circulating plasma cells ($> 5 \times 10^6$/L and/or > 5% plasma cells per 100 cytoplasmic immunoglobulin (Ig)-positive mononuclear cells), the progression risk at 2 years was significantly higher than for patients with low levels (71% vs. 24%; p = 0.001).[16]

PATTERN OF SERUM M-COMPONENT EVOLUTION

The pattern of evolution of the monoclonal component during the course of the disease enabled two types of SMM to be identified: the evolving and the nonevolving. The evolving type was defined based on the analysis of 207 SMM patients with the following criteria: if the concentration of M-protein was 3 g/dL or greater at baseline, the evolving type featured an increase in M-protein of at least 10% within the first 6 months following diagnosis; if the concentration of M-protein was less than 3g/dL at baseline, the evolving type featured a progressive increase in M-protein in each consecutive annual measurement over a 3-year period.[17] The evolving pattern was recognized in 25% of patients, and was associated with a probability of progression of 45% at 2 years, with a median TTP to active MM of 3 years compared with 19 years for those with the nonevolving type. The Southwestern

Oncology Grup (SWOG) also found that patients with an increase in the M component of at least 3 g/dL during the 3 months since their previous determination had an associated risk of progression of approximately 50% at 2 years.[18]

BENCE JONES PROTEINURIA

Although Bence Jones proteinuria in the 24-hour urine sample can be replaced by the FLC ratio at the time of diagnosis of MM and related disorders, it continues to be a mandatory assessment during follow-up.[19] In one study, 147 patients with SMM were examined for the presence of Bence Jones proteinuria at diagnosis and its effect on progression to symptomatic disease was assessed. The study showed that in patients with SMM in whom the M-protein was defined by a complete Ig, but who were also positive for Bence Jones proteinuria regardless of the amount, the risk of progression to active disease was significantly higher than in patients who were negative for Bence Jones proteinuria (22 vs. 83 months; p < 0.001). In addition, when Bence Jones proteinuria in the 24-hour urine sample exceeded 500 mg, the risk was even higher, with a median TTP of 7 months.[20]

NOVEL IMAGING ASSESSMENTS

The novel imaging assessments have contributed to the updated criteria for the definition of MM and SMM, as has been

previously mentioned. However, the new imaging assessments can also help predict progression risk in patients with SMM. The first studies with spinal MRI were conducted in patients with asymptomatic MM and the presence of a focal pattern was associated with a shorter TTP than those patients with a diffuse or variegated pattern (median, 6 vs. 16 vs. 22 months, respectively). Hillengass et al recently evaluated the role of MRI during the follow-up of patients with SMM. Radiologic progressive disease (MRI-PD), defined as the detection of new focal lesions or the increase in diameter of existing focal lesions, and a novel or progressive diffuse infiltration was identified as a feature for classifying patients with SMM at high risk of progression to symptomatic disease.[21] The role of PET/CT has also been evaluated in SMM. The Italian group recently reported that in a series of 73 patients with SMM, approximately 10% had a positive result with PET/CT with no underlying osteolytic lesion and were predicted to be at high risk of progression to symptomatic disease (48% at 2 years compared with 32% for PET/CT-negative patients; p = 0.007).[22] The Mayo Clinic group also identified a subgroup within a series of 132 patients with SMM who had a positive result with PET/CT in which the rate of progression to MM within 2 years was 56% compared with 28% among patients who had a negative PET/CT result (p = 0.001). The rate of progression was even higher among patients in whom PET/CT was performed within 3 months of their diagnosis of SMM (74% vs. 27% in PET/CT-negative patients).[23]

CYTOGENETIC ABNORMALITIES

Neben et al have identified t(4;14), gain of 1q21, or hyperdiploidy as independent prognostic factors of shorter TTP. The median TTP for patients with del(17p13) was 2.7 years compared with 4.9 years for patients without the deletion (p = 0.019), 2.9 years for patients with t(4;14) compared with 5.2 years for patients without the deletion (p = 0.021), and 3.7 years for patients with +1q21 compared with 5.3 years for those without the deletion (p = 0.013). In addition, hyperdiploidy was associated with a significantly shorter median TTP of 3.9 years compared with 5.7 years for patients without hyperdiploidy (p = 0.036).[24] The Mayo Clinic group also analyzed the cytogenetic abnormalities in a series of 351 patients with SMM and identified a high-risk subgroup of patients with t(4;14) and/or del(17p) with a substantially shorter median TTP (24 months) than the intermediate-, standard- and low-risk patient subgroups.[25] Finally, the SWOG evaluated the Gene Expression Profiling 40 (GEP40) model in a group of 105 patients with SMM, and estimated 7.05 to be the optimal cut point for risk of progression to active disease. The 3-year TTP probability was 83% compared with only 11% for patients with scores below this threshold.[26]

In summary, the diagnosis of SMM is associated with a variable risk of progression to active disease, and the presence of the aforementioned prognostic factors can discriminate subgroups of patients with respect to their degree of risk (Sidebar 2).

MANAGEMENT OF SMM

The standard of care for the management of SMM was observation until MM develops. However, because of the heterogeneity of the disease, several groups evaluated the role of early intervention in patients with SMM using conventional and novel agents.

Three small studies compared early therapy consisting of melphalan and prednisone (MP) with observation alone. In the Hjorth study, the response rate to therapy in patients treated at diagnosis was similar to that of patients who received deferred therapy at the time of progression (52% vs. 55%).[27] In the other two trials, there were no differences in OS between early treatment and observation (54 vs. 58 months in the former, and 64 vs. 71 months in the latter).[28,29] Two small phase II trials, one by the Mayo Clinic and the other by The University of Texas MD Anderson Cancer Center, evaluated the role of thalidomide as a single agent in patients with SMM.[30,31] The rates of partial response (PR) or better were 34% and 36%, respectively, and most patients who discontinued treatment did so because of peripheral neuropathy. Barlogie et al conducted another nonrandomized phase II trial with thalidomide plus pamidronate in 76 patients with SMM, obtaining a PR rate of at least 42%, with a 6-year median TTP to symptomatic disease. The development of peripheral neuropathy was the main problem in patients who received long-term thalidomide treatment.[32] Novel agents have also been evaluated in SMM. Anakinra is an antagonist of the receptor of interleukin (IL)-1 and produced stabilization of the disease (in 8 patients), minor responses (3 patients), and partial responses (5 patients) in a group of 47 patients with SMM, with a median TTP of 37 months.[33] A phase II study of an anti-KIR monoclonal antibody in 21 patients found no clinical response.[34] Immunotherapy using a vaccine consisting of peptides from unique regions of three MM-associated antigens is currently being evaluated in patients with SMM and is producing promising efficacy results.[35] It is difficult to draw firm conclusions from the results of these trials, only one of which was randomized, although we can be confident that approximately one-third of patients with SMM responded to thalidomide. Only one randomized trial has compared the outcome of thalidomide plus zolendronic acid and that of zolendronic acid alone in patients with SMM. The rate of PR was a minimum of 37% in the thalidomide arm compared with 0% in the zoledronic acid–only arm, but there were no differences in the TTP to symptomatic MM (4.3 vs. 3.3 years) or in the 5-year OS (74% vs. 73%).[36] The role of bisphosphonates has also been analyzed in three trials, considering pamidronate as a single agent in one of them,[37] pamidronate versus abstention in another,[38] and zolendronic acid versus observation in the third.[39] All three studies confirmed that bisphosphonates have no antitumoral effect but reported an increase in bone density and a decrease in bone resorption, both of which were related to the bone markers. It is important to note that in the two randomized trials comparing bisphosphonates with abstention, a substantial reduction in the incidence of skeletal-related events in the bisphosphonate arms

was reported at the moment of progression to active MM (39% vs. 73% and 55% vs. 78%).

None of these trials provided evidence favoring the early treatment of patients with SMM. However, they were conducted without considering the differences in the risk of progression to active disease, and although the high-risk subgroup of patients may have benefited, this could have been counterbalanced by the absence of benefit in low-risk patients. The Spanish Myeloma Group (GEM/Pethema) conducted a phase III randomized trial in 119 patients with SMM at high risk of progression to active disease (according to the Mayo and/or Spanish criteria) that compared early treatment with lenalidomide plus dexamethasone as induction followed by lenalidomide alone as maintenance versus observation. The primary endpoint was TTP to symptomatic MM, and after a median follow-up of 40 months, the median TTP was significantly longer in patients in the early treatment group than in the observation arm (not reached vs. 21 months; hazard ratio [HR] 5.59; p < 0.001). Secondary endpoints included response, OS, and safety. The PR or better after induction was 82%, including 14% of cases of stringent complete response (sCR) plus CR, and after maintenance the sCR/CR rate increased to 26%. The safety profile was acceptable and most of the adverse events reported were grade 1 or 2. The OS analysis showed that the 3-year survival rate was also higher for the group of patients who received early treatment with lenalidomide-based therapy (94% vs. 80%; HR, 3.24; p = 0.03).[40] A recent update of this trial confirmed the efficacy of early treatment in terms of TTP (HR 6.21; 95% CI, 3.1 to 12.7; p < 0.0001) and the benefit to OS was even more evident with longer follow-up (HR 4.35; 95% CI, 1.5 to 13.0; p = 0.008).[41] This study showed for the first time the potential for changing the treatment paradigm for high-risk patients with SMM based on the efficacy of early treatment in terms of TTP to active disease and of OS. Moreover, several trials that are currently underway are focusing on high-risk patients with SMM using novel agents such as lenalidomide alone, siltuximab (anti-IL6 monoclonal antibody), elotuzumab (anti-SLAMF7 monoclonal antibody), or lenalidomide-dexamethasone plus elotuzumab. Promising efficacy results have been reported for the combination of lenalidomide plus dexamethasone with the novel proteasome inhibitor carfilzomib in a series of 12 high-risk patients with SMM. All patients achieved CR and most were in immunophenotypic CR.[42] The next step will be to develop a more intensive approach to therapy for high-risk patients with SMM, similar to the treatment planned for young patients with symptomatic MM, for whom "cure" should be the objective.

MANAGING SMM IN CLINICAL PRACTICE: WHEN TO OBSERVE AND WHEN TO TREAT

Given the extensive background to this disease described above, the first step in clinical practice is to identify the risk of progression to active disease for each patient newly diagnosed with SMM. The key question is which risk model is better for evaluating the risk of progression to symptomatic disease for

each individual patient with SMM. The Mayo Clinic and Spanish models enable initial risk stratification of SMM and both were validated in a prospective trial. However, new risk models are emerging that incorporate new clinical and biologic features (Table 2).[10,12,14,17,18,24,43,44] The components of these models are not identical, and each patient's risk should probably be defined on the basis of all the available data rather than through the use of a restricted model (Sidebar 2).

CLASSIFYING PATIENTS WITH SMOLDERING MULTIPLE MYELOMA

Patients with SMM should be classified as follows:

(1) The first group includes patients at low risk of progression who are characterized by the absence of the aforementioned high-risk factors (using the validated Mayo and Spanish risk models), with a probability of progression at 5 years of only 8%. The patients in this group behave similarly to patients with MGUS and should be followed annually.

(2) The second group includes patients at intermediate risk of progression, who display only some of the aforementioned high-risk factors. These are probably the patients with true SMM. The risk of progression at 5 years is 42%, and patients should undergo follow-up every 6 months.

(3) The third group includes high-risk patients classified on the basis of one of the risk models mentioned above. Half of the patients will progress during the 2 years following diagnosis. These patients require close follow-up every 2 to 3 months. The key question is whether this high-risk group should be treated. Although the Spanish trial showed substantial benefit from the early treatment in high-risk patients with SMM, there are some limitations that prevent the results being generally applicable at present; these may be resolved when the results of the ongoing clinical trials become available. The best approach for these patients should be to refer them to centers specialized in MM therapy and to include them in clinical trials to better understand their biology and to confirm the survival benefit of early treatment in this cohort.[45]

As mentioned at the beginning of the review, the updated IMWG criteria have enabled us to define patients with MM as those who would have been considered in the past as having SMM due to the presence of specific biomarkers such as 60% or greater BMPCs, or a serum FLC level of 100 or higher, or at least two focal lesions of the skeleton as revealed by MRI. These patients can begin treatment on diagnosis without the presence of CRAB features.

FUTURE DIRECTIONS

The treatment philosophy for patients with MM has mainly focused on symptomatic patients. This approach is clearly different from those adopted to treat other malignancies, such as cancers of the breast, colon, or prostate, for which

TABLE 2. Risk Models for the Stratification of SMM

Risk Model	Risk of Progression to MM	
Mayo Clinic		**Median TTP (years)**
≥ 10% clonal PCBM infiltration	1 risk factor	10
≥ 3 g/dL of serum M-protein	2 risk factors	5
Serum FLC ratio between < 0.125 or > 8	3 risk factors	1.9
Spanish Myeloma		**Median TTP (years)**
≥ 95% of aberrant PCs by MFC	No risk factor	NR
Immunoparesis	1 risk factor	6
	2 risk factors	1.9
Heidelberg		**3-year TTP**
Tumor mass using the Mayo Model	T-mass low + CA low risk	15%
t(4;14), del17p, or +1q	T-mass low + CA high risk	42%
	T-mass high + CA low risk	64%
	T-mass high + CA high risk	55%
SWOG		**2-year TTP**
Serum M-protein ≥ 2 g/dL	No risk factor	30%
Involved FLC > 25 mg/dL	1 risk factor	29%
GEP risk score > −0.26	≥ 2 risk factors	71%
Penn		**2-year TTP**
≥ 40% clonal PCBM infiltration	No risk factor	16%
sFLC ratio ≥ 50	1 risk factor	44%
Albumin ≤ 3.5 mg/dL	≥ 2 risk factors	81%
Japanese		**2-year TTP**
Beta 2-microglobulin ≥ 2.5 mg/L	2 risk factors	67.5%
M-protein increment rate > 1 mg/dL/d		
Czech & Heidelberg		**2-year TTP**
Immunoparesis	No risk factor	5.3%
Serum M-protein ≥ 2.3 g/dL	1 risk factor	7.5%
Involved/uninvolved sFLC > 30	2 risk factors	44.8%
	3 risk factors	81.3%
Barcelona		**2-year TTP**
Evolving pattern = 2 points	0 points	2.4%
Serum M-protein ≥ 3 g/dL = 1 point	1 point	31%
Immunoparesis = 1 point	2 points	52%
	3 points	80%

Abbreviations: SMM, smoldering multiple myeloma; MM, multiple myeloma; TTP, time to progression.

early intervention is not only appropriate, but also essential for success and cure. This difference in philosophy arose for several reasons: 1) in the past, only a few drugs, most of which were alkylating agents, were available to treat MM; 2) the trials conducted in asymptomatic patients with MM failed to produce a benefit; and 3) the risk of progression to active disease in patients with SMM is relatively low (10% per year).

However, important advances are being made in the understanding and management of SMM. From the biologic point of view, different subgroups of patients with SMM have been identified and patients with MM should receive antimyeloma therapy be started before myeloma-related symptoms develop. Additional studies will help us better understand the biology of the disease and identify the key drivers of the transition from monoclonal gammopathy to smoldering and symptomatic disease. These drivers will be considered as targets for new therapies.

We will soon have the results from several current trials conducted in high-risk patients with SMM, which will enable us to offer early treatment for a selected group of asymptomatic patients with myeloma with the confidence that some of them will be "cured." The cure-versus-control debate is pertinent to asymptomatic patients with myeloma. Some physicians argue in favor of controlling the disease through continuous oral therapy mainly based on immunomodulatory agents, whereas others support the intensive therapy approach, including high-dose therapy and transplant, with the objective of curing the disease.

Multiple Myeloma: Is It Time for Biomarker-Driven Therapy?

Manisha Bhutani, MD, Ola Landgren, MD, PhD, and Saad Z. Usmani, MD, FACP

OVERVIEW

Remarkable strides have been made in understanding the molecular mechanisms by which multiple myeloma develops, leading to more sophisticated classification that incorporates not only the traditional diagnostic criteria, but also immunophenotype, genetic, and molecular features. However, even with this added information, considerable heterogeneity in clinical outcomes exists within the identified subtypes. The present paradigm for myeloma treatment is built on the basic step of defining transplant eligibility versus noneligibility, as determined by age, performance status, and cumulative burden of comorbidities. An incredibly complex heterogeneous disease is, therefore, treated in a generalized way with the result that large interpatient variability exists in the outcome. As antimyeloma therapeutics continue to expand it is becoming even more crucial to personalize treatment approaches that provide the most value to a specific patient. Development of biomarkers, either individually or as larger sets or patterns and ranging from analysis of blood or bone marrow to biomedical imaging, is a major focus in the field. Biomarkers such as involved serum free light chain ratio and MRI focal lesions have been implemented in the new definition of multiple myeloma and guide clinicians to initiate treatment in otherwise asymptomatic individuals. Currently, however, there is not enough evidence to support intensifying the treatment for high-risk disease or reducing the treatment for low-risk disease. Minimal residual disease-negative status is an important biomarker that holds promise for monitoring the effectiveness of response-adapted strategies. This article sheds light on the forward landscape and rear-mirror view of biomarkers in myeloma.

The outcome for patients with multiple myeloma (MM) has considerably improved over the last decade with the incorporation of active agents including immunomodulatory drugs (IMiDs) and proteasome inhibitors, such that the median survival of newly diagnosed patients is now between 5 and 9 years.[1,2] Increasingly effective salvage therapies have resulted in durable remission as well as long-term survival for selected patient subgroups. Nonetheless, despite these advances the current therapy for MM remains noncurative, and a subset of cases show a rapidly relapsing and refractory disease course. Myeloma therapy is currently based on studies that largely predate the molecular classification, and most patients are treated by the conventional one-size-fits-all therapeutic approach. Over recent years, great progress has been made in our understanding of the key genetic abnormalities, central signaling pathways, the role of the bone marrow microenvironment, and monitoring of minimal residual disease (MRD). It is undoubtedly clear that there is extensive heterogeneity, not only between patients but also within patients, resulting from complex genetics and clonal evolution during the course of disease. The MM genome is extremely complex, with approximately 35 nonsynonymous mutations identified per case.[3] Underlying this vast landscape of genetic alterations are multiple deregulated core signaling pathways and

mutations of diagnostic and therapeutic significance that open several possible avenues for the optimization of risk-adapted strategies and biomarker-focused clinical trials in MM.[3,4]

A biomarker is typically defined as any characteristic (e.g., gene, protein, clinicopathologic variable, imaging feature) that can be objectively and reproducibly measured to serve as an indicator of disease biology or response to a therapeutic intervention.[5] For clinical purposes, disease-related biomarkers assist in diagnosis, prognosis, and response monitoring. Drug-related biomarkers, on the other hand, indicate whether a drug will be effective in a specific patient and how the patient's body will process it. Within the context of a clinical trial, an integral biomarker is defined as a marker that must be measured in real time for the trial to proceed, for example when the test is used to establish eligibility, treatment assignment, or stratification, or to detect early response to decide further treatment.[6] In contrast, integrated biomarkers are measured during the clinical trial; however, their results do not determine the treatment or course of the ongoing trial, but instead inform future studies.[6] Biomarker research in myeloma continues to advance in many spheres. The first pertains to biomarkers that aid in risk stratification of patients and provide guidance in the selection or titration

of therapeutic agents. Second, it is becoming increasingly apparent that certain biomarkers offer the promise of distinguishing aggressive from indolent disease evolution, such that individuals most at risk of progressing from precursor states to MM can be targeted at the earliest and most treatable stage. The third area of thrust is biomarkers of benefit, which indicate the effect of therapeutic intervention and predict sensitivity or resistance, and thus correlate with outcomes. Additionally, the technologies for standardization and interpretation of MRD continue to evolve. Clinical trials based on integral and integrated biomarkers remain a key area of research, and correlative science within the context of these trials will be vital in determining the significance of defined biomarkers. We provide an overview of the current knowledge in each area in which biomarkers are being explored in MM. In addition, we discuss the potential and limitations of designing biomarker-driven clinical trials.

MONOCLONAL PROTEIN BIOMARKERS

Myeloma-related plasma cell disorders are typically characterized by monoclonal protein biomarkers, which can be in the form of intact immunoglobulin, immunoglobulin fragments, or free immunoglobulin light chains (FLC), in either the serum or urine. These biomarkers play an important role in diagnosis and response monitoring. One of the earliest identified biomarkers is Bence Jones protein, which was described in 1848.[7] A cutoff of serum monoclonal protein of 3 g/dL or greater and/or bone marrow plasmacytosis of at least 10% is used to distinguish smoldering multiple myeloma (SMM) from monoclonal gammopathy of undetermined significance (MGUS).[8] During the past decade the measurement of serum kappa and lambda FLC has also become part of routine clinical testing. An abnormal FLC ratio indicates

KEY POINTS

- Intra- and interpatient heterogeneity in multiple myeloma underscores the need for personalized treatment approaches.
- New International Myeloma Working Group 2014 biomarker-based definitions identify a subset of patients that require therapy in the absence of clinical manifestations of serious end-organ damage.
- At present, there is no strong evidence for escalating or de-escalating therapy based on favorable, standard, and high-risk categories.
- The new generation of biomarkers—including epigenetics, novel imaging, clone burden, GEP signature, and next-generation sequencing—coupled with established prognostic biomarkers holds promise for improved stratification of patients with myeloma into specific therapies and clinical trials.
- Improvement in patient outcomes can be achieved through adaptive clinical trials involving risk models based on multiple biomarkers.

the presence of clonality in approximately one-third of patients with MGUS and in at least 90% of patients with MM.[9] The assay is particularly indicated for the diagnosis and follow-up of patients with nonsecretory and oligosecretory myeloma, light chain myeloma, and amyloidosis.[10] Revised International Myeloma Working Group (IMWG) 2014 criteria define myeloma biomarkers that indicate a requirement for therapy in asymptomatic individuals, including bone marrow plasmacytosis of 60% or greater and involved FLC ratio greater than 100 (Table 1).[11] In an era of broadened treatment options, there are substantial data showing the association of depth of response and outcome. Following treatment, complete response (CR) criteria include negative immunofixation of serum and urine and the presence of less than 5% plasma cells. Normalization of the FLC ratio plus the absence of clonal plasma cells by immunochemistry or immunofluorescence is considered a deeper level of response that is termed stringent CR (sCR).[12] Achievement of CR is considered one of the strongest prognostic biomarkers in MM, both in the transplant and nontransplant settings, although the sCR criteria have failed to unequivocally demonstrate superior prognostic value compared with CR.[13,14] More sensitive ways of measuring CR are required when results from serum protein electrophoresis are difficult to interpret, including problems resulting from polyclonal immunoglobulins, comigration of monoclonal bands, and poor sensitivity at low levels of monoclonal protein (<10 g/L). These drawbacks could be overcome by the new U.S. Food and Drug Administration (FDA)-approved heavy/light chain (HLC) assay (Hevylite). The unique ability of this assay to measure suppression of the uninvolved HLC pair (e.g., IgG-lambda, IgA-kappa, and IgA-lambda for a patient with IgG-kappa disease) adds sensitivity for monitoring disease response and detecting residual disease. The HLC ratio reflects the balance between monoclonal and polyclonal immunoglobulins of involved and uninvolved isotypes taking into account the polyclonal plasma cell suppression or expansion that occurs with the treatment. A few studies have shown that this assay affords additional prognostic information in MGUS and MM.[15,16] If confirmed by other studies and long-term follow-up, HLC could be a noninvasive marker of response.

CYTOGENETICS AND FISH BIOMARKERS

Many studies have reported on the prognostic value of cytogenetics and fluorescence in situ hybridization (FISH) biomarkers; however, some have yielded conflicting results.[17-21] Reasons for these discrepancies include retrospective analyses, small sample size, variable techniques, lack of a standard definition of high risk, and failure to control for other biologic or treatment processes that may confound the outcome. In general, t(14;16), t(14;20), and del(17p) are associated with a poor prognosis, whereas t(11;14), t(6;14), and hyperdiploid myeloma are considered to impart standard risk, provided there are no additional adverse features such as +1q21 and del(17p) (Table 1).[22] Trisomies are typically associated with a

TABLE 1. The Changing Biomarker Landscape

Biomarkers	Old	Updated	Future
Smoldering Multiple Myeloma			
Diagnostic	≥ 10% clonal marrow plasma cells*	10% to 60% clonal marrow plasma cells	High circulating clonal plasma cells by flow cytometry
	≥ 3 g/dL serum M-protein	Urinary M-protein ≥ 500 mg per 24 h	10% increase in M-protein within 6 months
Prognostic	Serum free light-chain ratio 0.125 to 8; Immunoparesis; ≥ 95% marrow plasma cells of aberrant phenotype** by flow cytometry		High bone marrow plasma cell proliferative rate; GEP 70 Risk score ≥ 0.26; Cytogenetic subtypes: t(4;14), 1q amp, or del 17p
Multiple Myeloma			
Diagnostic	Clonal bone marrow plasma cells ≥ 10% or biopsy-proven bony or extramedullary	Clonal marrow plasma cell ≥ 60%	
	Plasmacytoma PLUS	Involved:uninvolved serum free light chain ratio‡ ≥ 100	
	CRAB myeloma defining events	> 1 focal lesion on MRI§	
		CRAB events including bone lesions on CT or PET/CT	
Low/Standard Risk†	Trisomies	ISS I/II and NO t(4;14) or del 17p13	New GEP-based prognostic signatures
	Hyperdiploidy	Age < 55	
	ISS I		
	t(11;14)		
	t(6;14)		
Standard/Intermediate Risk	ISS II	t(4;14)	
		1q gain	
		Deletion 13 or hypodiploidy by conventional karyotyping	
		Complex karyotype	
		Plasma cell labeling index > 3%	
High Risk	ISS III	ISS II/III plus t(4;14) or del 17p13	
	Monosomy 13	t(14;16)	
	Hypodiploidy	Plasma cell leukemia	
	t(4;14)	LDH ≥ 2 ULN	
		GEP 70 High Risk Signature	
Treatment/Response	CR	sCR	MRD-negative
		Immunophenotypic CR	HLC ratio
			Immune signature
			Proteasome signature
			IMiD signature
			Clone burden/Clone status
Imaging Prognostic	Skeletal survey lytic lesions	MRI focal lesions > 7	Novel PET probes
		FDG/PET focal lesions > 3	DCE-MRI diffusion/perfusion

Abbreviations: LDH, lactate dehydrogenase; ULN, upper limit of normal; sCR, stringent CR; GEP, gene expression profiling; MRD, minimal residual disease; IMiD, immunomodulatory drugs; DCE-MRI, dynamic contrast enhanced-magnetic resonance imaging.

*Clonality should be established by the demonstration of κ/λ-light-chain restriction on flow cytometry, immunohistochemistry, or immunofluorescence. Bone marrow plasma cell percentage should preferably be estimated from a core biopsy specimen; in cases of disparity between the aspirate and core biopsy, the highest value should be used. M-protein: monoclonal protein.

**Aberrant immunophenotype of plasma cells on flow cytometry: absence of CD19 and/or CD45 expression, overexpression of CD56, or weak expression of CD38. CRAB: hypercalcemia, renal insufficiency, anemia, and bone lesions.

†Mayo Clinic risk classification includes standard risk, intermediate risk, and high-risk categories; International Myeloma Working Group consensus risk classification includes low risk, standard risk, and high-risk categories. ISS: International Staging System: stage I: serum beta-2 microglobulin < 3.5 mg/L, albumin ≥ 3.5 g/dL; stage II: beta-2 microglobulin between 3.5 and 5.5, or albumin < 3.5 g/dL; stage III: beta-2 microglobulin ≥ 5 mg/L. CR: complete response.

‡These values are based on the serum Freelite assay (The Binding Site Group, Birmingham, UK). The involved free light chain must be ≥ 100 mg/L.

§Each focal lesion must be at least 5 mm in size. PET-CT: ^{18}F-fluorodeoxyglucose PET with CT.

better prognosis, except when associated with gains of 1q and monosomy of chromosome 13. Gain of 1q is seen in approximately 40% of newly diagnosed cases, and has been linked to adverse prognosis in patients treated intensively with or without IMiDs.[23,24] Although monosomic 13/13q deletion (present in approximately 50% of cases) has been typically associated with an unfavorable prognosis when detected by conventional cytogenetics,[25] the prognostic implication of this abnormality is difficult to assess because of its close association with other high-risk genetic features, such as t(4;14), in 80% of cases.[19] Approximately 32% of patients presenting with MM have a deletion of 1p affecting *FAF1* and *CDKN2C*, which has been associated with short survival.[26] Some of these biomarkers have treatment-specific prognostic implications; for example, an approach that combines bortezomib-based therapy for 2 to 3 years in conjunction with tandem autologous stem cell transplantation (ASCT) has been shown to abrogate or attenuate the prognostic influence of t(4;14).[27,28] No single genetic abnormality by itself defines high-risk MM and it is important to determine the presence or absence of a panel of cytogenetic abnormalities to properly identify patients with adverse prognosis.

INTERNATIONAL STAGING SYSTEM

The International Staging System (ISS) was developed as a multicenter effort before IMiDs and proteasome inhibitors became available and has been the primary clinical tool used to predict outcome.[29] This system stratifies patients into three groups based on serum albumin and β2-microglobulin. Although the ISS remains prognostic within clinical trials, this system has limited utility for assessing risk on an individual patient basis and does not take into account genetic abnormalities and the role of intrinsic myeloma cell variability to allow for tailored therapy approaches. Importantly, the ISS and FISH/cytogenetic abnormalities can be combined in a prognostic model (Table 1).[11] There are good data supporting the application of a combined approach for risk prognostication in the design of biomarker-focused clinical trials.[30]

GENE EXPRESSION PROFILING BIOMARKERS

Global gene expression profiling (GEP) is an alternative technology that integrates the influence of multiple genetic abnormalities on important cellular pathways associated with proliferation, differentiation, apoptosis, and other biologic features in a single signature. The University of Arkansas for Medical Sciences (UAMS) group was the first to define a 70-gene classifier (GEP70) characterizing 7 distinct gene expression clusters that identified patients with high risk for short progression-free survival (PFS) and overall survival (OS).[31] The prognostic significance of the UAMS GEP70 assay has been validated in several studies performed independently by U.S. and international groups. In another study, GEPs obtained from patients with newly diagnosed MM included in the HOVON65/GMMG-HD4 trial were used to generate a

prognostic signature of 92 genes (EMC-92-gene signature) capable of distinguishing between patients with high risk and low risk that was subsequently confirmed in independent validation sets of newly diagnosed and patients who relapsed.[32] Other signatures linked to short survival have been defined, including a 17-gene signature identified by UAMS, a 15-gene signature in the IFM trials, and a 6-gene signature in the MRC Myeloma IX trial.[33,34] Interestingly, the 17-, 15-, and 6-gene signatures do not share any common genes, reflecting variation in treatment strategies or patient selection between studies, or perhaps different aspects of myeloma biology. Although GEP provides valuable information regarding disease biology in the context of clinical trials, more work is required to define a standardized user-friendly GEP signature that can be more widely applied as a prognostic tool in clinics. To this end, the International Myeloma Working Group (IMWG) is conducting a study to unify the GEP signatures using prognostic modeling.

FLOW CYTOMETRIC BIOMARKERS AND MRD MONITORING

Flow cytometric methods have become an integral part of diagnosis and monitoring in many hematologic malignancies, such as acute and chronic leukemias; however, consensus regarding their routine use in plasma cell disorders is still evolving. Multiparameter flow cytometry (MFC) allows quantification and characterization of clonal plasma cells through their aberrant phenotypes rather than by light chain restriction. The immunophenotypic features of plasma cells vary depending on the diagnosis, stage of disease, and the type of therapies employed. Multiple studies have demonstrated the prognostic value of specific patterns of antigen expression by neoplastic plasma cells; for example CD19+, CD28+, CD81+, or CD117− expression has been associated with inferior outcome.[35] Patient-specific immunophenotypic profiles with the sensitivity to detect one or more tumor cells in 10,000 normal cells make MFC an attractive strategy for MRD monitoring. From a clinical perspective, achieving an immunophenotypic CR predicts extended survival in younger patients undergoing intensive therapy and older patients treated with novel agents. The pitfalls of flow cytometric MRD assessment include its lack of standardization and the need for experienced personnel.[36,37] A recent survey across 30 major medical institutions in the United States found that immunophenotypic features defining abnormal plasma cells varied substantially among institutions, as did the sensitivity of the MFC assays for MRD, which exhibited a 100-fold difference ranging from 0.0005% to 0.02%.[38] The NCI, FDA, MMRF, and EuroFlow Consortium have initiated concerted efforts to overcome these drawbacks. In addition to MFC, polymerase chain reaction techniques are well standardized and highly sensitive (10^{-5} to 10^{-6}), with several studies showing that, among patients achieving a CR, MRD-negative status is associated with substantial improvements in PFS and OS.[39,40] However, designing allele-specific oligonucleotides for each individual is

laborious and time consuming, relatively expensive, and requires high-quality DNA, not only for post-treatment samples but also at baseline. Moreover, the genetic mutations are not stable longitudinally. Systematic assessment of MRD by next-generation sequencing (NGS) offers a novel platform with increased sensitivity, in particular for serial monitoring of mutational shifts between diagnosis and relapse.[41] Progression is characterized by dynamic clonal equilibrium resulting from multiclonal presentation, clonal dominance, and post-treatment clonal selection. With respect to the potential need for frequent MRD sampling, the question of whether NGS of peripheral blood plasma cells could replace bone marrow testing is being studied. It should be noted that MRD negativity does not equate with complete tumor eradication, particularly in a disease that is typically characterized by patchy marrow infiltration and extramedullary involvement. In parallel with standardizing assays and validating prognostic MRD thresholds, there is an increasing interest in MRD monitoring as a tool for risk-adapted clinical trials.[42]

IMAGING BIOMARKERS

Paralleling the improvements in laboratory techniques, great advances have been made in imaging biomarkers. For a disease like MM that is characterized by bone involvement in at least 80% of patients, imaging plays a critical role in diagnosis. The use of imaging biomarkers is as old as skeletal surveying itself; moreover, as the field of medical imaging has expanded to include MRI and PET, the number of available biomarkers has also increased. The principal imaging biomarkers are currently topographic markers such as lytic bone lesions and/or abnormal plasma cell proliferations in bone marrow or soft tissues. The major advantages of MRI and PET/CT compared with skeletal survey are discrimination between normal and invaded bone marrow, visualization of extramedullary disease (EMD) and cord involvement, and better sensitivity for lytic bone lesions. MRI and PET/CT biomarkers of focal marrow abnormalities (with or without osteolysis) provide a method to assess disease burden and prognosis and monitor response to therapy. The number of focal lesions at baseline on MRI or ^{18}F-FDG PET/CT adversely affected both OS and event-free survival (EFS), as did the presence of EMD and failure of FDG suppression. Specifically, more than three baseline PET focal lesions and more than seven baseline MRI focal lesions (present in 32% and 36% of newly diagnosed patients with MM, respectively) were each associated with shorter EFS and OS.[43-45] Moreover, complete suppression of FDG before the first ASCT conferred a favorable outcome.[44] Additionally, the absence of PET suppression by day 7 of the first induction cycle in patients with MM who were treated in the Total Therapy 3 trials was associated with inferior OS and PFS.[46] These observations have important implications and require further validation in the era of novel therapy induction regimens. PET/CT provides a complementary tool to biopsy for assessing heterogeneity and the effect of treatment within and across multiple disease sites. Emerging biomarkers, such as novel PET probes and dynamic contrast-enhanced (DCE) MRI parameters, including diffusion/perfusion, angiogenesis, and mismatches in tumor metabolism, provide a unique opportunity to evaluate response and resistance to antimyeloma therapy. Data demonstrating the efficacy of ^{11}C-thymidine PET and ^{18}F-fluorothymidine for response evaluation are promising.[47] Although the newer imaging biomarkers have not yet been fully validated, recent advances in functional and molecular imaging provide a wealth of opportunities and accumulating data suggest that these biomarkers will become increasingly important in the future.

BONE TURNOVER BIOMARKERS

Biomarkers of bone turnover (resorption and formation) are attractive noninvasive tools for detecting early bone involvement and for evaluating the risk of skeletal morbidity and response to antiresorptive treatment.[48] These markers can be divided into two categories: collagen fragments released from the bone matrix during degradation, and enzymes released from either osteoblasts or osteoclasts. Biomarkers reflecting osteoclast-mediated degradation of collagen, including N-terminal cross-linking telopeptide of type-1 collagen (NTX), C-terminal cross-linking telopeptide of type-1 collagen (CTX), C-terminal cross-linking telopeptide of type-1 collagen generated by metalloproteinase (ICTP), and deoxypyridinoline, provide information on the remodeling process and reflect whole-body bone turnover as opposed to local changes in skeletal homeostasis.[49] Urinary NTX, serum CTX, and serum ICTP levels are elevated in patients with MM and correlate with advanced osteolytic disease.[50-52] Furthermore, urinary NTX and serum ICTP correlate with risk for skeletal complications, PFS, and OS.[51,53,54] Procollagen type-1 N-propeptide and procollagen type-1 C-propeptide signify new bone formation.[55] Receptor activator of nuclear factor-kappa B ligand (RANKL) and osteoprotegerin are also important markers of bone turnover.[54,56] Newer techniques using a label-free mass spectrometry-based strategy have been used to distinguish no versus high levels of bone disease.[57] Results from ongoing trials evaluating biomarkers that mirror the dynamics of bone disease in MM will help to identify their true value in clinical practice.

EPIGENETIC BIOMARKERS

There is now substantial evidence supporting the notion that epigenetic changes, including DNA methylation, histone acetylation, and microRNAs, are important for MM development and progression. Normal B cells, plasma cells, and MGUS cells have a methylation pattern that is distinct from that of malignant cells in patients with newly diagnosed MM and plasma cell leukemia.[58] The transition from MM to plasma cell leukemia has been associated with promoter hypermethylation of genes involved in cell signaling and cell adhesion pathways, and with patterns of global hypomethylation.[59,60] Unsupervised clustering of myeloma samples de-

fined several independent methylation profiles of cytogenetic groups; the most distinct of these belonged to the t(4;14) translocation associated with histone methyltransferase activity of MMSET.[61] The importance of miRNAs in the regulation of cell differentiation, survival, and apoptosis was highlighted soon after their discovery and it is now known that aberrant miRNA expression occurs in MM, in which miRNAs can act as oncogenic drivers or tumor suppressors and can also interact closely with other critical epigenetic regulators.[62] Data indicate that MGUS and MM share a common miRNA signature that distinguishes them from normal plasma cells, but MM cells exhibit changes in additional miRNAs compared with MGUS cells. Commonly deregulated miRNAs in MM include miR-21, the miR-17–92 cluster, the miR-15a/16 cluster, and the miR-29 and miR-34 families.[63] Thus, the discovery of epigenetic changes has provided additional insights into the pathogenesis of myeloma.

BIOMARKERS FOR RISK OF PROGRESSION IN MYELOMA PRECURSORS

At present, there are no reliable biologic markers that predict which individuals with MGUS or SMM will progress to MM. In the absence of such markers, patients are risk stratified based on two commonly used models developed by the Mayo Clinic and the Spanish study group that are derived from clinical variables identified through retrospective studies.[64,65] The Mayo Clinic model is based on quantification of M spike and bone marrow plasma cells, whereas the Spanish model includes the degree of clonality assessed by immunophenotyping (i.e., the balance between malignant and residual normal plasma cells). Recent studies indicate that chromosomal abnormalities are also critical determinants of the rate of progression in SMM. Two studies showed that the presence of del(17p) or t(4;14) is associated with the shortest time to progression and that trisomies and gains of 1q21 are risk factors for progression (Table 1).[66,67] Genetic heterogeneity is established early during clonal plasma cell development. GEP has identified major differences between MGUS and normal plasma cells, yet no clear distinctions have emerged between MGUS and MM.[68,69] The Arkansas group used GEP clustering in 351 patients with MM, 44 with MGUS, and 12 with SMM, and identified four major signatures; a MGUS-like signature in patients with MM was associated with improved survival.[70] A recent prospective observational study showed that increased GEP70 score was an independent predictor of risk of progression from precursors to MM.[71] Functional MRI incorporating DCE, diffusion weighting, or PET has the potential to detect small volumes of active tumor before morphologic changes become apparent. In a small study, DCE MRI microvascular parameters represented as rate constant (kep) and transfer constant (ktrans) showed moderate correlation with microvessesl density (MVD) in patients with MGUS, SMM, and MM, whereas MVD increased progressively along the myeloma spectrum, recapitulating an angiogenic switch.[72] The presence of MRI focal lesions is a predictor of early progression. In the largest study to date, involving 149 patients with SMM, focal marrow abnormalities were identified in 28% of subjects and the presence of two or more focal lesions was shown to have independent prognostic significance for progression to symptomatic disease.[73] A recently published trial of longitudinal MRI in untreated SMM patients revealed that MRI-progressive disease, as defined by new or increasing focal or diffuse bone marrow abnormalities, was associated with a 16.5-fold increased risk of progression to MM compared with MRI-stable disease (p < 0.0001).[74] Although further technical refinement is needed, it is likely that biomarkers based on GEP, imaging, and immunophenotyping that can be followed in patients with MGUS or SMM will be introduced into the clinic, allowing us to better understand variations in sequential trajectories and predict those patients who are at high risk of disease progression and for whom treatment intervention is essential to prevent the emergence of serious end-organ damage.

CONSIDERATIONS ON DESIGNING BIOMARKER-FOCUSED CLINICAL TRIALS

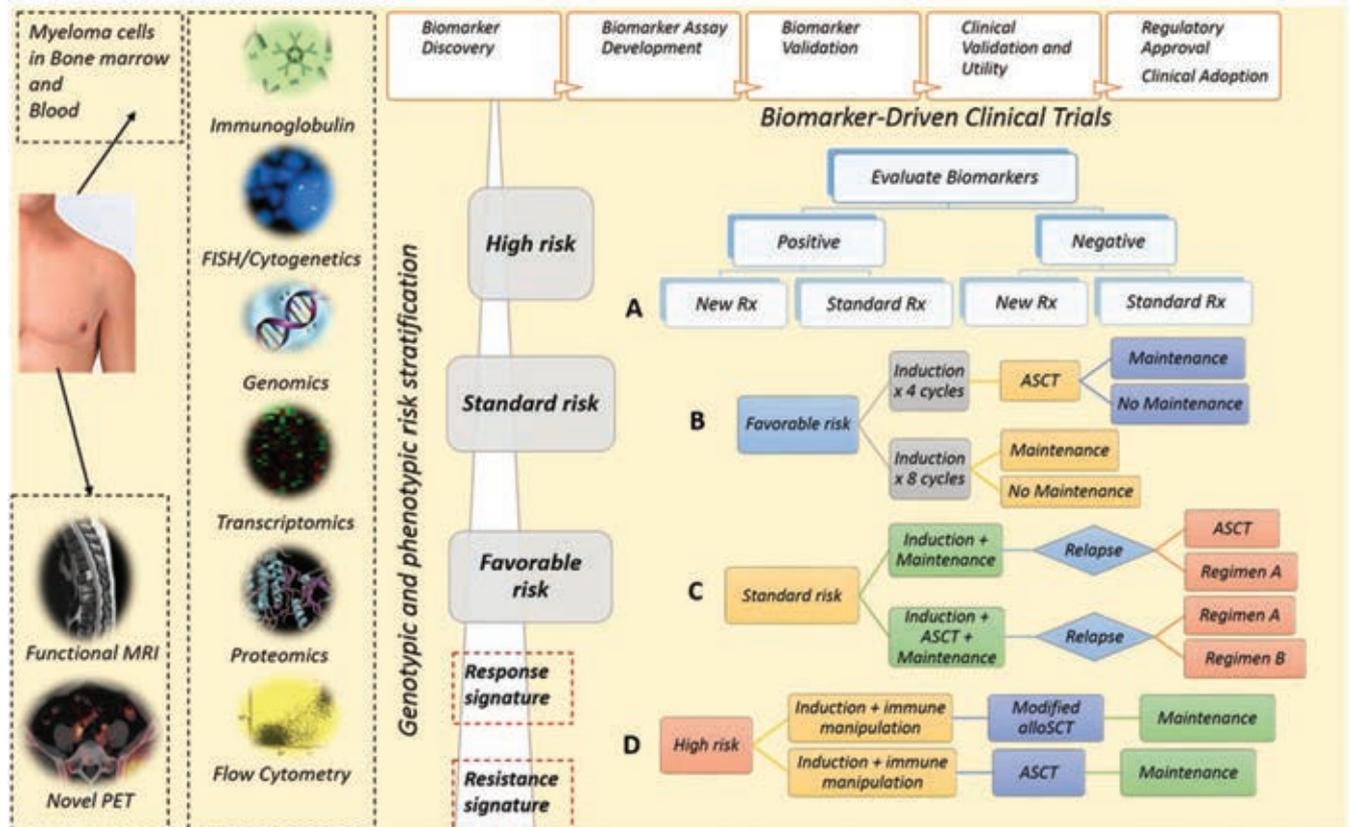
Although it is currently feasible to define different risk groups using sets of prognostic biomarkers, we are not yet at the point where this can actually drive go/no-go decisions or support a specific alternative treatment strategy in a high-risk group or less intense therapy for those with favorable risk. Some might argue that this concept of optimization of therapy would not apply for an incurable malignancy, and that all patients should receive the optimal currently available treatment strategies (including ASCT) that have been tested in phase III clinical trials to achieve the best outcome. However, emerging evidence based on use of the best available treatments for newly diagnosed MM and SMM, together with refinements in risk categorization, clearly indicates that many patients have a greater than 50% chance of surviving more than 10 years and may not need up-front intensification of treatment.[75] In contrast to standard-risk patients, for whom progress has been made in improving outcomes, clinical trials based on a 'one-size-fits-all' strategy have in general been disappointing for high-risk MM, which constitutes a distinct subgroup based on clinical and biologic biomarkers (Table 1).[75-77] For this patient population the median survival has remained poor (approximately 2 to 3 years) despite aggressive therapy incorporating almost every available drug and treatment modality. In such cases, treatment intensification with dose-dense chemotherapy that is rotated and maintained for a long period of time to potentially induce consistent therapeutic pressure on the myeloma clone has not yielded encouraging results.[31] An early IFM study compared the efficacy of allogeneic stem cell transplantation and ASCT in high-risk patients defined by high β2-microglobulin and del(13q) detected by FISH.[78] Although the definition of high-risk disease has improved since the inception of this trial, no difference in EFS was seen between the two transplant types. The strategy of tandem ASCT followed by nonmyeloablative allogeneic transplant led to improved CR but did not translate into a survival benefit compared with double ASCT be-

cause of greater treatment-related mortality.[79] Current studies are looking into immune manipulation in the context of allogeneic transplantation. Tumor/stromal interactions, signaling pathway dependencies, and genetic and epigenetic alterations in MM provide novel targets for the development of drugs that are intended to abrogate malignant progression through specific drug protein interactions (Table 2; reviewed in Boyd et al.[80]). Combinations of molecular targeted drugs or monoclonal antibodies and a tolerable conventional chemotherapy regimen seem promising, specifically for high-risk MM. As more effective treatment options become available, it is imperative to refine the yardstick for measuring the depth of responses that correlate with outcome. Once the definition of MRD in MM is standardized, the next generation of randomized studies should include MRD as a surrogate endpoint to assess which therapeutic strategy produces the deepest and most sustainable response.

The ability of high-throughput "omics" platforms to profile a large number of analytes in a single assay, together with the rapid expansion of next-generation sequencing for clinical use, is increasing the technical and logistical complexity of biomarker validation. As a result, biomarkers for identifying high-risk disease will undergo refinements and will need to be validated in order for us to screen an adequate number of patients for clinical trials focused on the subgroup of interest. Steps in the development, validation, and qualification of candidate biomarkers are shown in Fig. 1. The Clinical Laboratory Improvement Amendments (CLIA) approach suggests that the development of biomarkers should be performed in defined laboratories according to relevant standard operating procedures in order to establish consistency in sample handling, sample testing, assay interpretation, and reporting of results across laboratories. This implies that all biomarkers should be developed in CLIA-certified laboratories and in the context of clinical trials in which data are collected according to the principles of good clinical practice.[81] For a biomarker to be used to direct patient care, it must be shown to have clinical utility with very high levels of evi-

TABLE 2. Biomarkers for Molecularly Targeted Therapies in Multiple Myeloma

Alterations/Genes	Target/Biomarker	Prevalence	Prognosis	Targeted Drug
t(4;14) *FGFR3/MMSET*	FGFR3 tyrosine kinase receptor	10-15%	Intermediate	PRO-001, CHIR 258, PKC412
t(14;16) *c-MAF* t(14;20) *MAFB*	MAF overexpression	5-10%	Poor	MEK inhibitors
t(11;14) *CCND1* t(6;14) *CCND3*	Cyclins	19%	Standard	Cyclin D inhibitors
8q24 translocations (*c-MYC*)	c-MYC		Poor	Bromodomain inhibitors e.g., JQ1
+1q (*CKS1B*, *PDZK1* and *BCL9*)	STAT3 and MEK/ERK signaling	39%	Poor	STAT3 and MEK inhibitors
Deletion of 1p (*FAF1* and *CDKN2C*)	-	11%	Poor	
Deletion of 13q (*RB1*)	-	45% by FISH and 19% by conventional cytogenetics	Earlier studies showed poor survival	Mutant RB1 inhibitor
Deletion of 17p (*TP53* and *MDM2*)	Mutant or WT TP53	10%	Poor	Nutlin, PRIMA-1, CHK inhibitors, and filanesib (target G2M)
Proliferative myeloma	Ki67, GEP-PR subtype		Poor	Spindle kinase inhibitors, Aurora kinase inhibitors
NF-κB pathway (multiple genes e.g., *NFKB2*, *NFKB1*, *CYLD*, *TACI*, *NIK*, *TRAF2*, *TRAF3*, *BIRC2*, *BIRC3*, *VWOX*, and *CD40*)	Gene expression signature		Poor	MLN120B (inhibitor of IKKβ)
JAK/STAT pathway (*CCND2*)	Cyclins	50%		JAK inhibitors: atimprimod, AZD1480, TG101209, and INCB16562
MAPK/RAS pathway	*RAS* mutations (20-35%)	20-35% *BRAF* mutations (4%)	Poor	Farnesyl transferase inhibitors: perillic acid, FTI-277, and tipifarnib. MEK inhibitors: AZD6244 and AS703026. BRAF kinase inhibitors
PI3 kinase pathway	Cyclins			PI3K inhibitors: SF1126, pichromene, and CAL-101
				AKT inhibitor: Perifosine
				mTOR inhibitors: Rapamycin, Temsirolimus
Epigenetic changes	Histone methyltransferase activity of MMSET	15%		HDAC6 inhibitor: ACY-1215
				DNA methyltransferase inhibitors e.g., 5-azacytidine, 5-aza-2´deoxycytidine

FIGURE 1. Roadmap for the Identification of Fit, Robust, Valid, and Clinically Useful Biomarkers


In the future, several new biomarkers will be identified through a "discovery" approach utilizing techniques such as high-throughput sequencing, omics technologies, gene expression arrays, mass spectroscopy, multiplex flow cytometry, and innovative imaging strategies. Several steps must be completed before the marker can be applied in the clinic. First, a cohort of samples is analyzed to determine whether the effects observed in cell assays or animal models are recapitulated in humans. After demonstrating target engagement/modulation, subsequent testing involves analyzing an independent sample cohort to validate the original hypothesis-generating findings, and evaluation to confirm that the new biomarker will provide additional information that is useful for clinical decision-making. These concepts have been termed analytic validity, clinical validity, and clinical utility. Based on the new set of biomarkers, risk stratification schemas and treatment response/resistance signatures are expected to evolve. It will be important to utilize the correct biomarker-focused trial designs to evaluate a biomarker's ability to predict treatment response. Biomarker-stratified designs (A) that aim to evaluate both a new treatment and a biomarker within the same trial by enrolling all-comers to new versus standard treatment with a planned biomarker subset analysis will be more suitable for evaluating biomarkers such as t(4;14). If phase IIb shows a significant interaction of effects in patients with/without t(4;14), the integral selection of only patients with t(4;14) for the confirmatory phase III trial would follow. Development of multibiomarker risk assessment models for clinical applications will require well-designed clinical trials within the framework of carefully selected questions, such as whether maintenance can be omitted for a standard biologic risk group (B), whether up-front autologous transplant is a uniform requirement for all eligible patients (C), and whether the high-risk group can be offered alternative investigational strategies to improve outcome (D).

dence. Clinical utility refers to the ability of the biomarker to improve clinical decision-making and patient outcomes. Whereas a good predictive biomarker indicates who should receive the targeted treatment, a good prognostic biomarker does not necessarily have clinical utility. We already have several risk stratification biomarkers that are prognostic; however, these have not been validated for clinical utility. For example, even if the ISS distinguishes outcomes between three subgroups, clinical evidence supporting de-escalating or escalating treatment according to the risk group is not available. Improvement in patient outcomes can be achieved by conducting strategic clinical trials involving risk models based on multiple biomarkers.

Evaluation of prognostic biomarkers for clinical utility will require carefully designed clinical trials within the framework of carefully asked questions (Fig. 1). Prospective enriched integral biomarker trial designs that predefine an eligible population by the presence of a strong biomarker (i.e., HER2 in breast cancer or BCR-ABL in CML) may not be

appropriate for testing a new treatment in patients with MM as positive results from such a study would leave one wondering whether the treatment might also have worked in the biomarker-negative subgroup. Moreover, selecting patients with, for example, BRAF-mutated tumors (which have a 4% incidence within MM) for anti-BRAF therapy presents a difficult challenge. Such a phase III trial would require screening of thousands of patients with MM to accomplish a BRAF-mutated phase III selection. Moreover, if we are to generate high-quality data supporting the magnitude of benefit of a biomarker for a patient, clinician, or third party payer, it is important to evaluate and report biomarker-focused clinical trials within the framework of defined guidelines such as REMARK (Reporting Recommendations for Tumor Marker Prognostic Studies) to ensure that all necessary information is included.[82]

The presence of clonal heterogeneity and subclonal evolution within a single patient across time (with treatment) and space (within medullary and extramedullary sites) has im-

portant implications for the development of biomarkers. In the future, characterization of the size of the subclone carrying the target will very likely influence the choice of treatment because completely eradicating a clone that is present 90% of the time would be much more important than targeting a clone that is present only 5% of the time.[81] In this regard, samples should be prospectively collected from large clinical trials, not only at the time of diagnosis but also longitudinally, for the creation of repositories to either validate existing prognostic markers/signatures or generate new ones. Several ongoing multinational efforts, such as the CoMMpass study, aim to provide a comprehensive understanding of MM in the era of novel agents.

CONCLUDING REMARKS

Studies performed over the last few years have emphasized that MM is a complex disease that is not amenable to treatment through a single therapeutic approach or inhibition of a single target or single pathway. A new generation of biomarkers based on cytogenetics, epigenetics, focal lesions, clone status, and GEP signature is beginning to provide clinicians with more information about the clinical behavior of the disease, providing a basis on which risk stratification models and therapies can be continuously refined. The new biomarker-based definition of MM has direct clinical implications for initiating treatment in a biomarker-positive subgroup. Further studies should apply risk stratification in the trial design to specifically answer questions regarding treatment within each risk group. Currently, few data are available to support the use of biomarker-guided treatment optimization, although with a robust pipeline of novel targeted agents and standardized definitions of MRD linked to traditional clinical endpoints, this remains an important goal of ongoing research. A systems-based approach including collaboration across multiple institutions and investigators will enhance our ability to conduct biomarker-focused clinical trials in a more effective manner.

Multiple Myeloma: From Front-Line to Relapsed Therapies

Philippe Moreau, MD, and Cyrille Touzeau, MD, PhD

OVERVIEW

Recent developments in the treatment of multiple myeloma (MM) have led to improvements in response rates and to increased survival. A major advance in the last decade has been the introduction of the novel agents thalidomide, bortezomib, and lenalidomide as part of front-line treatment in both the transplant and nontransplant settings. However, disease relapse is inevitable for the majority of patients and myeloma typically recurs more aggressively with each relapse, eventually leading to the development of treatment-refractory disease. Several phase II and III trials have demonstrated the efficacy of recently approved agents in the setting of relapsed and relapsed and refractory MM, including pomalidomide and carfilzomib. Ixazomib, an oral proteasome inhibitor, and multiple other novel classes of agents are being investigated. These include monoclonal antibodies and histone deacetylase inhibitors, which may further add to the therapeutic armamentarium for this malignancy. Therefore, in a disease characterized by multiple relapses, the optimal sequencing of the different effective options is an important consideration in attempting to prolong survival.

Multiple myeloma accounts for 1.5% of all cancers and approximately 13% of all hematologic malignancies.[1] Approximately 86,000 new cases of MM occur annually worldwide. In the United States, 24,050 new cases were estimated for 2014 (age-standardized rate of 5.9 per 100,000) with MM accounting for 11,090 deaths.[2] In Europe, there were an estimated 17,935 new cases in 2012, with an age-standardized rate of 5.5 per 100,000, and 10,390 deaths because of MM.[3] This malignant neoplasm primarily affects older individuals with a median age at the time of diagnosis of about age 70.[4]

The median survival of patients with MM has improved substantially over the past decade, from 3 to 4 years to approximately 7 to 8 years,[5] a development due to the establishment of high-dose therapy followed by autologous stem cell transplantation (HDT-ASCT) as a routine procedure; significant improvements in supportive care strategies; and the introduction and widespread use of novel agents, including the immunomodulatory drugs (IMiDs) thalidomide and lenalidomide, and the proteasome inhibitor (PI) bortezomib. These agents now form the basis of many current standard-of-care approaches for first-line therapy in the transplant and nontransplant settings, and for the treatment of relapsed disease. Active research into new therapies has resulted in the development of additional novel agents, some of which are now approved for relapsed/refractory MM. These include the next-generation IMiD pomalidomide, which was approved in the United States and Europe in 2013, and the PI carfilzomib, which was approved in the United States in July 2012. Ixazomib, an oral PI, and multiple other novel classes of

agents, such as monoclonal antibodies and histone deacetylase (HDAC) inhibitors, currently are being investigated. These agents will further add to the therapeutic armamentarium and possibly increase the number of lines of therapy that patients will receive during the course of their disease treatment.[6] The optimal sequence of combination therapies from the time of diagnosis to the time of the most advanced phase of myeloma has to be considered carefully to minimize resistance and toxicity, and to improve quality of life (QOL), the treatment-free interval (TFI), and, most importantly, overall survival (OS).

FRONT-LINE TREATMENT IN YOUNG PATIENTS: ASCT IS THE STANDARD OF CARE

For young patients, who generally are considered to be those younger than age 65 to 70 and without prohibitive comorbidities, HDT-ASCT is the treatment of choice in newly diagnosed MM. This is based on a number of randomized studies conducted in the 1990s, which showed that intensive therapy with ASCT improved survival over conventional chemotherapy.[7] In the last decade, the introduction of the novel agents thalidomide, bortezomib, and lenalidomide into the front-line setting has markedly improved the rate of complete remission (CR) that can be achieved both before and after ASCT without substantially increasing toxicity. This has important implications because the achievement of high-quality responses is a significant prognostic factor for outcome.[4,7-8] Based on a number of trials investigating different combinations of agents as induction reg-

Corresponding author: Philippe Moreau, Department of Hematology, University Hospital Hôtel-Dieu, Place Ricordeau, 44093, Nantes, France; email: philippe.moreau@chu-nantes.fr.

imens,[4,6,9] the 2015 recommendation is the use of a three-drug regimen based on bortezomib/dexamethasone, with the third agent cyclophosphamide, adriamycin, thalidomide, or lenalidomide.[4,10]

Novel agents also have been included in the post-ASCT setting. Their incorporation into consolidation therapy[11] has resulted in the achievement of deep molecular- or flow cytometry– defined complete responses, with some patients remaining alive and free of disease, with a minimal residual disease (MRD) negativity, which are vital prerequisites for extended disease-free survival.[12] These unprecedented results were only possible previously with allogeneic transplantation (alloSCT), the routine use of which is not recommended outside clinical trials in MM because of excessive transplant-related mortality.[13] Recent data also show that maintenance following HDT may dramatically increase progression-free survival (PFS) by almost 2 years.[14] The implementation of an optimal strategy, consisting of novel agent-based induction, HDT, and the use of novel agents in consolidation and maintenance, may result in a 5-year survival rate of 80%, which is unprecedented. Moreover, a subset of patients who present with good prognostic features at the time of diagnosis might be considered cured.[15-16] However, the strategy of optimized induction, HDT, and ASCT followed by PI- and/or IMiD-based consolidation and maintenance is currently restricted to clinical trials.

The high efficacy of novel agents has resulted in questioning of the role of up-front ASCT. A number of studies have been initiated to investigate these agents up front without ASCT. In a nonrandomized phase II trial of RVD (lenalidomide, bortezomib, dexamethasone) in the up-front setting, no difference in outcome was seen for patients undergoing HDT or not.[17] Impressive results, including high rates of MRD-negative responses, also have been reported for the combination of carfilzomib/lenalidomide and low-dose dexamethasone (KRd) without up-front ASCT in another phase II study.[18] Based on these results, some physicians are considering that delaying ASCT to the time of the first disease relapse could be an attractive option. In 2015, only limited data from randomized studies are available to address the issue of early versus late ASCT. However, preliminary results favor early ASCT plus novel agents over novel agents alone. The first prospective study comparing conventional chemotherapy plus novel agents to tandem ASCT in newly diagnosed MM patients is being conducted by the Italian myeloma group and was recently reported by Palumbo et al.[19] Patients received lenalidomide/dexamethasone (Rd) induction and then were randomly assigned to melphalan/prednisone/lenalidomide (MPR) or tandem ASCT. Both PFS and OS were substantially longer with high-dose melphalan plus ASCT than with MPR (median PFS, 43.0 vs. 22.4 months; and 4-year OS, 81.6 vs. 65.3%). Two other ongoing trials, one conducted by the European Myeloma Network (EMN02 study, NCT01208766) and another by the IFM in conjunction with a U.S. consortium (IFM/DFCI 2009 study, NCT01208662) are investigating the same question and have enrolled 1,500 and 1,000 patients, respectively. Although variability in consolidation and maintenance strategies may affect PFS when comparing early versus

late transplant approaches, these two studies will solve many issues regarding the role of systematic front-line ASCT in the treatment of young patients eligible for HDT. Results, however, are not expected before the end of 2015.

FRONT-LINE TREATMENT OF PATIENTS NOT ELIGIBLE FOR ASCT

Since the introduction of thalidomide, bortezomib, and lenalidomide, the median OS in older newly diagnosed multiple myeloma (NDMM) patients has increased from approximately 30 to 60 months.[5,20] Several regimens that include one or two of these novel agents have been explored. The combination of melphalan/prednisone/thalidomide (MPT) is a standard option for NDMM patients who are not candidates for ASCT.[4,10,21-22] The addition of thalidomide to melphalan/prednisone (MP) was shown to delay disease progression in several randomized trials and to improve OS in some patients.[4,21] A meta-analysis of published data from six randomized trials confirmed an improvement in PFS and OS with MPT compared to MP.[22] The reported median PFS and OS with MPT were 20.3 and 39.3 months, respectively.

The combination of bortezomib/melphalan/prednisone (VMP) is another well-established standard of care. This regimen initially consisted of 2 times a week intravenous administration of bortezomib, based on the phase III VISTA trial,[23] which showed that VMP was superior to MP across all efficacy endpoints, including response rate, CR rate, median time to progression (TTP, 24 vs. 16.6 months) and OS. Based on clinical data published in 2010, bortezomib use evolved from 2 times a week to 1 time a week,[24] and from 2012, the subcutaneous route of administration has found increasing use over the intravenous route based on data demonstrating improved tolerability for this mode of administration.[25] The final analysis of the VISTA trial after a median follow-up of 60 months confirmed the superiority of VMP versus MP in terms of median time to second-line antimyeloma therapy (31 vs. 20.5 months) and median OS (56 vs. 43 months).[26] Bortezomib/dexamethasone (VD) and bortezomib/thalidomide/dexamethasone (VTD) have yielded similar results in the up-front setting in nontransplant eligible patients.[27]

Lenalidomide mainly has been used in combination with MP (MPR),[28] or with low-dose dexamethasone (Rd).[29,30] For the MPR regimen, tolerability was found to be reduced in patients over age 75, and the combination also has been associated with an increased incidence of second primary hematologic malignancies.[28] In the recent phase III FIRST study, which included 1,623 transplant-ineligible patients, the continuous Rd regimen administered until disease progression, intolerance, or for a fixed duration of 18 cycles (72 weeks; Rd18) was compared to MPT administered for 12 cycles (72 weeks). Continuous Rd substantially extended PFS and OS compared to MPT. With a median follow-up of 37 months, the median PFS was 25.5 months for Rd, compared to 20.7 months for Rd18 and 21.2 months for MPT. The 4-year estimated OS was 59% for Rd, 56% for Rd18, and 51% for MPT. In addition, Rd was superior to MPT across all

other efficacy endpoints, including response rate, TTP, time to treatment failure, time to second-line antimyeloma therapy, and duration of response (DOR). Rd also was generally better tolerated than MPT.[30]

The current standard regimens MPT and VMP are based on melphalan and are administered for a fixed duration (9 to 12 cycles).[4] The alkylator-free doublet regimen Rd, delivered as a continuous therapy, has demonstrated superiority over MPT,[30] and continuous Rd will likely become a new standard of care for transplant-ineligible patients with NDMM. This represents a dual paradigm change in a disease in which alkylating agents and fixed-duration therapy have been standard for decades. We anticipate that the two most important front-line therapeutic options in 2015 and 2016 probably will comprise either VMP or Rd.

RELAPSED MULTIPLE MYELOMA AFTER ASCT

Four general approaches to the management of symptomatic disease relapse following initial ASCT may be considered: (1) reinduction followed by salvage ASCT, (2) reinduction followed by alloSCT, (3) reinduction with continuation of conventional chemotherapy using rational combinations of novel therapies for relapsed/refractory disease, and (4) participation in clinical trials to evaluate any of the first three possibilities. Currently, only limited comparative data are available to support one approach over another.[31]

REINDUCTION FOLLOWED BY SALVAGE ASCT

No guidelines on the optimal salvage regimen exist. The choice of the reinduction regimen typically depends on patients' responses to the initial induction therapy; comorbidities, such as persistent peripheral neuropathy (PN) related to prior bortezomib; burden of disease; or patients whose disease relapsed on maintenance lenalidomide and/or bortezomib.[31-32] Triplet reinduction regimens commonly are used. In case of prolonged TFI following front-line ASCT, it is reasonable to consider using the same combination regimen that was used as the initial induction therapy, such as VCD, VTD, or RVD. Patients who will benefit most from salvage ASCT are those with chemotherapy-sensitive disease at relapse and those with a long duration of response to the initial ASCT.[31-33] On average, the PFS benefit following a salvage transplant is approximately one-half that of the PFS after the first transplant. Salvage ASCT may not be recommended if the time to relapse following the first ASCT is less than 18 to 24 months.[31-33] Whether salvage ASCT yields better outcomes than salvage chemotherapy is not conclusively known. Retrospective and uncontrolled data have suggested a possible trend toward improved survival with salvage transplant versus salvage combination chemotherapy.[31] A recent multicenter randomized phase III study compared salvage ASCT to cyclophosphamide single-agent administered for 12 weeks.[34] Patients were eligible if their disease had progressed or relapsed at least 18 months after the initial ASCT. All patients received re-induction with the PAD (bortezomib, doxorubicinm dexamethasone) regimen and were randomly assigned to either ASCT or cyclophosphamide. Although the median time to progression was substantialy longer for patients undergoing ASCT (19 vs. 11 months), the OS did not differ between the two arms. Many experts considered the cyclophosphamide arm of this trial to be suboptimal. Since salvage regimens that are more effective than single-agent cyclophosphamide are now available, additional prospective randomized trials comparing novel triplet combination therapies to salvage ASCT are needed.

REINDUCTION FOLLOWED BY SALVAGE ALLOASCT

Reduced-intensity conditioning alloSCT in the salvage setting sometimes is considered an appropriate option for younger patients with good performance status and high-risk features, including adverse cytogenetics, a high-risk gene expression profile, high LDH, or plasma cell leukemia. No prospective randomized studies comparing salvage alloSCT to salvage ASCT are available. Some retrospective analyses comparing these two approaches have been reported; they show a higher nonrelapse mortality rate with alloSCT, and PFS/OS rates in salvage ASCT.[31] A limited number of studies with few patients have evaluated salvage alloSCT versus no alloSCT. These studies have shown improved PFS for patients undergoing salvage alloSCT but without an OS benefit.[31] As the number of effective regimens for relapsed MM continues to increase, the use of salvage alloSCT should be restricted to clinical trials.[13,31]

SALVAGE CHEMOTHERAPY AND CLINICAL TRIALS

Numerous options exist for relapsed disease and the number of effective and available agents and combinations is increasing rapidly (Table 1). Only one trial has prospectively compared two- versus three-drug combinations in patients whose disease relapsed following front-line ASCT. Garderet et al demonstrated that the triplet combination of VTD was associated with a higher response rate, a longer time to progression (18.3 vs. 13.6 months), and a trend toward improved OS. However, VTD also was associated with a higher incidence of grade 3/4 toxicities as compared to thalidomide/dexamethasone.[35]

Two other recent prospective phase III trials have confirmed that triplet combinations are superior to doublets. However, these studies enrolled not only young, but also older patients. All had received one to three prior lines of treatment, and only a part of the patients were treated with front-line ASCT. In the PANORAMA-1 study, which compared VD-placebo versus VD plus the HDAC inhibitor panobinostat, 58% of the patients were younger than age 65, 56% had received a previous ASCT, and 51% were treated at the time of their first disease relapse.[36] Overall, the median PFS was substantially longer in the panobinostat group than in the placebo group (12 vs. 8 months; hazard ratio [HR] 0.63). This benefit was observed across the subgroups of patients younger than age 65 (HR 0.59), those who were treated for their first disease relapse (HR 0.66), and those previously treated with ASCT (HR 0.64). Of note, this triplet combi-

Abbreviations: ORR: overall response rate, PR: partial response; PFS: progression-free survival; mo, months; OS: overall survival; TD: thalidomide-dexamethasone; VTD: bortezomib-thalidomide-dexamethasone; VD: bortezomib-dexamethasone; Rd: lenalidomide-dexamethasone; NA, not available.

nation was associated with more gastrointestinal toxicities, thrombocytopenia, and fatigue compared to VD. In the second recently reported phase III ASPIRE study, in which Rd was prospectively compared to Rd-carfilzomib, 43% of the patients were treated in first relapse of disease, whereas 56% had received a prior transplant.[37] This trial showed that the addition of intravenous carfilzomib to Rd resulted in a substantially improved PFS (median, 26.3 vs. 17.6 months in the control group); this was observed across all predefined subgroups. Rd-carfilzomib had a favorable risk-benefit profile and patients in the carfilzomib group reported a superior health-related QOL.

Triplet combinations at first relapse probably will become standard in the near future, but the benefit in terms of overall response rate (ORR) and PFS will have to be balanced with cost and toxicity. Overall survival as a secondary endpoint also is important. In the setting of relapsed disease, the results of ongoing trials investigating other classes of agents, such as the monoclonal antibodies, are eagerly awaited. Although elotuzumab, which targets SLAMF7, lacks activity as a single agent in relapsed myeloma, an ORR of 82% and more than 30 months PFS was reported when this agent was combined with Rd in a phase II trial.[38] These results were the basis of the ongoing ELOQUENT-2 trial that is prospectively comparing Rd versus Rd-elotuzumab in patients whose disease had relapsed. The same design also was selected for the prospective comparison of Rd versus Rd-daratumumab in the ongoing

phase III randomized trial POLLUX. Daratumumab, a monoclonal antibody targeting CD38, has shown impressive activity as a single agent in patients with advanced disease[39] and in combination with Rd in phase II trials.[40] Another monoclonal antibody targeting CD38, SAR650984, currently is also being developed in relapsed disease.[41] A further phase III trial using Rd as a control arm could change the treatment landscape of relapsed myeloma. The placebo-controlled TOURMALINE-MM1 study is currently comparing Rd versus Rd-ixazomib in patients with relapsed disease. This combination also was tested along with Rd as front-line treatment in a phase II study resulting in impressive response rates.[42] The all-oral triplet combination Rd-ixazomib could become a convenient rescue treatment, provided that toxicity in relapse is similar to that observed in the front-line setting. VD is, as mentioned above, another backbone regimen in relapsed myeloma, and this combination also is currently being compared to VD plus pomalidomide in a prospective phase III international trial.

RELAPSED MULTIPLE MYELOMA IN PATIENTS NOT PREVIOUSLY TREATED WITH ASCT

As discussed previously, the front-line treatment of older patients in 2015/2016 consists of VMP, Rd, and, to a lesser extent, MPT. If their disease relapses, patients may either repeat the initial therapy—if this treatment had a fixed duration and

was able to induce a long TFI— or switch to a different treatment regimen. Several factors influence this decision, including drug availability in the specific country, patient age, comorbidities, performance status, prior treatment, duration of remission to the front-line regimen, and initial toxicities. Although anti-MM treatments have proven efficacious in older patients with relapsed MM, their use is often associated with substantial adverse effects that can affect treatment choice. As such, older and frail patients usually are treated with mild, low-dose regimens, typically thalidomide or bortezomib combined with either melphalan/prednisone or cyclophosphamide/dexamethasone.

RELAPSE FOLLOWING INITIAL VMP

For patients previously exposed to a PI plus an alkylator, Rd is the preferred option; it is approved, administered orally, and easily manageable. As described above, the results of ASPIRE (carfilzomib-Rd), POLLUX (daratumumab-Rd), Eloquent-2 (elotuzumab-Rd), and TOURMALINE-MM1 (ixazomib-Rd) will soon modify the landscape of relapse therapies. The choice of the particular regimen will depend on safety, duration of response, OS rates, and cost. The population of older patients is a very heterogeneous group, and the studies described above generally have selected a fit population of patients, excluding frail patients, for whom QOL is a major issue. In early 2015, only the results of the ASPIRE study are available as a full manuscript and the PFS benefit was described in patients older than age 65 (HR 0.85).

RELAPSE FOLLOWING MPT

For patients treated up front with a combination of an alkylator and thalidomide, several possibilities at the time of first disease relapse exist. Rd is one possibility. A bortezomib-based approach also is possible if patients did not experience PN with thalidomide. Bortezomib/dexamethasone and bortezomib/liposomal doxorubicin are two approved options. The first is the preferred option because of convenience and reduced toxicity. The triplet combination of RVD also was tested in first disease relapse in a phase II study with good results.[43] Similarly, the combination of bortezomib/dexamethasone plus bendamustine has proven to be effective in phase II studies.[44] Other triplet combinations currently undergoing evaluation in phase III trials could present future options, such as panobinostat plus bortezomib and dexamethasone following the PANORAMA-1 results, or pomalidomide plus VD.

RELAPSE FOLLOWING RD

The FIRST trial demonstrated the superiority of continuous Rd over MPT in terms of ORR, PFS, and OS. When approved, Rd will be a well-tolerated and effective oral front-line regimen. At the time of progression on Rd, the addition

of a third drug will not be the preferred option. Instead, the combination of a PI plus/minus alkylator (VD, VCD, or VMP) could be the best choice. Depending on approval, the triplet VD/panobinostat or VD/pomalidomide also could be proposed.

TREATMENT OF RELAPSED AND REFRACTORY MULTIPLE MYELOMA

Relapsed-and-refractory disease is defined as a minimal response to salvage therapy, as disease progressing during salvage therapy, or disease progressing within 60 days of the last therapy. These patients present a challenge because they are likely to have a more aggressive disease and to be heavily pretreated, thus having more pre-existing toxicities. Clinical trials remain an important option for these patients.

Depending on the treatment to which a patient is refractory, thalidomide, lenalidomide, or bortezomib (as single agents or in combination) can be used for the subsequent line of treatment. However, response rates tend to be lower than in patients whose MM had relapsed because of the more advanced state and aggressive nature of the disease and the development of treatment resistance. Patients whose disease is refractory to bortezomib and an IMiD have a median survival of only 9 months with salvage treatment.[45] Therefore, there is an unmet need for additional treatments for patients whose disease is refractory to current regimens.

Two agents, pomalidomide and carfilzomib, recently have been approved for use in patients with relapsed and refractory MM, who have failed bortezomib- and lenalidomide-based therapy.

POMALIDOMIDE

In the pivotal phase I/II study MM-002, the combination of pomalidomide with low-dose dexamethasone (Pd) was found to be more efficacious than single-agent pomalidomide in patients with relapsed and refractory MM (ORR, 34 and 15%, respectively).[46] In a randomized phase III study (MM-003), Pd was compared to high-dose dexamethasone in patients with primary refractory or relapsed and refractory MM. At 10 months' median follow-up, the PFS was substantially longer in patients treated with Pd versus patients treated with high-dose dexamethasone alone (median PFS, 4.0 vs. 1.9 months, respectively).[47] Comparable results were seen in a subgroup analysis of patients who were dual-refractory to bortezomib and lenalidomide (74% of patients in the MM-003 trial) (median PFS, 3.7 months).[47] A substantial improvement in OS was observed in the final analysis (median OS, 12.7 vs. 8.1 months).[47]

Pomalidomide in combination with low-dose dexamethasone has been approved in Europe and the United States for patients with relapsed and refractory MM whose disease has progressed following at least two prior therapies, including lenalidomide and bortezomib. As discussed previously, ongoing studies are examining pomalidomide in combination

with other anti-MM treatments and its use in earlier lines of treatment.[32]

CARFILZOMIB

Carfilzomib initially was evaluated in patients with very advanced MM. In the single-arm phase II study PX-171-003-A1, the treatment of patients with relapsed and refractory MM with single-agent carfilzomib led to durable responses, resulting in an ORR of 23.7%, a median DOR of 7.8 months, and a median OS of 15.6 months.[48] Furthermore, the phase II study PX-171-004 examined carfilzomib in patients with relapsed and/or refractory MM who were treated previously with bortezomib and in patients who were bortezomib-naive.[49,50] In patients previously treated with bortezomib, the ORR was 17.1%, with a median DOR of more than10.6 months and a median TTP of 4.6 months,[50] whereas in 126 response-evaluable bortezomib-naive patients, an ORR of 47.6% and a median TTP of 12.0 months were seen.[49] The lower ORR in patients previously treated with bortezomib may be attributable to a subset of patients who developed resistance to the class of PIs.

Both the PX-171-003-A1 and PX-171-004 trials examined a target dose of 27 mg/m^2 of carfilzomib. Higher doses of carfilzomib have been examined in phase Ib/II studies and appear to be associated with an increased likelihood of achieving a clinical response.[32] However, this requires confirmation in further trials. Thus far, doses higher than those recommended in the label have not been examined in patients with relapsed and refractory disease.

CONCLUSION

The tremendously active research into treatments for MM has resulted in a number of highly active new agents and encourages optimism to the goal of transforming MM into a chronic disease. Although none of the agents with novel mechanisms of action (those following the PIs or IMiDs) are yet to be approved, it is reasonable to believe that several will be in the near future. Our task will be to define the optimal sequence of treatment, the optimal combinations both for front-line and relapsed myeloma, according to age, comorbidities, cost, drug availability, and patients' choice.

Management of Chronic Lymphocytic Leukemia

Stephan Stilgenbauer, MD, Richard R. Furman, MD, and Clive S. Zent, MD

OVERVIEW

Chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL) is usually diagnosed in asymptomatic patients with early-stage disease. The standard management approach is careful observation, irrespective of risk factors unless patients meet the International Workshop on CLL (IWCLL) criteria for "active disease," which requires treatment. The initial standard therapy for most patients combines an anti-CD20 antibody (such as rituximab, ofatumumab, or obinutuzumab) with chemotherapy (fludarabine/cyclophosphamide [FC], bendamustine, or chlorambucil) depending on multiple factors including the physical fitness of the patient. However, patients with very high-risk CLL because of a 17p13 deletion (17p-) with or without mutation of *TP53* (17p-/*TP53*mut) have poor responses to chemoimmunotherapy and require alternative treatment regimens containing B-cell receptor (BCR) signaling pathway inhibitors. The BCR signaling pathway inhibitors (ibrutinib targeting Bruton's tyrosine kinase [BTK] and idelalisib targeting phosphatidyl-inositol 3-kinase delta [PI3K-delta], respectively) are currently approved for the treatment of relapsed/refractory CLL and all patients with 17p- (ibrutinib), and in combination with rituximab for relapsed/refractory patients (idelalisib). These agents offer great efficacy, even in chemotherapy refractory CLL, with increased tolerability, safety, and survival. Ongoing studies aim to determine the best therapy combinations with the goal of achieving long-term disease control and the possibility of developing a curative regimen for some patients. CLL is associated with a wide range of infectious, autoimmune, and malignant complications. These complications result in considerable morbidity and mortality that can be minimized by early detection and aggressive management. This active monitoring requires ongoing patient education, provider vigilance, and a team approach to patient care.

Chronic lymphocytic leukemia/small lymphocytic lymphoma is the most prevalent lymphoid malignancy in many parts of the world, and approximately 90% of patients are diagnosed with asymptomatic, early-intermediate stage (Rai 0-I, Binet A) disease.[1-3] Many of these patients have indolent disease and could have a normal life expectancy, whereas others have rapid disease progression and poor outcome. There is no proven survival benefit from early therapy in patients with CLL.[4,5] There are now multiple prognostic factors that can be used to predict the risk of disease progression including serum thymidine kinase (TK) and beta-2-microglobulin (β2MG) levels, genomic aberrations assessed by fluorescence in situ hybridization (FISH), ZAP70, CD38, and CD49 expression, somatic hypermutation of the immunoglobulin heavy chain variable region genes (*IGHV*), and mutations of other genes, most prominently *TP53*.[6,7] Despite multiple published studies of these prognostic factors in early-stage CLL, none have been prospectively validated.[8-14] Moreover, there is currently no evidence that early, risk factor–guided intervention with chemoimmunotherapy can alter the natural course of early-stage CLL.[4,5] Therefore, "watch and wait" remains the standard of care for patients with early-stage, asymptomatic CLL. The intervals of monitoring can be adjusted to a patient's risk profile, that is, with 3-monthly follow-up for patients with high-risk markers such as 17p- with or without *TP53*mut, unmutated *IGHV*, 11q22.3 deletion (11q-), and high β2MG or TK serum levels.

INITIAL MANAGEMENT OF CLL
Early-Stage Asymptomatic Patients

A small proportion of patients with early-stage CLL (approximately 3% to 5%) have 17p-/*TP53*mut,[15] which predicts a very high risk of disease progression[16-21] based on data from chemoimmunotherapy studies in patients who required treatment (discussed later). However, a small proportion of early-stage patients with 17p-/*TP53*mut CLL do not have early disease progression,[15,22] and 17p-/*TP53*mut at diagnosis in a patient who does not have active disease[1] is not an indication for treatment. However, these patients deserve a more extensive prognostic work-up and closer monitoring, including the discussion of allogeneic stem cell transplantation (ASCT) as an option in young/fit patients when their disease progresses and treatment is indicated. In summary, outside of clinical trials, the decision to start therapy requires the presence of active disease and is not modified by the presence of any high-risk marker. Prognostic markers can, however, be very helpful in counseling patients and planning patient follow-up.

Up-Front Management of Advanced Stage, Symptomatic Patients with an Indication for Treatment

Conventional chemoimmunotherapy regimens. The current up-front standard of care in physically fit patients with CLL who require treatment based on IWCLL criteria[1] is fludarabine, cyclophosphamide, and rituximab (FCR; Fig. 1).[17,18,23] This is based on high response rates (40% to 50% complete response [CR]), prolongation of median progression-free survival (PFS), and, notably, median overall survival (OS) compared with FC. However, many patients with CLL cannot tolerate FCR because of age (e.g., age > 65 to 70), decreased fitness (e.g., Cumulative Illness Rating Scale [CIRS] score > 6) and decreased renal function (e.g., creatinine clearance < 30 to 50 mL/min). In these patients, recent trials have suggested that other regimens could be more tolerable.

The German CLL Study Group (GCLLSG) CLL10 study compared FCR versus bendamustine/rituximab (BR) among fit (CIRS ≤ 6, creatinine clearance ≥ 70 mL/min) patients without 17p-, and showed that overall BR was inferior to FCR in terms of response rate and PFS.[24] However, FCR was associated with markedly increased toxicity without substantially better outcomes in patients over age 65, suggesting that BR is a reasonable alternative treatment for this population.

There are now new monoclonal antibody–based treatment options for patients who are not considered fit for FCR-type

KEY POINTS

- Careful observation for disease progression and complications, together with appropriate preventative interventions, remains the standard of care for patients with early-stage, asymptomatic, chronic lymphocytic leukemia. Patients with very high-risk chronic lymphocytic leukemia should not receive treatment until they meet standard criteria for progressive disease.
- The most critical determinants of treatment choice are the presence of 17p-/*TP53*mut, physical fitness/age, and duration of prior response in patients who have received previous treatment. In addition, 17p-/*TP53*mut analysis should be repeated before initiation of therapy.
- The combination of anti-CD20 antibody (rituximab, ofatumumab, or obinutuzumab) and chemotherapy (FC, bendamustine, or chlorambucil) is the standard up-front treatment for the majority of patients with chronic lymphocytic leukemia, with the specific choice of agents mostly determined by fitness of the patient. Based on the dramatic efficacy and favorable toxicity profile of the BCR and BCL2 inhibitors compared with historic chemoimmunotherapy regimens, these agents are the preferred treatment approach for very high-risk chronic lymphocytic leukemia (17p-/*TP53*mut and early relapse).
- Ongoing and future clinical trials are essential to further improve treatment efficacy, determine treatment duration, and eventually develop curative therapy.
- The role of allogeneic stem cell transplant in the management of chronic lymphocytic leukemia requires careful and early discussion in patients who are very high-risk.

treatment. Ofatumumab in combination with bendamustine or chlorambucil was licensed based on the randomized, phase III COMPLEMENT-1 trial that compared chlorambucil with ofatumumab/chlorambucil and showed substantially higher efficacy with only moderately increased toxicity for the combination therapy.[25] The phase III CLL11 trial compared chlorambucil, rituximab/chlorambucil, and obinutuzumab/chlorambucil in a three-arm design. Obinutuzumab/chlorambucil showed higher efficacy compared with both chlorambucil and rituximab/chlorambucil with an acceptable safety profile, which led to the approval of obinutuzumab/chlorambucil for the up-front treatment of patients with CLL who are less fit.[26] Therefore, the combination of anti-CD20 antibody (rituximab, ofatumumab, or obinutuzumab) and chemotherapy (FC, bendamustine, or chlorambucil) is the standard up-front treatment for the vast majority of patients with CLL.

Initial therapy of patients with 17P-/*TP53*mut. Patients with 17p-/*TP53*mut CLL have markedly inferior outcomes with both chemotherapy and chemoimmunotherapy.[6,16,18,19,27] In the subset of patients with 17p- CLL enrolled in the randomized CLL8 study that compared FC with FCR, FCR was superior in terms of overall response rate (ORR, 68% for FCR vs. 34% for FC; p = 0.03) and PFS (median 11.3 months for FCR vs. 6.5 months for FC; p = 0.02), but there was no difference in complete remission rates (CRR, 5% for FCR vs. 0% for FC) or 3-year OS (38% for FCR vs. 37% for FC).[18,27] *TP53*mut and 17p- were the two markers that had the strongest independent effect on PFS and OS in a multivariable analysis after FC and FCR treatment.[27] These unacceptable outcome data were clearly inferior to all other disease subgroups. In the British CLL4 trial, *TP53* mutation was identified as an adverse prognostic marker after treatment with chlorambucil, fludarabine, and FC.[19] These findings of inferior response and poor prognosis are supported by the reported results for 17p- patients undergoing initial treatment of active CLL in studies conducted by MD Anderson Cancer Center/Mayo Clinic,[22] the Spanish Group for CLL,[28] and the Memorial Sloan Kettering Cancer Center[29] which showed that only about 25% of patients with 17p- CLL achieve remissions of 3 years or longer after treatment with purine analog–containing chemoimmunotherapy.

There is limited data on bendamustine containing chemoimmunotherapy for the first-line treatment of patients CLL with 17p-. The GCLLSG CLL2M phase II study of front-line BR enrolled only eight patients with 17p- CLL, of which three responded; all responses were partial, and the median PFS was only 7.9 months.[30] Therefore, BR is likely inferior to FCR as initial therapy in 17p- CLL. In the relapsed/refractory setting, both FCR and BR were unsatisfactory, with response rates of 35% and 7%, respectively, and median PFS of 5 months and 7 months, respectively.

The value of using other recurrently mutated genes in the definition of high-risk disease and the treatment of patients with CLL is less well defined. There is data from heteroge-

FIGURE 1. Treatment Options for CLL

Optimal therapy for patients with CLL requires evaluation of disease biology, patient fitness, and treatment history. **(A)** Initial treatment of patients with CLL requires determination that they meet the International Workshop on CLL (IWCLL) criteria for active disease. These patients should then be clinically evaluated for fitness, and those considered fit for treatment then require FISH analysis for 17p13 deletion (17p-) and gene sequencing for mutations in *TP53* considered to be dysfunctional (*TP53*mut). **(B)** In patients with relapsed/refractory CLL, the response to previous treatment should also be considered when determining the treatment of choice. Patients who previously responded to chemoimmunotherapy with a response duration of 2 years or longer (late relapse) can be considered for retreatment with a chemoimmunotherapy regimen. In contrast, patients with a response duration of less than 2 years should be considered to have early relapse and should be treated with nonchemotherapy regimens.

Modified from the Onkopedia Guidelines of the German Society of Hematology and Oncology, available at www.onkopedia-guidelines.info.

neous cohorts outside clinical trials that mutation of genes such as *NOTCH1*, *SF3B1*, and *BIRC3* could improve the prognostic accuracy of genomic analysis.[20] However, data

from the U.K. CLL4 and GCLLSG CLL8 clinical trials have only partly confirmed the independent prognostic role of these gene mutations and their effect was less pronounced

than 17p-/*TP53*mut.[19,27] An interesting finding from the GCLLSG CLL8 clinical trial was that patients with CLL and *NOTCH1* mutations had a reduced benefit from the addition of rituximab to FC.[27]

Additional biologic markers associated with inferior treatment response include unmutated *IGHV*, 11q-, increased expression of CD38, ZAP70, and CD49, and high serum levels of β2MG and TK. Nevertheless, these markers do not define a subgroup of patients with CLL who require a different standard therapeutic approach. There are ongoing efforts by an international consortium trying to integrate biologic and clinical variables into a universal risk score to predict outcome in all patients with CLL (CLL-IPI consortium, see corresponding 2015 ASCO Annual Meeting abstract). This model uses five independent predictors for OS (age, clinical stage, 17p- and/or *TP53*mut, *IGHV* status, and β2MG) in a weighted grading to define four different CLL subgroups with significantly different OS rates at 5-years (93.2%, 79.4%, 63.6%, and 23.3%; p < 0.001). This system could be an improvement on risk stratification based on staging and single parameters alone, but is limited by data from trials based on chemoimmunotherapy rather than the novel agents discussed below.

In summary, conventional chemoimmunotherapy combining an anti-CD20 antibody (rituximab, ofatumumab, or obinutuzumab) and chemotherapy (FC, bendamustine, or chlorambucil) is the standard of care in front-line CLL treatment, except for the subgroup with 17p-/*TP53*mut CLL.

Alemtuzumab-based regimens. Alemtuzumab is a humanized anti-CD52 monoclonal antibody effective against refractory CLL cells irrespective of 17p-/*TP53*mut.[31,32] However, in patients with 17p-/*TP53*mut relapsed/refractory CLL, alemtuzumab monotherapy achieves only a modest ORR of 39% to 60% and CRR of 0% to 20%, and median remission durations are short (6 to 8 months). The addition of high-dose corticosteroids to alemtuzumab for the treatment of patients with CLL with 17p- was tested in two studies. The U.K. CLL206 study administered alemtuzumab and methylprednisolone to 39 patients.[33] The German/French CLL2O study treated 131 patients with fludarabine-refractory or 17p- CLL (front-line use in 42 patients with 17p-, 28 with relapsed 17p- disease) with alemtuzumab and dexamethasone followed by ASCT or maintenance alemtuzumab.[21] Among patients with 17p- CLL who received front-line therapy, ORR from the two studies were encouraging at 88% to 97%. In the CLL206 study, the CRR was very high at 65%, but remissions were only moderately durable with a median PFS of 18 months. In contrast, remissions in the CLL2O study were more durable with a median 33 months, with the key difference being the use of postinduction therapies. The overall result (considering both front-line and patients whose disease relapsed) from CLL2O showed that ASCT was superior to maintenance alemtuzumab as postinduction therapy, with approximately 50% of transplanted patients remaining free of disease beyond 3 years. As a result of the inferior risk/benefit ratio of alemtuzumab compared with novel agents (see below) and the withdrawal of alemtuzumab from the market, these regimens have a limited role in the current management of CLL. However, the results of these studies provide a historic benchmark to compare efficacy data from phase II trials of novel agents in 17p-/*TP53*mut CLL.

The role of ASCT. There is unequivocal evidence that reduced intensity conditioning (RIC) ASCT is effective therapy in CLL, and can result in prolonged disease-free survival even for patients with advanced, chemotherapy-refractory disease.[34-39] Patients with CLL with 17p-/*TP53*mut have shown equivalent outcomes in these studies with approximately 40% to 50% of patients achieving sustained long-term remission and possibly cure, although the substantial morbidity and about 20% mortality rate restricts the use of this therapy. Factors associated with inferior outcomes included more than three prior treatment regimens, advanced clinical stage, and refractory disease at the time of RIC ASCT. Thus, RIC ASCT should be considered earlier in the course of CLL when therapeutic options for remission induction still exist, and is preferably performed in patients with low disease burden. In the chemoimmunotherapy era, consolidation with RIC ASCT would have been considered for all fit patients with CLL with early (within 24 to 36 months) relapsed or refractory disease, as well as 17p-/*TP53*mut as a component of initial treatment. The availability of more effective therapy for relapsed/refractory CLL has altered this strategy as detailed in a recent ERIC/EBMT consensus paper, which concluded that there are now few indications for RIC ASCT in the initial therapy of patients with CLL.[40] Even in early relapse and for patients with 17p-/*TP53*mut CLL, there is no universal indication for RIC ASCT and a careful consideration of the risk profile must be performed including genetics (17p-/*TP53*mut, 11q-), age, comorbidities, and degree of donor matching. To facilitate this, immediate referral of patients with early relapse and/or undergoing initial therapy for 17p-/*TP53*mut CLL to a transplant center for evaluation and counseling is recommended.

Novel Agents Targeting BCR Signaling and BCL2 in the Management of 17P/*TP53*mut CLL

The two major classes of novel agents with substantial activity across all genomic subgroups of CLL are the BCR signaling inhibitors[41-43] and the BCL2 antagonists.[44] These drugs are orally bioavailable and show dramatic efficacy and favorable tolerability compared with chemoimmunotherapy (see Relapsed/Refractory CLL below). In contrast to chemotherapy, these drugs are not genotoxic and are therefore active in patients with p53 dysregulation (i.e., 17p-/*TP53*mut). Over 200 patients with relapsed/refractory CLL with 17p-/*TP53*mut have been treated with ibrutinib monotherapy across three clinical trials[41,45,46] with excellent results compared with historic controls treated with chemoimmunotherapy. Over 80% of these patients achieved objective responses (including partial response with persistent lymphocytosis) with 12-month PFS of approximately 80% and projected 24-month PFS of approximately 50% to 60%. However, CRs were rare (< 5%), and in one study patients with 17p- CLL had a substantial increase in relapse rates com-

pared with patients without 17p- CLL.[41] In addition, the efficacy of idelalisib/rituximab appeared to not be impacted by 17p-/*TP53*mut in a retrospective subgroup analysis,[47] suggesting that this regimen is another treatment option for this subgroup.

Whereas the BCR antagonists very rarely achieve CR in the relapsed/refractory setting, the results may be different when these drugs are used as front-line therapy. For example, two CRs were recorded in the four treatment-naive patients with 17p- CLL enrolled in the ibrutinib/rituximab study,[48] and in a study of front-line idelalisib and rituximab, ORR and CRR of 100% and 33%, respectively, were reported in nine patients with 17p- CLL.[49] Prospective studies of these agents in the front-line setting are currently underway. Notably, both the U.S. Food and Drug Administration (FDA) and European Medicines Agency have granted approval of ibrutinib and the European Medicine Agency has approved idelalisib/rituximab for the up-front treatment of patients with 17p-/*TP53*mut, clearly underlining the dramatically superior efficacy of these agents in these patients. However, there are data that suggest that resistance to novel agents may be related to genomic instability of the CLL clone, resulting in either development of diffuse large B-cell lymphoma (DLBCL; Richter transformation) or acquired resistance to ibrutinib (see below).[50,51] These observations suggest that patients with 17p-/*TP53*mut CLL, which is associated with a high degree of genomic instability, could still benefit from ASCT.

The antiapoptotic members of the BCL2 family are targeted by BH3-mimetics (ABT-737, ABT-263, and ABT-199).[44,52] The current drug in clinical development for CLL is venetoclax (ABT-199, GDC-0199), which is a specific inhibitor of BCL2 and does not cause BCLXL inhibition–related thrombocytopenia.[45] The results of venetoclax in CLL have been presented in abstract form.[51,53] Both as single-agent and in combination with rituximab, venetoclax achieved high response rates of approximately 80%, and importantly—and differently from the results of BCR antagonists— complete remission rates of approximately 25% were reported even in the relapsed/refractory 17p- setting.[51,53] A number of patients have become negative for minimal residual disease (MRD) following venetoclax (with or without rituximab) therapy, and five have discontinued venetoclax in remission without recurrent disease at early follow-up. A pivotal phase II study of venetoclax in 17p- CLL (front-line and relapsed/refractory) is currently underway.

MANAGEMENT OF RELAPSED/REFRACTORY CLL
BCR Inhibitors

The importance of the BCR pathway in the pathogenesis of CLL is exemplified by the use of stereotypic immunoglobulin variable regions, biased *VH* gene family usage, prognostic implications of mutational status, and the profound clinical efficacy of the BCR pathway inhibitors in CLL (reviewed in Jones[43] and Stevenson[54]). As a result of their novel mechanisms of action, BCR antagonists have required a re-evaluation of several key aspects of our management practices in CLL. First,

the initial lymphocytosis seen with these agents would be considered progressive disease based on the standard IWCLL criteria.[1] This lymphocytosis likely results from the inhibition of several adhesion molecule pathways, including CXCR4/5, and could contribute to the efficacy of these agents.[55,56] Fortunately, the lymphocytosis is usually accompanied by a very rapid decrease in lymphadenopathy, and improvement in cytopenias and symptoms. As a result, the IWCLL criteria have been revised by a group sponsored by the Lymphoma Research Foundation[57] to exclude use of lymphocytosis as the sole indicator of progression in patients who are receiving treatment with a BCR antagonist. This new response category has been termed "PR with lymphocytosis."

Second, maximal response is often measured shortly after the completion of therapy. The German CLL Study Group validated the prognostic effect of measuring MRD 2 months after completion of cycle six in the CLL8 study.[18,58] For the BCR signaling pathway inhibitors, responses evolved over time[41] and treatment is often ongoing. Patients receiving treatment typically move from stable disease (or partial response with lymphocytosis) to partial response when the lymphocytosis resolves, to CR. Although we know the median time to response to treatment, the median time to CR has not yet been determined because half of the population has not yet achieved CR or had progressive disease. In addition, although we can assume that negative MRD studies will predict for an excellent outcome, the presence of MRD can no longer be seen as indicative of a poor response. Thus, comparison of responses to therapy with BCR signaling inhibitors to chemoimmunotherapy in clinical trials should not use the previously used conventional endpoints of partial response, CR, and MRD status, but should rather focus on PFS and OS.

The third issue to re-evaluate is the role of prognostic markers. Although the prognostic markers commonly used in clinical practice (CD38, ZAP70, *IGHV* mutation status, and interphase FISH) retain their predictive value for time to treatment, they do not predict response to treatment with BCR antagonists.[41,42] It is also worth noting that in the first publication of the phase II data on ibrutinib therapy in CLL,[41] patients with mutated *IGHV* were reported to have poorer responses. However, analysis at a later time point showed no difference in response rates based on *IGHV* mutation status.[59] The initial difference could have been because the CLL cells in patients with unmutated *IGHV* were more dependent on BCR signaling, and therefore more sensitive to its inhibition. With regard to possible predictors of resistance developing to ibrutinib, complex karyotype and a "mutator phenotype" might predict for the development of resistance. Resistance to ibrutinib has been shown to occur because of a single base pair mutation resulting in a cysteine-to-serine change at amino acid 481 in BTK that alters the ibrutinib binding site, or gain-of-function mutations in the *PLCγ2* gene that overcome the inhibition of BTK.[50,60] These data alter the role of use of prognostic factors in treatment planning for patients with CLL. Important considerations include the role of ASCT and the ability to avoid DNA-damaging drugs that

could be associated with the increased risk of secondary myeloid neoplasms[61] and other second malignancies (see below).

Ibrutinib therapy. Ibrutinib was the first BCR pathway inhibitor approved for treatment in CLL. The phase I study demonstrated a wide therapeutic window, with all patients who were treated with doses of ibrutinib greater than 2.5 mg/kg demonstrating complete inhibition of BTK at 4 hours. Two subsequent phase II studies used a fixed dose of ibrutinib of 420 mg/day. Patients with relapsed/refractory CLL study who received ibrutinib experienced a 90% ORR. Response were durable and the median PFS had not been reached at a median follow-up of 35.2 months, with an estimated PFS of 69% at 30 months.[41,59] In the study of initial therapy of previously untreated CLL patients with progressive disease over the age of 65, the ORR including partial response with lymphocytosis was 84%, with an estimated PFS of 96% at 30 months. Of the 31 patients enrolled in this study, three discontinued treatment for adverse events, two patients withdrew consent, and one patient demonstrated progressive disease in the form of a Richter transformation that was diagnosed at month 8.

Overall, treatment with ibrutinib was well tolerated, with the most common adverse events reported being transient diarrhea (58%), fatigue (28%), infections (32%), and bleeding (61%). The diarrhea appeared to be transient with a median duration of 20 days and was only severe ($\geq$ grade 3) in 6% of patients. Diarrhea was controllable in most patients with antimotility agents and only led to treatment discontinuation in one patient, and ibrutinib dose reductions in two patients. The frequency of severe infections was considerably higher in patients with relapsed/refractory disease compared with previously untreated patients (51% vs. 13%). In addition, the frequency of severe infections was highest in the first year of treatment and then decreased in subsequent years for both relapsed/refractory (36%, 32%, and 24%) and previously untreated (10%, 8%, and 4%) disease. Long-term ibrutinib therapy did not appear to increase the risk of infection in these patients.[41,59,62] Bleeding was reported in 61% of CLL patients treated with ibrutinib and was severe in 8% with one death. Bleeding resulted in treatment discontinuation in three patients. In these studies, 58% of patients were receiving antiplatelet agents and 22% were receiving anticoagulants.[41,59,62]

An obvious shortcoming in when evaluating phase II data is the lack of a control population to assess what would be the expected adverse events in the population being studied. When ibrutinib was compared to ofatumumab in the RESONATE study, several important findings related to adverse events were noted. First, fatigue was seen in equal numbers in both arms (28% ibrutinib vs. 30% ofatumumab). Second, severe infections were seen in similar numbers in both arms (24% ibrutinib vs. 22% ofatumumab). Third, atrial fibrillation, an adverse event not previously attributed to ibrutinib in phase II trials, was found to occur more frequently in patients treated with ibrutinib compared with ofatumumab (4% ibrutinib vs. 1% ofatumumab). Whether atrial fibrillation is associated with ibrutinib treatment will require

subsequent phase III trials to ascertain, but for now, clinicians might consider cardiac risks when making treatment decisions.

Data for ibrutinib in patients with 17p- CLL are derived from three studies.[46,49,63,64] In the pivotal RESONATE study, 127 of the 391 patients had 17p-. The overall response rate, excluding partial response with lymphocytosis, was 47.6% with ibrutinib, compared with 4.7% with ofatumumab. The median PFS for ibrutinib was not reached compared with 5.8 months for ofatumumab. In patients who received ibrutinib, 83% with 17p- were progression-free at 6 months. There was no difference in response rate or PFS based on the presence or absence of 17p-.[46] An NIH phase II study of 51 patients with *TP53* aberrations demonstrated a 97% response rate in previously untreated patients, with a 91% PFS at 24 months (35 patients), and an 80% response rate in previously treated patients, with an 80% PFS at 24 months (16 patients). The third study, RESONATE-17, involved 144 patients with CLL with 17p- whose disease had relapsed or was refractory to one prior therapy. The overall response rate was 82.6%, with a PFS at 12 months of 79.3%. Progressive disease occurred in 20 patients (13.9%), including Richter transformation in 11 patients, seven of which occurred within the first 24 weeks of treatment.[49,64] These data suggest that treatment of patients with relapsed/refractory CLL and 17p-/*TP53*mut using ibrutinib results in better outcomes than that achieved with any previously used therapies.

Idelalisib therapy. Idelalisib, which targets PI3K-delta, demonstrated excellent efficacy and tolerability in patients with relapsed/refractory CLL. Across its phase I/II studies, idelalisib used as a single agent resulted in a 72% response rate with a median PFS of 15.8 months[65] in a high- to very high-risk relapsed/refractory CLL population (70% treatment-refractory, 24% 17p-/*TP53*mut). Severe adverse events included diarrhea/colitis (5.6%), transaminitis (1.9%), and pneumonia (20.4%).

Idelalisib's pivotal phase III study was conducted in a heavily pretreated population of patients considered unlikely to benefit from chemotherapy because of a previous response duration of less than 2 years who had additional comorbidities (persistent myelosuppression or creatinine clearance < 60 mL/min).[42] Two-hundred and twenty patients were randomly assigned to receive rituximab/placebo or rituximab/idelalisib (150 mg twice daily). The patient population had a median CIRS score of eight, median creatinine clearance of 64.5 mL/min, and 43.5% had 17p-. The study met its primary endpoint at the first interim analysis with an 85% reduction in the risk of progression or death between the two arms (median PFS, 5.5 months for placebo vs. not reached for idelalisib) and a substantial improvement in OS (survival at 12 months of 80% for placebo vs. 92% for idelalisib). A subsequent update after the second interim analysis demonstrated a 12-month PFS for the idelalisib/rituximab arm of 66% compared with 13% for the placebo/rituximab arm.[47] PFS and response rates were not affected by prognostic factors, including deletion 17p-/*TP53*mut, ZAP70 expression, or *IGHV* mutational status. Severe adverse events occurred in

40% compared with 35% of patients for idelalisib or placebo, respectively. Severe adverse events of note for idelalisib compared with placebo included diarrhea (19% vs. 14%), pneumonia (6% vs 8%), and transaminitis (35% vs. 19%). The risk of rituximab infusion reactions decreased with idelalisib compared with placebo (15% vs. 28%).

BCR inhibitor therapy. The studies detailed above have clearly demonstrated the effectiveness of ibrutinib and idelalisib as treatments for CLL patients. The FDA approvals for these agents reflects the populations studied in the clinical trials; ibrutinib has been approved for the initial therapy of CLL in patients with 17p- and for all patients with relapsed/refractory disease, and idelalisib has been approved for use in combination with rituximab for patients who are considered candidates for treatment with single-agent rituximab. Choice of the best BCR antagonists for an individual patient should currently be based on the toxicity profiles of ibrutinib and idelalisib. For ibrutinib, the risks of bleeding, diarrhea, atrial fibrillation, and drug interactions affecting CYP3A4 are the most worrisome. Idelalisib can cause liver injury, inflammatory colitis, and pneumonitis, and should be avoided in patients with hepatic dysfunction or autoimmune diseases.

The optimal duration of therapy with BCR has not yet been determined. Because these therapies are effective and relatively well tolerated, it could be reasonable to continue treatment. However, we do not yet know the long-term effects of continuing therapy and conversely have little data on the mechanisms of resistance and how development of resistance may be affected by stopping treatment. Studies are currently underway looking at discontinuing therapy once patients reach MRD negativity. Until the data from these studies are available, it is prudent to continue patients on therapy indefinitely.

COMPLICATIONS OF CLL

Acquired immune defects occur early in the course of CLL and increase the risk of infection and autoimmune disease. Defective immune surveillance could also contribute to the increased risk of second malignancy. In addition, clonal evolution can cause transformation to DLBCL.

Infections

Patients with CLL have a high risk of serious infection, which causes considerable morbidity and mortality.[66] Defective nonmalignant B-cell function impairs humoral responses to antigens, and although absolute T-cell counts are usually increased, CD4/CD8 ratios are reversed with decreased T-cell receptor repertoire, and impaired T-cell function.[66-68] Monocyte, dendritic, and natural killer cell dysfunction, decreased serum complement levels, and bone marrow failure–associated neutropenia result in defective innate immunity.[66,69-71] Immune dysfunction is further impaired by chemotherapy and monoclonal antibody therapy.

Clinical. Impaired humoral immunity increases the risk of bacterial infections by encapsulated organisms (e.g., *Streptococcus pneumoniae* and *Staphylococcus aureus*) in all stages of CLL.[66,68,72] T-cell defects increase the risk of herpesvirus reactivations. The clinical consequences include shingles (frequently complicated by postherpetic neuralgia), disseminated varicella zoster, herpes simplex infections (including lymphadenitis), and cytomegalovirus-induced disease.[66,73-75] The risk of herpesvirus reactivation is increased by treatment with lymphotoxic drugs (e.g., purine analogs, corticosteroids, and alemtuzumab) that can cause prolonged T-cell lymphopenia. Patients with advanced-stage CLL and those undergoing immunosuppressive therapy or ASCT are at high risk of contracting fungal and atypical bacterial infections. Major concerns are *Pneumocystis jiroveci* pneumonia, cryptococcal meningitis, and systemic histoplasma, *Aspergillus*, *Nocardia*, *Candida*, and atypical Mycobacteria infections.[66]

Prevention. Active monitoring and treatment of patients with CLL can decrease the risk of serious infections and their complications. Patient education is essential and should emphasize the need for immediate medical evaluation of systemic infections and fevers at 38.5°C or higher. Vaccination efficacy is suboptimal in patients with CLL.[66,76,77] Pneumococcal vaccine responses are improved by the use of the conjugated 13-valent vaccine, and additional use of the 23-valent polysaccharide pneumococcal vaccine, as well as the influenza vaccine, could be of value, especially in patients with early-stage CLL.[76,77] Live vaccines (e.g., shingles and yellow fever) are contraindicated.[66,73]

There are limited data on the efficacy of the use of prophylactic antimicrobial therapy in CLL.[66] *Pneumocystis* and herpesvirus prophylaxis is commonly used during and for 3 to 6 months after treatment with purine analog–containing chemoimmunotherapy, alemtuzumab, and high-dose corticosteroids.[73] Prophylactic antiviral therapy can decrease the risk of recurrent varicella zoster and herpes simplex infection in patients with recurrent infections.[73]

Intravenous immunoglobulin (IVIG) can normalize serum IgG levels and decrease the risk of infections but has not been shown to improve survival.[66,78] IVIG therapy can cause serious toxicities and is time consuming and expensive. Use should probably be limited to patients with recurrent major infections (two or more in 6 months).

Effective management of established infections in patients with CLL requires a vigorous effort to determine the cause of infection with a high index of suspicion for encapsulated bacteria, atypical, and opportunistic infections. Therapy planning should assume that all CLL patients are immunocompromised.

Hematologic Autoimmune Disease

Patients with CLL have an approximate 5% to 10% lifetime risk of hematologic autoimmune complications,[79-81] but CLL related nonhematologic autoimmune complications are rare.[82]

In most (> 90%) patients with CLL and autoimmune cytopenia, loss of immune self-tolerance results in the produc-

tion by nonmalignant B cells of pathologic high affinity polyclonal IgG antibodies directed against blood cell antigens.[81] Self-reactive monoclonal antibody production by CLL cells (usually IgM) causes less than 10% of autoimmune hemolytic anemia (AIHA) in patients with CLL.[81] Pure red blood cell aplasia (PRCA) can be mediated by either pathologic autoantibodies or T-cell dysfunction. Autoimmune cytopenias can occur at any time in the course of CLL and are the cause of approximately 15% to 20% of noniatrogenic cytopenias in patients with CLL.[79-81] Onset can be acute or insidious. Patients with CLL should not be classified as advanced-stage disease because of their autoimmune cytopenia.[1,79-81]

AIHA: clinical. AIHA is the most common autoimmune complication of CLL and is characterized by reticulocytosis in the absence of bleeding, elevated lactate dehydrogenase and indirect bilirubin, and a positive direct antiglobulin test (DAT).[79] DAT tests detecting red blood cell (RBC)–bound anti-RBC IgG antibodies and the complement degradation product C3 are positive in over 90% of patients with CLL and AIHA. However, approximately 15% to 20% of all patients with CLL have a positive DAT during the course of their disease and only about 35% of these patients develop AIHA. The diagnosis of AIHA thus requires definitive evidence of hemolysis.[83,84] Patients with CLL with both AIHA and CLL-related bone marrow failure (complex AIHA) often do not have a reticulocytosis. These patients require a diagnostic bone marrow biopsy to ensure an accurate diagnosis of the cause of their cytopenia and thus appropriate treatment.

AIHA: management. Patients with AIHA and adequate erythropoiesis (simple AIHA) usually respond to immunosuppression with corticosteroids.[81] More rapid responses can be obtained with IVIG.[81] However, responses are not usually sustained when immunosuppression is decreased and patients frequently require long-term immunosuppression or additional treatment such as anti-CD20 monoclonal antibodies.[81] Patients with both AIHA- and CLL-related bone marrow failure require therapy that treats both their CLL and autoimmune complication. Purine analogs should be used with caution because myelosuppression can exacerbate the anemia and the risk that monotherapy can precipitate autoimmune complications of CLL. Combination therapies including alkylating agents (cyclophosphamide or bendamustine), corticosteroids, and anti-CD20 monoclonal antibodies are usually effective.[85,86] There is preliminary data that therapy with B cell receptor pathway inhibitors could be effective. Splenectomy is of limited value.

ITP: clinical. Patients with CLL with cytopenia caused by progressive bone marrow failure usually develop anemia followed by thrombocytopenia.[2] Patients with CLL who have thrombocytopenia without anemia should be evaluated for etiologies other than bone marrow failure including increased platelet sequestration. Those with insidious onset thrombocytopenia and platelet counts greater than 50×10^9/L should be evaluated for hypersplenism. Acute onset (<

2 weeks) or more severe thrombocytopenia (platelet counts $< 50 \times 10^9$/L) in patients with CLL is more likely to be caused by ITP, which still remains a diagnosis of exclusion. Antiplatelet antibodies have low specificity and sensitivity and are of limited diagnostic value.[81] The diagnosis of ITP thus requires a bone marrow biopsy to exclude other potential etiologies and demonstrate adequate megakaryocytopoiesis.

ITP: management. Patients with stable ITP without bleeding complications and platelet counts above approximately 20 to 30×10^9/L should be carefully observed and educated, but do not require treatment.[81] Patients with CLL and ITP without evidence of bone marrow failure should be treated with immunosuppression with the addition of thrombopoietin agonists if required. Splenectomy is less effective compared with primary ITP.[81] Patients with both ITP and bone marrow failure can be treated with the same regimens used to manage complex AIHA except that BTK inhibitors (e.g., ibrutinib) that affect platelet function and increase the risk of bleeding should be avoided.

PRCA: clinical. PRCA usually presents as progressive anemia with a very low absolute reticulocyte count and no evidence of hemolysis.[81] Definitive diagnosis requires a bone marrow study. The differential diagnosis includes parvovirus and other viral infections. Clinical testing for pathologic antibodies or T cells is not routinely available.

PRCA: management. PRCA responds slowly to immunosuppression (e.g., prednisone and cyclosporine) because of the lag time to restoration of erythropoiesis. Long-term immunosuppression (e.g., low dose cyclosporine) is frequently required to maintain adequate hematopoietic levels.[81,87]

Autoimmune neutropenia. This is a rare and poorly understood condition which should be considered in the differential diagnosis of patients with isolated neutropenia of uncertain etiology.[81,87]

Nonhematologic Autoimmune Disease

Patients with CLL have an increased risk of autoimmune acquired angioedema, paraneoplastic pemphigus, and glomerulonephritis.[74,82] A clinically important consequence of immune dysregulation in CLL is exaggerated cutaneous arthropod bite reactions.[74] These can be complicated by cellulitis and systemic infections.

Hematologic Second Malignancies

Lymphoid malignancies. Patients with CLL have an increased risk of second lymphoid malignancies.[88] The highest risk is for DLBCL (approximately 0.5% per year). DLBCL can occur at any time in the course of CLL and is more frequent in patients with *NOTCH1* mutations and 17p-/*TP53*mut.[89,90] The most common etiology of DLBCL (about 80%) is clonal transformation of a CLL cell and these patients have a poor

prognosis.[91] In contrast, approximately 20% of patients with CLL have clonally-unrelated DLBCL, which has a considerably better prognosis.[91] This clinically important distinction between clonally-related and -unrelated DLBCL can be made by *VDJ* rearrangement analysis of CLL and DLBCL cells.[91] Patients with CLL are also at an increased risk of developing Hodgkin lymphoma and other B-cell malignancies.

There is no standard of care for second lymphomas in patients with CLL. Patients with nonclonal DLBCL should be treated as having de novo disease.

Nonhematologic Second Malignancies

Skin cancer. Patients with CLL have a markedly increased risk of skin malignancies. Squamous cell carcinoma and basal cell carcinoma rates are increased by approximately 5- to 10-fold and these malignancies are more likely to be locally aggressive and metastatic.[74,92-94] Melanoma is also more common and aggressive with poorer outcome.[88,92,93,95]

Patients require education on avoidance of ultraviolet radiation and should be evaluated by a dermatologist at diagnosis and then at least annually. Patients and families need to be educated on how to conduct monthly skin inspections.

Other malignancies. Noncutaneous second malignancies are a major cause of morbidity and mortality in patients with CLL.[88,92,96,97] Patients should be encouraged to avoid smoking and excessive alcohol use, and to undergo routine preventative screening.

Prognostic Factors and the Role of Adjuvant Radiation Therapy in Non-Melanoma Skin Cancer of the Head and Neck

Sandro V. Porceddu, MD

OVERVIEW

Non-melanoma skin cancer (NMSC) is the most common cancer worldwide. Among the two types of NMSC, basal cell carcinoma (BCC) accounts for approximately 75% to 80% of cases and cutaneous squamous cell carcinoma (cSCC) accounts for 20% to 25% of cases. The majority of lesions are low risk and treated with simple surgical excision, which provides histopathologic information and is associated with high cure rates and acceptable cosmetic and functional outcomes. cSCCs are generally more aggressive than BCCs. NMSC commonly occurs in the sun-exposed head and neck region (80% to 90%). Approximately 5% of patients with NMSC (mainly cSCC) will have clinicopathologic features that predict for an increased risk for local and regional recurrence and, rarely, distant relapse. These features include locally advanced primary disease (stage T3-T4), regional nodal involvement, clinical perineural invasion, recurrent disease following treatment, and immunosuppression. Patients who have these features may warrant review by a multidisciplinary tumor board and might require combined modality treatment involving surgery and adjuvant radiation therapy (RT). This article focuses on our current understanding of the prognostic factors and role of adjuvant RT in high-risk NMSC of the head and neck.

Non-melanoma skin cancer is the most common cancer worldwide and represents a major global economic and health burden. Approximately 2.5 to 3.5 million individuals in the United States are diagnosed with an NMSC each year, with approximately 75% to 80% of diagnoses consisting of BCC and 20% to 25% consisting of cSCC.[1,2] The sun-exposed head and neck is the most common region affected (80%) with incidence rates continuing to rise.[2] Australia, which has the highest skin cancer rates in the world, has an age-standardized incidence rate of 387 cases per 100,000 individuals for cSCC and 884 cases per 100,000 individuals for BCC.[3] cSCC tends to be more aggressive than BCC.

The majority of patients with NMSC (95%) are at low risk for relapse and are typically treated with simple excision or, less commonly, with RT where surgery is not preferred. However, up to 5% of patients (mainly with cSCC) may harbor clinicopathologic high-risk features predicting for an increased risk for local and regional (locoregional) recurrence, or, rarely, distant relapse and death.[2] Factors that predict for high-risk disease include locally advanced disease (American Joint Committee on Cancer [AJCC] and Union for International Cancer Control [UICC] stages T3-T4), regional nodal involvement, clinical perineural invasion (cPNI), recurrent disease following treatment, and immunosuppression. Patients who have disease with these characteristics often warrant review by a multidisciplinary tumor board and treat-

ment with combined-modality therapy consisting of surgery and adjuvant RT.

This article will primarily focus on our current understanding of the prognostic factors in NMSC, the management of high-risk disease, and the role of adjuvant RT. The article will not discuss low-risk disease, the role of definitive or palliative RT, or the role of other treatment modalities beyond adjuvant RT.

PROGNOSTIC FACTORS
Clinicopathologic Factors
Studies have identified a number of adverse clinicopathologic prognostic factors that predict for recurrence in NMSC. The majority of recurrences tend to occur within 2 years of the initial primary diagnosis.[4] BCC and cSCC generally share the same risk factors for locoregional recurrence, although regional recurrences in BCC seldom occur. Many of the factors that predict for local recurrence in both BCC and cSCC also tend to predict for regional nodal involvement or relapse. In BCC, the development of distant metastases is rare ($\leq$ 1%).[4,5,6] Division into low- and high-risk categories for NMSC is somewhat arbitrary since the disease falls on a continuous spectrum, as determined from retrospective series reports that found different prognostic factors between published series.

A review by Alam and Ratner reported that the risk for local recurrence and metastases for cSCC increases in the presence of factors such as rapid growth, greater than 2 cm diameter, primary site of lip or ear, immunosuppression, previous RT, recurrence, greater than 4 mm thickness or Clark level IV, poor differentiation, infiltrative or peripheral margins, spindle or acantholytic features, and perineural invasion (PNI).[2]

Brantsch et al published the results of a prospective study assessing the risk factors for recurrence and regional metastases in cSCC. They reported that patients with a tumor thickness of 2.0 mm or smaller did not develop metastases. Metastases occurred at a rate of 4% among patients with tumors between 2.1 to 6.0 mm and 16% for tumors larger than 6.0 mm. The risk for local recurrence depended on increasing tumor thickness and desmoplasia.[5]

The National Comprehensive Cancer Network (NCCN) has produced a table detailing high- and low-risk factors for recurrence of BCC and cSCC based on a combination of available evidence and workshop group consensus.[6]

Clayman et al identified several factors that reduce disease-specific survival (DSS) in patients with cSCC. These factors include local recurrence at presentation, increasing tumor size and depth, invasion beyond subcutaneous tissues, and PNI. Patients with one or more risk factors, when compared with patients with no risk factors, had a significantly inferior 3-year DSS of 70% vs. 100%, respectively (p < 0.001, log-rank test).[7]

PNI, immunosuppression, and regional nodal involvement are well-recognized prognostic risk factors for LRC and distant relapse, and are discussed in greater detail below.

Table 1 summarizes the commonly accepted prognostic risk factors in NMSC of the head and neck.

KEY POINTS

- Non-melanoma skin cancer (NMSC) is the most common cancer worldwide. Approximately 75% to 80% of cases are basal cell carcinoma and 20% to 25% of cases are cutaneous squamous cell carcinoma.
- Division into low- and high-risk NMSC is somewhat arbitrary since disease type falls on a continuous spectrum, as data from retrospective series have shown.
- Approximately 5% of patients with NMSC (mainly cutaneous squamous cell carcinoma) are considered to be at high risk for relapse, either local, regional, or distant (rarely), following surgery.
- Because of the dearth of high-level evidence on the benefits of adjuvant radiation therapy (RT), there is a lack of universally adopted guidelines regarding its use. Use of adjuvant RT is commonly based on individual institutional policy.
- Retrospective series support consideration of adjuvant RT in the presence of advanced primary disease (stages T3-T4), regional nodal involvement, clinical perineural invasion (cPNI) and immunosuppression.

TABLE 1. Prognostic Risk Factors for Relapse of NMSC of the Head and Neck

Risk Factors	Low Risk	High Risk
Tumor size and T-stage (AJCC/UICC)	≤ 2 cm	> 2 cm
	T1-2	Stages T3-T4
Tumor thickness (SCC)	< 2 mm	≥ 2 mm
		Clark level ≥ 4
Sites		Lip, mask areas of face
Differentiation	Well	Poor
Subtype (SCC)		Basosquamous, desmoplastic, adenosquamous
Perineural invasion	Absent or single small nerve	Multifocal small nerve, named nerve
Rapid growth	Absent	Present
Borders	Well-defined	Poorly defined, in-transit
Lymphovascular space invasion	Absent	Present
Margin status	Negative	Positive
Immune status		Immunosuppressed
Chronic inflammation, scars (SCC)	Absent	Present
Previous radiation therapy	Absent	Present
Nevoid basal cell carcinoma syndrome* (BCC)	Present	Absent
Recurrent disease	No	Yes

Abbreviations: NMSC, non-melanoma skin cancer; AJCC, American Joint Committee on Cancer; UICC, Union for International Cancer Control; SCC, squamous cell carcinoma; BCC, basal cell carcinoma.
*Also known as Gorlin syndrome.

Perineural Invasion

PNI can be divided into two categories: (1) disease detected incidentally on pathologic assessment (pPNI) and (2) involving a named nerve (cPNI). For patients with cPNI, a prior history of pPNI is not always present.

PNI is more frequently seen in patients with cSCC (5% to 10%) than in patients with BCC (2% to 5%).[8,9] In the case of cPNI, the Trigeminal (V) and Facial (VII) cranial nerves (CN) are commonly affected, typically involving retrograde progression (progression of disease from the periphery (skin) toward the brain/brainstem). Diagnosis may be delayed with VII CN involvement because of an initial misdiagnosis of Bell's palsy. Diagnosis can be facilitated with the use of targeted 3 Tesla MRI neurography, which provides superior sensitivity and specificity compared with computed tomography (CT).[10]

There is some evidence that extratumoral disease (PNI seen extending beyond the main tumor mass), large nerve diameter involvement, and multifocal PNI are associated with more aggressive disease behavior.[8,11]

cPNI is more aggressive when seen in cSCC compared with BCC. Jackson et al reported 5-year local control (LC) rates of 90% for pPNI compared with 57% for cPNI (p < 0.0001). The pPNI and cPNI groups also differed in relapse-free survival (76% vs. 46%, p = 0.003), DSS (90% vs. 76%, p = 0.002), and

overall survival (OS) (69% vs. 57%, p = 0.03). In a study of 55 patients, patients with pPNI with BCC histology had better LC rates compared with patients with pPNI with SCC histology (97% vs. 84%, p = 0.02).[12]

In a recent study of 114 patients with PNI, patients whose tumors met two criteria—greater than 2 cm and associated with other multiple unfavorable features (including lymphovascular invasion and deep invasion)—were at increased risk for death.[8] The authors suggested that patients with PNI of small caliber nerves (< 0.1 mm) and no other unfavorable risk factors are likely to have a better outcome. Further studies are required to better establish the interaction between PNI and other non-PNI prognostic risk factors.

IMMUNOSUPPRESSION

The importance of immunosuppression as a factor that increases the risk for both developing NMSC and experiencing poorer outcomes is well documented.[2,4] Patients with immunosuppression are more likely to develop regional nodal metastases, to be at greater risk for death, and to have tumors that exhibit higher rates of adverse risk features such as PNI.[2,13] In a study by Tomaszewski et al, 36% of patients with node-negative cSCC and chronic lymphocytic leukemia developed regional nodal recurrence, with disease-specific death reported for 33% of patients.[14]

REGIONAL NODAL METASTASES

The presence of primary disease with high-risk features, predominantly cSCC, increases the risk for regional nodal metastatic disease; the most common sites of regional involvement are intraparotid nodes, followed by cervical nodes.[15,16] The presence of regional nodal metastases is an adverse feature and predicts for inferior DSS and OS.[15,16,17,18] Depending on the extent of node disease, reported regional relapse rates following therapeutic surgery alone range between 20% and 80%.[16]

Although there is no universal consensus or high-level evidence to support the role of adjuvant RT following nodal surgery, research has identified a number of nodal metastatic prognostic factors that warrant consideration for combined modality treatment (these prognostic factors were identified mainly through retrospective series).[16] Table 2 presents a summary of these metastatic nodal prognostic factors. A study by Veness et al that examined the outcomes of patients with metastatic cSCC found that increasing nodal size (≥ 3 cm), multiple node involvement (≥ 2), and extranodal spread were associated with worse survival.[19] Another study, which reported on the outcomes of 250 patients with metastatic cSCC following treatment, found that the majority of recurrences (50 out of 70 patients; 73%) were regional and that several factors—immunosuppression, the presence of extranodal spread, and positive margins—were associated with inferior survival.[13]

Ebrahimi observed an excellent outcome in a subset of patients with one involved node, smaller than 3 cm in maximal

TABLE 2. Summary of Metastatic Nodal Prognostic Factors (High-Risk Nodal Disease) that Predict for Relapse after Treatment and Disease-Specific Survival

Prognostic Factor
> 3-cm node
≥ 2 nodes
Extracapsular extension
Positive/close margins (≤ 5 mm)
Dermal or in-transit metastases
Invasion into surrounding structures (e.g., bone, cranial nerves)
Recurrent disease after initial surgery
Immunosuppression

diameter, and no ECE. Three-year DSS in this patient subset was 97% following intraparotid and/or cervical node surgery alone.[20]

In addition, surgical series have shown that in the presence of intraparotid node disease, the risk for synchronous occult cervical node disease ranges between 15% and 45%, with range results between 15% and 20% reported in contemporary series that use modern imaging techniques; the data from the series justifies considering elective cervical nodal treatment for this group.[21]

TREATMENT

A number of guidelines recommend that complex and high-risk cases should be referred for consultation and management by a multidisciplinary tumor board. These cases may require the primary disease to undergo extensive resection with reconstructive surgery, elective or therapeutic nodal treatment, adjuvant RT, and close follow-up monitoring.[4,6] Table 3 summarizes the factors that might be considered for a referral to a multidisciplinary tumor board.

TABLE 3. Considerations for Referral to Multidisciplinary Tumor Board

Locally advanced primary disease (UICC/AJCC stages T3-T4) or in-transit disease
Difficulty obtaining complete margins
Clinical perineural nerve invasion
Cosmetic considerations
Immunosuppression
Suspected/confirmed lymph node metastases
Tumors in complex locations (lip, eyes)
Multiple primary lesions (e.g., nevoid basal cell carcinoma syndrome)
Distant metastases

Abbreviations: AJCC, American Joint Committee on Cancer; UICC, Union for International Cancer Control.

ADJUVANT RADIATION THERAPY

High-level randomized evidence confirming the benefit of adjuvant RT in advanced NMSC is lacking. NCCN clinical practice guidelines in oncology for NMSC acknowledge this fact, stating that its recommendations are based on low-level evidence (the evidence is in the 2A category, meaning there is uniform NCCN consensus that the intervention is appropriate).[6]

The use of adjuvant RT is based on data from retrospective studies (which are acknowledged to be inherently biased) that have shown that adjuvant RT reduces rates of recurrence when used in advanced disease, such as regional nodal metastatic cSCC.[13,15-18] There is a lack of universal guidelines that describe which adverse prognostic factors warrant adjuvant RT therapy and, therefore, the use of this therapy is typically based on institutional policy. The Trans Tasman Radiation Oncology Group has completed accrual to a randomized trial (TROG 05.01 NCT00193895) comparing the role of adjuvant concurrent chemoradiotherapy with the role of adjuvant RT in high-risk cSCC. High-risk disease was defined as and stratified into locally advanced primary disease (AJCC or UICC stage T3-T4 or in-transit disease) and high-risk nodal disease (defined as any of the following: extracapsular extension of any node size, intraparotid nodal metastasis regardless of size or number, two or more cervical nodes, and/or cervical node(s) that are 3 cm or larger). RT consisted of 60 Gy over 6 weeks, with 2 Gy fractions daily, with or without weekly carboplatin (AUC 2).

Table 4 summarizes indications where adjuvant RT may be considered. However, Table 4 does not include a number of other clinicopathologic prognostic factors for relapse, including lymphovascular invasion, rapid growth, and pPNI. These factors have been left out because there remains a question about the benefit of adjuvant RT in the presence of these factors and about the extent of disease where the benefit is seen.

ADJUVANT REGIONAL NODAL TREATMENT

Intraparotid and cervical nodes are the most common regional nodal basins involved in cSCC of the head and neck. Veness et al found that among patients whose cSCC had metastasized to lymph nodes, those who were receiving surgery/RT had a statistically superior 5-year disease free survival compared to patients receiving surgery alone (73% vs. 54%, respectively; p = 0.004).[18]

Unlike in mucosal head and neck SCC, the role of adjuvant chemoradiotherapy in high-risk disease is unknown. However, based on the NCCN guidelines and publications from Cooper et al and Bernier et al, some institutions have adopted the use of adjuvant chemoradiotherapy for high-risk disease, particularly in the presence of regional nodal metastatic SCC with extracapsular extension.[6,22,23] The TROG 05.01 (NCT00193895) is the only randomized trial currently examining the role of adjuvant chemoradiotherapy in high-risk cSCC, with results expected mid-2016.

ELECTIVE NODAL TREATMENT

Elective nodal treatment is often considered when the perceived risk for occult nodal involvement is around 15% to 20%. The risk for occult nodal involvement is based on the presence of high-risk clinicopathologic prognostic factors. In cases where regional nodal involvement is suspected, CT is typically used to stage the neck. However, the sensitivity and specificity of CT for nodal involvement is reduced when nodal diameter is smaller than 1 cm. Positron emission tomography (PET) appears to have a higher sensitivity and specificity than CT in the nodal staging of mucosal head and neck cancer.[24] It is likely that PET has a similar utility in cSCC, but this is yet to be confirmed in clinical studies.

Elective nodal treatment may consist of either elective nodal dissection, or, in cases where adjuvant RT is recommended for the primary site, the nodal basin may be treated electively with RT at the same time.

Although there is some evidence showing that sentinel lymph node biopsy may improve the detection of occult node disease, its routine use is not currently universally practiced.[25]

ADJUVANT PERINEURAL INVASION TREATMENT

The challenge in managing patients with cPNI is in achieving durable control. Despite the absence of randomized controlled studies, en bloc resection and adjuvant RT may offer select patients the best chance of cure. Tumors previously considered unresectable, such as those with intracranial PNI up to the gasserian ganglion (zone 2), may be operable and have the potential to improve patient survival.[26] However, this type of major surgery can require craniotomy, and thus is best limited to appropriately selected patients in specialized units. Furthermore, it is uncertain whether this type of surgery has substantially greater benefit compared with highly conformal intensity-modulated RT alone.[27,28] The role of elective nodal treatment and/or postoperative concurrent chemotherapy and RT in cPNI in the absence of other adverse risk factors remains inconclusive.

Gluck et al analyzed patterns of failure and proposed to include the following in the target volume: the portions of the

TABLE 4. Clinicopathologic Factors Indicating Consideration of Adjuvant Radiation Therapy*

UICC/AJCC stages T3-T4 or in-transit disease
Clinical perineural invasion
Recurrent primary disease
High-risk nodal disease
Immunosuppression

Abbreviations: AJCC, American Joint Committee on Cancer; UICC, Union for International Cancer Control.
*Postoperative radiation therapy is considered for sites where margins are incomplete or close (≤ 5 mm) and further surgery is not feasible or preferred.

nerve that are proximal and distal to the tumor site, skin that is innervated by the involved nerve, major communicating branches, and the compartment in which the nerve is embedded, such as the parotid gland for CN VII.[29]

ADJUVANT RADIATION THERAPY VOLUMES AND DOSES

The preferred minimum clinical target volume (CTV) margin on the resected primary tumor is 1.0 cm, although this may not always be possible depending on its proximity to organs at risk. For resected node disease, the preferred minimum CTV margin is 0.5 to 1.0 cm.

The doses used in adjuvant RT are similar to those used in mucosal head and neck cancer, and are not based on prospective data specific to NMSC. The NCCN guidelines provide recommendations on doses.[6]

Typically, it is recommended to give 60 Gy in 30 fractions over 6 weeks to the site of resected disease; for patients with smaller lesions, or in cases where shorter fractionation is preferred and optimal long-term cosmesis is not a clinical priority, there is the option of hypofractionated schedules, in which radiotherapy is given as a dose of 50 Gy in 20 fractions over 4 weeks or as 45 Gy in 15 fractions over 3 weeks. In the presence of positive microscopic margins, a dose of 66 Gy in 2 Gy fractions may be recommended.

For resected regional node disease in the presence of ECE, the NCCN guidelines recommend a dose of 60 Gy to 66 Gy in 30 to 33 fractions over 6.0 to 6.6 weeks; when ECE is not present, the guidelines recommend a dose of 56 Gy to 60 Gy in 28 to 30 fractions over 5.6 to 6 weeks.[6]

In the TROG 05.01 study, the recommended dose/fractionation to the surgically perturbed neck in the absence of disease was 54 Gy in 27 fractions over 5.5 weeks and, for the surgically unperturbed elective neck, the recommended dose/fractionation was 50 Gy in 25 fractions over 5 weeks.

CONCLUSION

Evidence, mainly from retrospective series, has identified adverse prognostic factors that predict for locoregional relapse in patients with NMSC; however, there is a lack of confirmatory prospective data examining the benefit of adjuvant RT in these patients. And although there is strong retrospective data supporting the role of adjuvant RT in high-risk disease—for example, in disease with metastatic regional nodal involvement—the data is less certain about the ways in which adverse features and the extent of disease should factor into the consideration of treatment with adjuvant RT. As a result of this uncertainty, the use of adjuvant RT in the treatment of NMSC is predominantly based on individual institutional policy. Further prospective studies in this area are warranted.

Disclosures of Potential Conflicts of Interest

The author(s) indicated no potential conflicts of interest.

Merkel Cell Carcinoma: Emerging Biology, Current Approaches, and Future Directions

Richard Tothill, PhD, Vanessa Estall, MD, BHB, MBChB, FRANCZR, and Danny Rischin, MBBS, MD, FRACP

OVERVIEW

Merkel cell carcinoma (MCC) is an aggressive neuroendocrine cutaneous cancer that predominantly occurs in patients who are older, and is associated with a high rate of distant failure and mortality. Current management strategies that incorporate surgery and radiotherapy achieve high rates of locoregional control, but distant failure rates remain problematic, highlighting the need for new effective systemic therapies. Chemotherapy can achieve high response rates of limited duration in the metastatic setting, but its role in definitive management remains unproven. Recent developments in our knowledge about the biology of MCC have led to the identification of new potential therapeutic targets and treatments. A key finding has been the discovery that a human polyomavirus may be a causative agent. However, emerging data suggests that MCC may actually be two distinct entities, viral-associated and viral-negative MCC, which is likely to have implications for the management of MCC in the future and for the development of new treatments. In this review, we discuss recent discoveries about the biology of MCC, current approaches to management, and new therapeutic strategies that are being investigated.

Merkel cell carcinoma is an uncommon neuroendocrine carcinoma that mostly arises in sun exposed areas, with the head and neck being the most frequent site. There is geographic variation in incidence with higher rates in Australia than in the United States.[1,2] It predominantly occurs in patients who are older, with onset occurring at a median age of 75 to 80, and it is more common in males.[1,2] Recognized risk factors are ultraviolet (UV) sunlight exposure and immunosuppression, and more recently, the Merkel polyomavirus (MCV) has been identified as a causative agent.[3]

Pathologically, MCC has features of a trabecular neuroendocrine carcinoma arising from Merkel cells, which act as sensory touch receptors in the basal layer of the epidermis.[4,5] A diagnosis of MCC from small cell lung cancer is challenging based on morphology alone, but can often be distinguished by the presence of CK20 and absence of TTF-1 with immunohistochemical (IHC) staining.[6] Approximately 15% of MCCs are diagnosed at the metastatic stage without evidence of a primary and appear to be associated with a better prognosis.[7] Heath et al have recently defined the clinical features that may serve as clues to the diagnosis, summarized by the acronym AEIOU: asymptomatic/lack of tenderness, expanding rapidly, immunosuppression, older than age 50, and UV exposed site on a fair-skinned person.[8]

BIOLOGY

Merkel Cell Polyoma Virus

A higher risk of developing MCC in patients who are immunosuppressed provided a strong impetus to search for a viral etiology in MCC. The search for viral sequences in tumors was subsequently enabled by the development of deep transcriptome sequencing, which led to the seminal discovery of the MCV in 2008.[3] Despite the now clear oncogenic role of the virus, MCV is likely to be part of normal skin flora, as viral DNA can frequently be detected at low levels in the normal skin of healthy individuals.[9] This is further supported by serologic studies showing that children can be infected by MCV from a very young age and that up to 80% of adults in North America have been exposed to the virus by age 50.[10] MCV is a double-stranded DNA virus that harbors large and small-T antigens (LT; ST) required for modulation of the host cell and viral replication. The oncogenic potential of MCV is thought to only occur on chance sequential events of clonal integration into the host genome and then acquisition of mutations in the 3′ end of the LT. Mutations in the LT truncate the C-terminus of the oncoprotein, disrupting the helicase domain, which renders the virus replication incompetent. This may be important for several reasons, but primarily to prevent cell death through inappropriate DNA replication at integration sites, which would lead to

replication-fork collisions and DNA-strand breakage.[11] Importantly, the mutation does not affect the functional ability of LT to sequester the retinoblastoma protein (RB), a cell cycle regulator and tumor suppressor that is frequently disrupted in cancer.

Continuous expression of T-antigens have been shown to be required for maintenance of MCV-positive cell lines.[12] However, unlike the related and intensively studied simian vacuolating virus 40 (SV40), the expression of MCV LT alone does not appear to be sufficient to transform cells, which is in contrast to the MCV ST, which has more potent oncogenic potential.[13] MCV ST has been shown to act downstream of mTOR in the PI3K/AKT/mTOR signaling pathway, preventing dephosphorylation of 4E-BP1, which regulates cap-dependent translation of mRNAs.[13] More recently, the MCV ST has been shown to bind to cellular FBXW7, which is a subunit of the SKP1/CULLIN1/F-box (SCF) protein ubiquitin ligase complex that negatively regulates the LT and other cellular proto-oncogenes such as cMYC and cyclin E.[14] A transgenic mouse harboring MCV ST driven by a bovine keratin 5 promoter has been recently described (K5-ST). Induction of K5-ST in adult mice resulted in epidermal transformation and squamous cell carcinoma in situ. The mice, however, failed to develop MCC, which indicates there is perhaps a requirement of both LT and ST expression or that targeted expression is required in an alternative Merkel cell precursor cell type. Development of an immunocompetent MCC animal model would be an invaluable research tool for the preclinical evaluation of novel therapies.

Viral-Negative MCC

In Europe, the United States, and Japan, the frequency of cases with MCV is variable, but generally thought to be approximately 80% of MCC tumors.[15] This still leaves a substantial fraction of viral-negative cases with a relatively unknown biology. Clues to the underlying origins of viral-negative tumors can be drawn from observations in different geographic regions. In Australia, the association of MCV infection with MCC appears to be much lower. Three independent studies from major Australian cities report a frequency of 18% to 24%,[15-17] with the exception being a study from Sydney reporting a similar frequency to that found in Germany (80%).[18] Variability in the reported prevalence of viral-associated MCC between studies has been attributed to the choice of the individual antibody used for IHC detection of viral LT expression in tumors.[19] However, the difference between studies in Australia and the Northern hemisphere would appear outside the expected variance between IHC assays. Furthermore, IHC and polymerase chain reaction detection of viral DNA have both been used in Australian studies and these assays have been shown to be mostly concordant.[20]

A higher prevalence of MCC in the Australian population with a predominance of viral-negative tumors suggests that excessive sun damage is likely key to the pathogenesis of the viral-negative subtype. Potential mechanisms explaining increased risk associated with sun damage could involve combined effects of localized immune suppression and the strong mutagenic effects of UV-mediated DNA damage.[21] A telling indicator of UV damage is the DNA mutation signature involving C to T transitions at dipyrimidine bases (i.e., CC to TT) frequently observed in skin cancers such as melanoma.[22] Importantly, these types of mutations have been identified in MCC tumors through sequencing the *TP53* tumor-suppressor gene.[23]

Further cumulative evidence to support the notion of two subtypes includes the histologic, clinical, and molecular differences that have been observed between viral and nonviral MCC. MCV-positive and -negative tumors have been reported to have specific morphologic differences.[24] Viral status has also been associated with different growth properties of the respective cell lines.[11] Gene expression profiling can also broadly cluster MCC tumors, which is predominantly driven by an elevated immune signature in the viral-positive group.[25] A poorer prognosis has been associated with viral-negative MCC in some studies, although this has not been consistently demonstrated in different patient cohorts.[17,18,26-29]

Genetic differences observed between MCC tumors based on viral status can be explained in part by the convergent, yet distinct mechanisms for disruption of common pathways. As previously mentioned, the tumor-suppressor protein RB is a key target of the polyoma virus LT.[30] Viral-negative tumors show low to absent protein expression of RB[20] and *RB1* copy number loss and loss-of-function mutations account for genetic disruption in a large proportion of viral-negative MCC tumors.[31-33] Pathogenic mutations in *TP53* and overexpression of the p53 protein (commonly associated with *TP53* mutation), also appear to be largely restricted to viral-negative tumors.[20] Curiously, unlike SV40, the MCV LT is not thought to directly regulate p53 and therefore may be altered through an indirect mechanism.[34] Oncogenic muta-

<div>

KEY POINTS

- Merkel cell carcinoma is an uncommon aggressive neuroendocrine cutaneous malignancy that predominantly occurs in patients who are older and is associated with a high rate of distant failure and death.
- Current management strategies that incorporate surgery and radiotherapy achieve high rates of locoregional control.
- Progress has been hampered by the lack of high-quality evidence, with current management strategies largely derived from retrospective studies.
- Merkel cell polyomavirus has been identified as a causative agent, but emerging data suggests MCC may be two distinct entities, viral-associated and viral-negative.
- Recent developments in our knowledge about the biology of Merkel cell carcinoma have led to the identification of new potential therapeutic targets and clinical trials investigating novel treatments including immunotherapeutic approaches.

</div>

tions in *PIK3CA* predominantly occur in viral-negative tumors, although most MCC cancers regardless of viral status show activated PI3K/AKT signaling and are responsive to PI3K and dual PI3K/mTOR inhibitors.[35,36]

Despite evidence for the aberrant expression of common oncogenic and tumor suppressor pathways in MCC, the search for somatic mutations in other known cancer genes has revealed few tangible leads to date.[37] Genome-wide copy number analysis has revealed recurrent large regions of chromosomal gain and loss with more alterations observed in viral-negative tumors.[31] Focal high-level amplification of 1p34 harboring the *MYCL1* oncogene is a striking feature in approximately 40% of MCC cases, highlighting an interesting molecular parallel to small cell lung cancer.

A general paucity of new cancer gene discoveries in MCC may reflect the focused interrogation of just a few genes and the small sample sets analyzed to date. Furthermore, given the already potent oncogenic potential of MCV, it is plausible that this disease subtype is genetically quite simple and does not require additional cooperative gene mutations. Focused interrogation of the viral-negative group, which is ostensibly driven by mutagenic effects of sun damage, could be more informative from a genetic perspective and it will be interesting to search for convergence involving mutations in genes targeted by viral LT and ST. A "genomic landscape" interrogation of MCC by massively parallel (next-generation) sequencing is therefore clearly required.

MANAGEMENT OF MCC

The main aim of current treatment strategies is to obtain locoregional control without inducing unnecessary toxicity. Cases should be managed in the context of a specialized multidisciplinary team to ensure care can be individualized and all potential treatment modalities considered.

Optimal management of MCC is a therapeutic challenge in part because of its rarity and lack of high-quality evidence to direct treatment. Although we can extrapolate management principles from other skin cancers, such as melanoma and squamous cell carcinoma, MCC differs importantly from these conditions by being extremely sensitive to radiotherapy.

Potential treatment paradigms have been published previously, are readily available, and include the 2015 National Comprehensive Cancer Network (NCCN) guidelines.[38] In this review, we highlight recent developments and some of the differences in approach to the management of MCC.

Staging

MCC is associated with high rates of early nodal and distant metastatic spread. Relapse in nodal stations reportedly occurs in up to 76% of cases[39-42] and is associated with a substantial reduction in survival.[43,44] Effective staging of nodal and distant metastatic disease at diagnosis is essen-

tial. Previously, this has been limited to diagnostic CT scanning, but in recent years other useful staging modalities have emerged.

PET. MCC exhibits high fludeoxyglucose (FDG) avidity on PET scanning,[45,46] permitting the detection of involved subcentimeter nodes that may not be appreciated on the initial CT.[47] Although there are no published multicenter, prospective studies evaluating FDG PET/CT in MCC, there are many retrospective, single-institution studies that have suggested that FDG PET may have a role, as most studies have found that PET changes stage and management in up to 30% of patients.[48-50] The largest study published to date from the Peter MacCallum Cancer Centre assessed 102 consecutive patients who were staged with PET/CT, which resulted in changed staging in 22% of patients and management in 37% of patients.[50] On multivariable analysis of prognostic factors, PET stage was associated with overall survival. In general, these studies were too small to report the positive and negative predictive value, but a recent systematic review of the literature suggested that PET/CT has a sensitivity of 90% and a specificity of 98% in detecting MCC.[51]

Although there has been no clear evidence to date that PET/CT staging will substantially change clinical outcomes for patients, a change in stage and treatment intent (and/or modality) in up to 30% of patients warrants its inclusion in to the current NCCN guidelines as a potential staging tool. In our department, PET/CT staging is recommended for all patients with T2 or clinically node-positive disease. An ongoing study being conducted by the Trans-Tasman Radiation Oncology Group (TROG) is prospectively evaluating the role of PET/CT in a multicenter trial of patients with MCC (ClinicalTrials.gov identifier NCT01013779).

Sentinel lymph node biopsy (SLNB). SLNB has become a standard tool in the nodal staging of MCC in many centers. SLNB detects lymph node spread in up to one-third of patients whose tumors would have otherwise been staged as N0.[52] MCC series data indicate an SLN positivity rate of 20% in T1 tumors, and 45% to 50% in T2 lesions.[52,53] Primary tumor factors such as size, depth of invasion, and lymphovascular invasion may be prognostic, but this has not been demonstrated conclusively.[54] In a large analysis of prognostic factors in 5,823 patients with MCC, investigators found that pathologic evaluation of node involvement was substantially better at prognosticating with regard to survival compared with clinical/radiologic examination alone.[55] Certainly, SLNB in MCC appears to be able to detect microscopic nodal spread and is prognostic for survival.

Most series indicate that patients with SLNB-positive disease receive treatment to the nodal region. Regional relapse rates following treatment in this setting are very low.[42,54,56] However, in the setting of a negative SLNB result, it is less clear whether prophylactic treatment can be omitted. The false-negative rate of SLNB has been re-

ported to be 10% to 20%.[54,55,57] This may be particularly problematic in the head and neck region where SLNB may be less accurate as a result of the complex and variable lymphatic drainage, postoperative tissue changes, and the presence of more than one sentinel lymph node.

SLNB has been recommended as a standard procedure for the staging of patients with MCC in the NCCN guidelines.[38] This is not unreasonable, but patients should be carefully selected for the procedure in light of the limited evidence of efficacy in some settings (postreconstructive surgery, immunosuppressed patients, or high-risk lesions). In our department, patients with lesions larger than 2 cm are considered sufficiently high risk to warrant prophylactic nodal irradiation, regardless of a SLNB result and so it is not recommended. For patients with tumors smaller than 2 cm, we will recommend SLNB in patients with tumors larger than 1 cm and is planned as part of their initial surgery. In patients with lesions smaller than 1 cm, we make an individual assessment based on risk factors. Further studies are required to better define the benefit and utility of SLNB.

Definitive Management

Stage I and II disease (node-negative).
Treatment in stage I and II MCC generally involves surgical resection of the primary tumor with clear margins followed by adjuvant radiotherapy. However, it is not necessary to obtain wide or even clear surgical margins if this would compromise cosmesis or function, or delay planned adjuvant radiotherapy.[38,58,59] Adjuvant radiotherapy provides superior locoregional control rates compared with surgery alone.[43,60-62] Patients with very small primary tumors (< 1 cm), or negative SLNB with clear margins and no adverse features, such as lymphovascular invasion and immunosuppression, may be able to avoid adjuvant radiotherapy.[63] If surgery is not feasible or refused, definitive radiotherapy can achieve high rates of locoregional control. Veness et al reported a 3-year locoregional control rate of 75% with radiation alone in a population with poor prognosis, but overall 60% of patients relapsed, most commonly outside the radiation field.[64]

Stage III disease (node-positive).
Stage IIIA disease (microscopic nodal) is usually detected via SLNB, and treatment of the nodal basin is recommended with radiotherapy or lymphadenectomy. Both modalities achieve excellent results,[56] with radiotherapy permitting concurrent adjuvant treatment to the primary site.

In IIIB disease, clinically evident node disease can be treated with lymphadenectomy and radiotherapy, or definitive radiotherapy. The NCCN guidelines recommend initial surgery as the standard therapy in this setting,[38] although a different approach may be adopted, particularly for MCC localized to the head and neck. Radiotherapy alone has been shown to provide good regional control of gross node disease, with isolated regional recurrence being uncommon.[56,65,66] The MD Anderson Cancer Center has recently reported its experience with radiotherapy in MCC localized

in the head and neck with 96% local and regional control rates, and notably no regional recurrences in 22 patients with gross nodal disease who were treated with radiation alone.[65]

If IIIB disease is treated surgically it is likely that the majority of patients would be recommended for postoperative radiotherapy based on multiple nodes or extracapsular extension. Decisions about the optimal approach must take into account the lack of evidence that bimodality treatment is more effective in achieving regional control than radiotherapy alone, as well as the predominant distant pattern of failure, and the additional toxicity and effect on quality of life associated with bimodality treatment.

In view of the high risk of distant metastases, and the similarities to small cell carcinoma of the lung, there has been interest in incorporating chemotherapy into the definitive management of patients at high risk. The TROG 96.07 trial evaluated the treatment of 53 patients with high-risk local and nodal MCC with radiotherapy and four cycles of carboplatin and etoposide.[67] Radiotherapy doses were moderate (50 Gy/25 fractions), and the bulk of disease treated ranged from microscopic to lesions larger than 5 cm. Gross node disease was present in 62% of patients. The 3-year overall survival, locoregional control, and distant control was 76%, 75%, and 76%, respectively. However, a high febrile neutropenia rate was observed that predominantly occurred during the peak of the radiation skin reaction. A subsequent trial demonstrated that giving weekly carboplatin during radiation followed by adjuvant carboplatin and etoposide was much better tolerated.[68] However, the single arm design of these trials does not permit any definitive conclusions about efficacy. Retrospective comparisons to patients treated with radiation alone have yielded mixed results with some studies finding no evidence of benefit, whereas a recent analysis restricted to head and neck primaries has suggested improved overall survival with chemoradiation. The role of chemotherapy in this setting remains unproven, and could only be established by a randomized trial.

Stage IV disease (distant metastases).
Distant metastases develop in 20% to 30% of patients with MCC.[50,65,69,70] The mainstay of anticancer management of metastatic MCC has been chemotherapy, which achieves high response rates (60% to 75%), but of limited duration. Based on apparent similarities to small cell carcinoma, regimens such as platinum and etoposide or cyclophosphamide, doxorubicin, and vincristine are most commonly used for first-line chemotherapy.[71] However, there is limited evidence to guide decision making, with no randomized trials evaluating different regimens, and limited data about the effect of chemotherapy on survival, symptom benefit, or quality of life. Bearing in mind that patients are frequently older with comorbidities, many patients are not good candidates for chemotherapy and are best managed by supportive care alone.

NEW TREATMENTS

The viral etiology and an epidemiologic link to immunosuppression suggest that immunotherapies may be effective in

treating MCC tumors. Many MCC tumors elicit a strong immune response with brisk infiltrates of intratumoral CD8+ T-cells (TILs), which is an independent indicator of better survival.[72-74] Viral-antigen specific CD8+ T-cells can also be detected in the peripheral blood of patients with MCC and fluctuate in response to treatment.[75] Antibody blockade of immune checkpoint receptors and ligands, such as CTLA-4 and PD-1/PD-L1 that reactivate cytotoxic T-cell activity, have demonstrated durable responses in the treatment of refractory solid tumors.[76,77] Importantly, viral specific T-cells in MCC express PD-1 and high tumor specific expression of the ligand PD-L1 has been observed in viral-positive, but not viral-negative tumors.[75,78] Phase II trials using anti-PD-L1 (MSB0010718C; NCT02155647), anti-PD-1 (pembrolizumab; NCT02267603), and anti-CTLA-4 (ipilimumab; NCT02196961) are currently open. An alternative or complementary immune strategy is adoptive immunotherapy, which involves the isolation of tumor-specific autologous T-cells from a patient, which are then cultured in vivo and infused back into the patient. This strategy has proven effective for treating melanoma.[79] Methods have been described for the isolation of MCV-specific cytotoxic T-cells from patients with MCC,[80] and a phase I/II clinical trial using autologous T-cell therapy with aldesleukin is currently underway (NCT01758458).

Targeting dysregulated cell growth and proliferation pathways within MCC tumors present another potential therapeutic avenue. MCC tumors overexpress receptor tyrosine kinases such as cKIT, PDGFR, and VEGFR2.[81-83] Despite promising early preclinical evaluation of imatinib (targeting KIT and PDFGR), a low response rate was observed in a clinical trial, although a complete response has been reported elsewhere.[84] The multikinase inhibitor pazopanib targets receptor tyrosine kinases, including cKIT, FGFR, PDGFR, and VEGFR, and a complete response to this drug has been observed in MCC resistant to cytotoxic therapy.[85] A phase II trial of pazopanib in patients with neuroendocrine tumors including MCC is currently open (NCT01841736). Cabozantinib, which targets VEGFR2/cMET, is being investigated in a phase II MCC trial (NCT02036476). As previously mentioned, MCC tumors may be responsive to inhibition of the PI3K/AKT/mTOR axis, and a number of clinical trials are currently active for treatment of solid tumors using PI3K inhibitors.

A low level of apoptosis is a feature of MCC. BCL-2, a prosurvival member of the intrinsic apoptosis pathway, is overexpressed in approximately 80% of MCC tumors.[86] Oblimersen sodium (G3139), a phosphorothioate antisense oligonucleotide that targets BCL-2, demonstrated good efficacy in a preclinical assessment,[87] but proved ineffective in patients with MCC.[88] The orally available drug ABT-263, which targets multiple BCL-2 family members, has also demonstrated preclinical activity against MCC cell lines by inducing apoptotic death.[89] Theoretically, ABT-263 may be more effective than G3139 in patients, given that it targets multiple BCL-2-family members. Survivin is a member of the inhibitor of apoptosis family and is upregulated by MCV LT.[90] High survivin expression corresponds with an aggressive clinical course and poor prognosis in patients with MCC.[91] Survivin expression can be attenuated using sepantronium bromide, also called YM155.[92] Treatment of MCC xenografts with YM155 demonstrated cytostatic response in MCC xenografts; however, this has yet to be tested in patients with MCC.[93]

The somatostatin receptor type 2 (SSTR2) is expressed in 90% of MCC tumors.[94] Somatostatin analogs such as octreotide bind to SSTR2 and elicit antiangiogenic, antisecretory, and antiproliferative responses in functional and nonfunctional neuroendocrine tumors.[95] Long-term response to octreotide has been reported in MCC,[96] and a French phase II trial testing the efficacy of the drug lanreotide is about to begin (NCT02351128). Peptide receptor radionuclide therapy (PRRT) involves covalent attachment of radioactive isotopes to somatostatin peptide analogs (e.g., $_{177}$lutetium octreotide). Given the exquisite radiosensitivity of MCC cells, there is a strong rationale for using PRRT in MCC. There have been several case reports demonstrating responses to PRRT used alone or with chemotherapy.[97-99]

Other biologically-targeted therapeutic strategies involve the use of antibody-drug conjugates and immunocytokines. Most MCC tumors demonstrate cell surface expression of CD56 (NCAM).[100] Lorvotuzamab mertansine (IMGN901) is a conjugate of a humanized anti-CD56 antibody with maytansinoids, such as DM1 (a microtubule targeting agent). The drug IMGN901 has showed efficacy against MCC in early phase trials and has been granted orphan status by the U.S. Food and Drug Administration (FDA). The immunocytokine F16-interleukin (IL)-2 is the fusion of the monoclonal antibody fragment F16 specific to tenascin-C fused to IL2. Tenascin-C is an angiogenesis marker and expressed in the reactive stroma of many solid tumors, whereas IL-2 is a potent immune stimulator. Preclinical studies have shown efficacy in human xenograft models of breast carcinoma and glioblastoma,[101,102] and phase IB and II trials in solid tumors and breast cancer have shown the drug is well tolerated and efficacious in some patients. A phase II trial using F16-IL2 in combination with paclitaxel for metastatic MCC is currently underway (NCT02054884).

CONCLUSION

Current management strategies achieve high rates of locoregional control, but distant failure rates remain problematic. Management of metastatic disease is challenging; chemotherapy can achieve high response rates of limited duration and is often associated with toxicity in this older population. The recent upsurge in our understanding of the biology of MCC is opening up new potential therapeutic targets and treatments. Finally, the recognition that MCC may be two distinct entities, viral-associated and viral-negative MCC, is likely to have implications for the management of MCC in the future and for the development of new treatments, somewhat analogous to oropharyngeal cancer following the identification of the HPV as a causative agent.

Perfusion and Infusion for Melanoma In-Transit Metastases in the Era of Effective Systemic Therapy

Dirk J. Grünhagen, MD, PhD, Hidde M. Kroon, MD, PhD, and Cornelis Verhoef, MD, PhD

OVERVIEW

The management of melanoma in-transit metastases (IT-mets) is challenging. For many years, the absence of effective systemic therapy has prompted physicians to focus on regional therapies for melanoma confined to the limb. The introduction of isolated limb perfusion (ILP) and isolated limb infusion (ILI) has enabled effective delivery of cytotoxic drugs in an isolated circuit, so as to overcome systemic toxicity and maximize local response. Both techniques have evolved over years and both tumor necrosis factor (TNF)-alpha–based ILP and ILI have distinct indications. The development of new systemic treatment options for patients with melanoma in the past decade has shed a new light on melanoma therapy. The present manuscript focuses on the modern role of ILI and ILP in the treatment of patients with melanoma with in-transit metastases in the era of effective systemic therapy. The response and control rates of ILI/ILP are still superior to rates achieved with systemic agents. The extent of disease in patients with stage III disease, however, warrants effective systemic treatment to prolong survival. There is great potential in combining rapid response therapy such as ILI/ILP with systemic agents for sustainable response. Trial results are eagerly awaited.

Melanoma incidence in the United States has increased during recent decades to an estimated number of 76,100 new cases in 2014,[1] comprising 4.6% of all new cancer cases. In approximately 5% to 8% of these patients, IT-mets will develop during the course of the disease. These IT-mets are a result of tumor emboli trapped within the dermal and subdermal lymphatics and can occur anywhere between the site of the primary tumor and the draining regional lymph node basin. The management of these IT-mets is challenging, as they are often numerous and can be bulky. The median time between diagnosis of the primary tumor and the development of IT-mets is between 13 months and 16 months. If a patient develops IT-mets, this is often a prelude to the appearance of systemic disease. In the current American Joint Committee on Cancer Melanoma Staging and Classification, patients with IT-mets are staged N2 or N3, depending on associated lymph node metastases. The corresponding 5-year survival rates are 69% and 52%, respectively.[2]

Various treatment options exist for melanoma IT-mets, as the presentation can range from very few and tiny lesions easily amenable to local excision, to more than 100 and extremely bulky lesions in previously extensively treated extremities. This wide range of clinical presentation demands a tailored approach for each patient. Whereas, in some patients, resection of limited disease is part of a curative approach, other patients may need treatment of their IT-mets even in the presence of stage IV disease for palliative reasons.

The treatment of these IT-mets can therefore be challenging, especially when the interval between new lesions is short, when numerous and bulky metastases are present, or when multiple treatment modalities have already been applied and failed. It is in this context that Creech and Krementz developed the concept of ILP in 1958.[3]

ILP TECHNIQUE

Until recently, melanoma was infamously refractory to any kind of systemic treatment. This resistance stimulated the search for techniques that could deliver high concentrations of chemotherapy or other agents to the affected limb, without the risk for systemic toxicity. In this way, drug concentrations would potentially suffice to achieve antitumor effect. As IT-mets of extremity melanomas are, per definition, confined to a limb, isolation of the affected limb from the systemic circulation would offer such an opportunity. This isolation can be achieved by surgical access to the artery and vein on either iliac, femoral, popliteal, axillary, or brachial level. The artery and vein are clamped and cannulated after which the catheters can be connected to a heart-lung machine to get an oxygenated circuit. To further isolate the limb, a tourniquet is placed proximal to the site of the perfusion. Melphalan (L-phenylalanine mustard) has been the standard drug used in ILP because of its efficacy and toxicity profile.[4] Drug concentrations in the limb are 20-times higher than can be achieved

Corresponding author: Dirk J. Grünhagen, MD, PhD, Erasmus MC Cancer Institute, Groene Hilledijk 301, 3075 EA Rotterdam, Netherlands; email: d.grunhagen@erasmusmc.nl.

systemically using this isolated circuit. Melphalan concentrations of 10 mg/L (leg) or 13 mg/L (arm) are considered standard dosages. The major concern of ILP is potential leakage of the effective agents to the systemic circulation. Therefore, leakage monitoring is mandatory and a precordial scintillation probe is placed to detect any radioactively labeled albumen administered to the isolated circuit that has potentially leaked to the systemic circulation.

Melphalan-based ILPs have been used for decades in the previous century as complete response (CR) rates of 40% to 50% and overall response rates of 75% to 80% were achieved, unmet by any other treatment modality.

ILP MODIFICATIONS

Since the introduction of ILP, many modifications have been applied to improve tumor response. These modifications have led to an improved insight in the optimal temperature, the optimal drugs, and the optimal indications for the procedure.

Temperature

Temperature of the perfused tissue is important in more than one way. The temperature of the skin has to be warmed during perfusion to prevent vasoconstriction in the dermal and subdermal tissues. Especially in superficial IT-mets, application of a warm water mattress can improve the local drug delivery as the uptake of the drug by in-transit metastases in vivo has proven to be twice as high at 39.5°C than at 37°C.[5] The second reason for hyperthermia is the idiosyncratic sensitivity of tumor cells to heat. Moreover, hyperthermia can improve the uptake of the drug in tumor cells, especially at temperatures greater than 41°C.[6,7] However, hyperthermia is associated with increased local toxicity. Tissue temperatures of 41.5°C to 43°C during ILP can yield high response rates,[8] but the local toxicity of these procedures can lead to major complications and even amputation of the perfused limb.[9]

KEY POINTS

- Therapy for patients with extensive melanoma in-transit metastases should be effective in providing local control.
- Tumor necrosis factor-based isolated limb perfusion (TM-ILP) is effective in the treatment of bulky melanoma in-transit metastases; isolated limb infusion (ILI) is effective in the treatment of lower-burden disease.
- Modern TM-ILP and ILI treatment is safe.
- New systemic agents for melanoma treatment have changed the treatment of patients with stage IV melanoma drastically, but response and local control rates do not reach ILI/ILP standards.
- Combination of ILI/ILP to induce rapid local response, followed by effective systemic therapy to increase overall survival, has great potential to become standard therapy in patients with extensive melanoma in-transit metastases.

The use of true hyperthermia should therefore be avoided. Mild hyperthermia for ILP is used as a compromise between response and toxicity.

Drugs

Several attempts have been made to improve the response on ILP by using other cytostatic drugs than melphalan. Commonly used drugs in the treatment of systemically metastasized melanoma, either alone or in a combination schedule, are dacarbazine and cisplatinum. Therefore, among others, these drugs were tested in the ILP-setting, but no drug or drug combination used for patients with melanoma has proven to achieve results superior to melphalan.[4,10] Probably the only alternative schedule still in use is the combination of melphalan and actinomycin-D.[11]

Probably the most influential adjustment of ILP has been the introduction of TNF by Lejeune and Liénard in 1988. TNF was isolated as an endogenous factor, especially active in inflammation, with necrotizing ability on tumor cells.[12] We now know that TNF has a dual mechanism of action: the direct cytotoxic effect of high-dose TNF to tumor cells certainly plays a role in antitumor activity,[13] but more importantly the TNF effect on the so-called tumor-associated vasculature induces a rapid change in tumor morphology characterized by hemorrhagic necrosis.[14] However, the systemic application in patients with melanoma was very disappointing.[15] TNF turned out to be a potent mediator in septic shock and, therefore, the systemic side effects (acute drop in vascular resistance leading to low blood pressure, fever, etc.) were the major factors hindering systemic application of this cytokine.[16] The maximum tolerated dose of TNF in humans turned out to be 10-times to 50-times lower than required for antitumor effect,[17] so that systemic, but also intralesional administration of TNF, was not clinically applicable. The concept of ILP combines the advantages of the TNF antitumor activity with the avoidance of systemic effects. Moreover, the cytotoxic effects of TNF are known to be enhanced in hyperthermic conditions and with the addition of alkylating chemotherapeutics,[18,19] both prerequisites already existing in the ILP model. The reintroduction of TNF in anticancer therapy by application in the ILP protocol combined optimal activity with minimal toxicity.[20]

Indications

The success of ILP in the treatment of melanoma IT-mets has prompted trials to test the efficacy of ILP in the adjuvant setting after excision of the primary melanoma. After the first disappointing results, this indication was largely abandoned by most melanoma centers.[21] Recently, the long-term results of a Swedish trial were published that affirmed the conclusion that adjuvant ILP after excision of high-risk primary melanomas does not improve survival of these patients.[22] Another plausible thought has been the repetition of perfusion soon after the first ILP, the so-called double perfusion schedule. The premise that repeated administration of chemotherapeutic agents is more effective than single use is adopted from the systemic chemotherapy situation and is based on the idea

that residual tumor cells after the first treatment may be eliminated and that partially damaged tumor cell after first exposure may be more vulnerable to chemotherapy on repeated exposures. In the ILP situation, the double perfusion schedule (interval 3 to 4 weeks, second perfusion with reduced melphalan dose, normothermic ILP) led to higher CR rates than single ILP,[23] but the median duration of response was not altered. Fractioning of melphalan administration and the use of true hyperthermia have been used in a double perfusion schedule in which a true hyperthermic perfusion with no chemotherapeutic agents was followed by a normothermic melphalan-ILP 1 week later. The achieved response rates with this protocol are high, probably because of the synergistic effect of hyperthermia and melphalan, whereas, because of to the fractioning, no increased toxicity was observed compared with single ILP.[24] It was postulated that the double perfusion schedule could be an alternative for a TNF-based ILP. In the TNF era, no further trials of repeat ILPs at short intervals have been conducted.

ISOLATED LIMB INFUSION

In the early 1990s, ILI was developed by Thompson et al at the Melanoma Institute Australia (MIA, formerly Sydney Melanoma Unit) as a simplified and minimally invasive alternative to ILP.[25] This has been the most fundamental change in the concept of ILP, although the basic principles are very much alike. Both ILP and ILI involve a method of vascular isolation and perfusion of the extremity with cytotoxic agents. Drug concentrations in the isolated limb can be administered up to 10-fold of the maximum tolerated systemic concentration, and systemic side effects are avoided in both ILI and ILP.[26] Like ILP the primary indication for ILI is patients with inoperable in-transit melanoma of the extremity.

During ILI, arterial and venous catheters are inserted percutaneously. Using a standard Seldinger technique the catheters are placed via the contralateral femoral artery and vein in the disease-bearing limb. In the operating room, the catheters are connected to an extracorporeal circuit primed with saline solution, incorporating a heat exchanger but no mechanical pump or oxygenator. To achieve reliable isolation, a pneumatic tourniquet is inflated proximally around the affected limb. In this isolated circuit a low blood flow can be achieved by repeated aspiration from the venous catheter and reinjection into the arterial catheter using a syringe. The lack of oxygenation results in a hypoxic and acidotic environment. Great care is given to heating the limb, which is achieved by a heat exchanger in the external circuit, a warm-air blanket placed around the limb, and a radiant heater placed above it. The cytotoxic drug of choice for ILI is melphalan. At MIA and most other ILI centers, actinomycin-D is used additionally because of the satisfactory results with the combination, without negative effects on toxicity. After infusion of the drugs, the blood in the isolated circuit is circulated for 30 minutes. Since the half-life of melphalan is 15 minutes to 20 minutes and both melphalan and actinomycin-D are quickly absorbed by the tissues, a relatively short circulation time of 30 minutes is sufficient.[26-28] During ILI real-time leakage control of the cytotoxic drugs to the systemic circulation is not required because of the low flow and low pressure in the isolated limb circuit and the effective isolation reliably achieved by the pneumatic tourniquet. After 30 minutes the limb vasculature is flushed, after which normal circulation to the limb is restored by removing the tourniquet and the catheters.[29]

Differences between both procedures include that during ILI, no open surgical procedure is required, such as in ILP and arterial and venous catheters are inserted percutaneously. This results in a lower blood flow and in the isolated extremity during ILI (150 mL/minutes to 1,000 mL/minute for ILP vs. 50 mL/minute to 100 mL/minute for ILI). Furthermore, the ILI procedure is a hypoxic procedure, which leads to marked acidosis of the isolated circuit, in contrast to ILP where the pump oxygenator maintains the oxygenation in the limb. Catheter insertion via the contralateral groin for ILI is usually straightforward, even for a repeat procedure or after groin or axillary lymph node dissection; whereas, vascular access for ILP can be technically difficult. Finally, blood transfusion or more recently the use of autologous blood, which is required for ILP to prime the perfusion circuit, is unnecessary during ILI.[29]

RESPONSE ON ILP AND ILI IN PATIENTS WITH MELANOMA

As mentioned before, at the introduction of melphalan-based ILPs (M-ILP), the results of this treatment were unmet by any of the then available systemic medical treatments for melanoma. Overall response rates of greater than 80% were achieved in patients with IT-mets (Table 1). The enthusiasm for ILP was only tempered by two major objections: the procedure is fairly time-consuming and complicated, and, second, in bulky melanoma the response rates were relatively disappointing. The tumor bulk of the melanoma IT-mets can indeed be crucial as these are large, sarcoma-like lesions. The inhomogeneous drug uptake of soft tissue sarcomas was once the reason for abandoning M-ILP as a treatment option for these unresectable tumors.[30] The application of TNF to the M-ILP protocol (TM-ILP) in the sarcoma setting has changed this fundamentally, and TM-ILP is now used widely for this indication.[31] The bulky melanoma IT-mets resemble the sarcoma situation and this tumor bulk can indeed be crucial in appraising the TNF effect, as these large lesions benefit the most from the destruction of tumor associated-vasculature by TNF. This has led to comparative studies of M-ILP and TM-ILP. A randomized trial was published in 2006 comparing M-ILP and TM-ILP showing no beneficial effect of adding TNF.[32] This trial had extremely low CR rates compared with the available case series worldwide and the true indication of a TM-ILP protocol (bulky disease) could not be analyzed separately. Furthermore, the response rate in this trial was assessed at 3 months rather than at maximum response reached, which is usually after 3 months to 6 months. This has led to criticism and further series have been

TABLE 1. Response to Different Isolated Limb Infusion/Isolated Limb Perfusion Regimens

Abbreviations: CR, complete response; ILI, isolated limb infusion; ILP, isolated limb perfusion; PR, partial response; M-ILP, melphalan isolated limb perfusion; NS, not stated; OR, overall response; TM-ILP, application of tumor necrosis factor to M-ILP; TNF, tumor necrosis factor.
*Response rates are stated for the combined TM-ILP and M-ILP cohort.

published showing improved results of TM-ILP, albeit in a nonrandomized setting.[33-35] A retrospective mixed series of M-ILP and TM-ILP published by Rossi et al has shown a significantly improved CR-rate when TM-ILP was used.[36] The results of TM-ILP in a large series published after 2000 showed that CR rates are consistently reported to be slightly greater than 60%.[37-39] Overall, the view of most melanoma centers dealing with TM-ILPs is that true indications for TM-ILP is bulky disease or failure after previous M-ILP.[40]

The second issue of relative complexity is overcome by the application of ILP when appropriate. The most robust data of ILI are from Australia where since 1992 more than 400 melanoma ILIs have been performed at MIA. Following ILI a CR rate of 38% and a partial response (PR) rate of 46% are seen with a median duration of response of 22 months and 13 months, respectively.[41]

To date, two multicenter retrospective analyses have been published. In a U.S. study, 31% of the patients experienced a CR, 33% a partial response (PR), and 36% showed no response to the treatment.[42] Another multicenter study reported the responses in Australian centers, excluding MIA. They reported a CR of 27% and a PR of 36%.[43] Recently a systematic review was published including all the published ILI papers showed a CR in 33% of the patients and PR in 40%.[44] Overall the results of ILI are at the lower end of the spectrum of those reported after ILP. ILI, however, is performed in older and more medically compromised patients, both of which are statistically independent prognostic factors for an inferior response rate when compared with ILP. The fact that the indications for ILI and ILP within the patient population with melanoma IT-mets differ, makes a head-to-head comparison impossible and unnecessary.

LOCAL CONTROL AFTER PERFUSION

Although TM-ILP can achieve excellent response rates in patients with melanoma IT-mets, the nature of the disease determines that the patients in this very unfavorable population often experience local recurrent disease in the limb. Reported recurrence rates after perfusion are approximately 50%. The duration of response is sustained for longer than 1 year.[38] The management of limb recurrences after ILI/ILP is essentially the same as for IT-mets in general: local excision if technically feasible, but repeat perfusion in extensive disease. After a PR following ILI, or when recurrent lesions appear, simple local treatment of the remaining or recurrent lesions by excision, laser ablation, electrodesiccation, injection with rose bengal, or radiotherapy can be effective in obtaining local disease control. A recent study showed that resection of residual disease after ILI leads to similar disease-free survival and overall survival as a CR after ILI alone.[45] Both ILI and ILP can be repeated in select patients showing results comparable to the first procedure.[46,47]

SURVIVAL AFTER PERFUSION

Melanoma IT-mets have a relatively poor prognosis because of the extent of the disease. A local treatment option such as ILI/ILP cannot be expected to alter this as survival is dictated by the presence or appearance of systemic disease. Median survival of patients after a perfusion is approximately 2 years but interestingly, this is highly correlated with response on perfusion. In patients undergoing ILI/ILP, a CR after perfusion corresponds to a median survival of 53 months and 44 months, respectively.[38,41] This implies that a perfusion can select those patients with high response rates who apparently have a more favorable tumor biology.

TOXICITY OF PERFUSION

An area of concern in the field of perfusions is the toxicity that is associated with the procedure. This can be divided into

systemic toxicity because of leakage of the perfusate to the systemic circulation, and local toxicity of the treated extremity. In the situation in which ILPs are performed in specialized and experienced teams, clinically relevant leakage percentages of greater than 10% are extremely rare and median leakage should be 0%.[38] In ILI, systemic leakage is not an issue because of the low pressure of the perfusion system.[48] Local toxicity of perfusions is scored according to the Wieberdink classification.[49] A few modifications of the ILP have reduced the local toxicity significantly. Firstly, TNF dose is reduced. In the original series it was 3 mg to 4 mg TNF for leg perfusions and 2 mg for the arm; at present dosages of 2 mg and 1 mg are used, respectively. This modification has widely been accepted after a randomized trial in patients with sarcoma showed equal effectiveness of the low-dose perfusions but with decreased local toxicity.[50] The effect of low-dose ILPs on local toxicity could be affirmed in further case series of patients with sarcoma but proved to be of no influence in patients with melanoma.[38] Reasons for this difference are unknown. Another adjustment in ILP leading to less local toxicity is the tendency to perform more distal perfusions to reduce the perfused limb volume. This has a profound effect on local toxicity in both ILP and ILI procedures.[40,51] Major local toxicity (Wieberdink grade greater than 3) is seldom seen in ILI/ILP and is in recent reports 3% for both procedures. It can be concluded that ILP, and ILI to even a higher extent, are safe procedures with little and manageable toxicity. Perfusions have been performed safely in the older population and repeat procedures can be performed without increased toxicity.

ILI/ILP AND SYSTEMIC THERAPY

The poor survival after perfusion, despite the excellent regional response rates, raise the question of whether a local therapy such as ILI/ILP should still be used on a stand-alone basis in patients with extensive disease. In this light, a parallel can be seen in patients with positive deep pelvic lymph nodes. Both IT-mets and deep pelvic nodes reflect extensive disease and, recently, it has been shown that the extent of surgery to the deep pelvic and obturator nodes does not improve the outcome of these patients. In other words, the prognosis of these patients is dictated by the biology of the disease rather than by the extent of surgery.[52,53] The same mechanism is likely to be applicable to the IT-met situation. Until recently, response rates on systemic therapies were poor, and complete focus lied on treating the local situation. Fortunately, this situation has changed dramatically by the introduction of BRAF/MEK/KIT inhibitors, anticytotoxic T-lymphocyte-associated (CTLA) protein-4 antibodies and programmed death (PD)-1 pathway inhibitors.[54] Patients with stage IV melanoma experience response rates of approximately 50% and, in a subset of patients, long-term benefit can be obtained.[54] Although the majority of patients who entered the trials of these new drugs indeed had stage IV disease, most protocols allowed patients with unresectable stage III disease to enroll as well. The patient with IT-mets eligible for perfu-

sion has by definition unresectable stage III disease and, therefore, trial results can be extrapolated to this subset of patients, albeit with caution and in the awareness that response to ILP is dependent on stage of disease.[55]

It is, however, unlikely that systemic therapy will replace ILI/ILP in patients with extensive IT-mets. The response rates of the new agents are impressive compared with standard chemotherapy but are far below those that can be achieved with a perfusion. BRAF inhibitors have impressive and rapid response rates of approximately 60% (overall response) in patients with *BRAF* mutation. Drawbacks are numerous, however; the median duration of response is only about 7 months, after which resistance seems almost inevitable, there is a wide interpatient variability in response to treatment, and toxicity associated with BRAF inhibition cannot be neglected.[54] A more durable response can be obtained with anti-CTLA4 antibodies, but only a minority of patients will respond. Patients with multiple unresectable IT-mets will remain unresectable after a PR, so that the aim of therapy should ideally be CR. The CR rates of ILI and especially ILP of around 60% are still unmet by any systemic agent. The superior local control rate of a perfusion combined with the mild toxicity compared with systemic treatment mean that perfusion remains the optimal treatment option in these patients.

Although replacement of a perfusion by systemic therapy is unlikely in the near future, the development of new potent agents in the systemic treatment of patients with melanoma offers new possibilities in combining drugs. The first data on combining new systemic agents are encouraging with OR rates of 64%, a duration of response of 11 months, and a 1-year overall survival rate of 72% with the combination of a BRAF and MEK inhibitor.[56] BRAF inhibition followed by anti-CTLA4 therapy is also appealing, but this regimen has produced disappointing results in retrospective series.[54] The combination of two different ways of drug delivery (systemic and in the isolated circuit) is a logical next step. When systemic targeted therapies are administered in combination with chemotherapy administered by ILI, chemotherapy resistance can potentially be overcome by increasing the cytotoxic efficacy and, thereby, the responses.[57] In a multicenter phase II study combining melphalan ILI and systemic ADH-1, a cyclic pentapeptide that disrupts N-cadherin adhesion complexes, an overall response rate of 60% was achieved without increasing toxicity, compared with an overall response rate of 40% achieved previously with melphalan alone at the same institutions.[58] Improved responses were also seen when melphalan ILI was performed after systemic bevacizumab, a monoclonal antibody against VEGF causing increased delivery of melphalan to the tumor cells, in a preclinical melanoma model.[59] A clinical trial administering bevacizumab in combination with melphalan ILI is eagerly awaited. Currently, the use of the systemic anti-CTLA-4 antibody ipilimumab, before or after melphalan ILI, is being investigated in phase I and II trials (NCT01323517, NCT02115243).

Potentially more attractive is the combination of ILI/ILP for rapid response, followed by systemic therapy for survival bene-

fit. A phase II trial protocol is presently open for recruitment combining ILP and systemic ipilimumab (NCT02094391).

In conclusion, ILI and ILP are here to stay. The procedures provide rapid responses that are still superior to the responses achieved by systemic therapy, even in the latest trials. The responses are obtained at the cost of only very mild local, and vir-

tually absent, systemic toxicity. Patients with extensive IT-mets do need local treatment for disease control, but as unresectable stage III disease is a reflection of poor tumor biology, survival remains relatively poor. We firmly believe that this provides a massive opportunity for systemic agents. The results of the combination trials are awaited with great expectations.

Neoadjuvant Therapy for Melanoma: A Promising Therapeutic Approach and an Ideal Platform in Drug Development

Ahmad A. Tarhini, MD, PhD

OVERVIEW

Patients with locoregionally advanced but surgically operable melanoma continue to carry a high risk of relapse and death despite the best available standard management approaches. Neoadjuvant studies targeting this patient population tested chemotherapy with temozolomide and biochemotherapy (BCT), in which BCT demonstrated high tumor response rates but was eventually abandoned with the failure of BCT to deliver survival benefits in randomized trials of metastatic disease. Smaller neoadjuvant immunotherapy studies with interferon (IFN) alfa and ipilimumab have yielded promising clinical activity and important mechanistic insights and biomarker findings. Newer targeted and immunotherapeutic agents and combinations currently are being translated into the neoadjuvant setting at an accelerated pace and carry significant clinical promise. In drug development, the neoadjuvant approach allows access to blood and tumor tissue before and after initiation of systemic therapy, which allows for the conduct of novel mechanistic and biomarker studies in the circulation and the tumor microenvironment. Such studies may guide drug development and allow for the discovery of predictive biomarkers selected on the basis of their capacity to classify patients according to the degree of benefit from treatment or the risk for significant toxicity.

Survival of patients with melanoma varies widely by stage, from a potentially highly curable disease with surgery alone when detected in early stages to a disease with an overall guarded prognosis when it reaches advanced inoperable stages.[1] The American Joint Committee on Cancer divides cutaneous melanoma into four stages. Primary tumors confined to the skin and without regional lymph node involvement are assigned stages I and II depending on the thickness (depth) of the tumor, ulceration of the overlying epithelium, or mitotic rate. Stage III comprises a disease with clinical or pathologic evidence of regional lymph node involvement or the presence of in-transit or satellite metastases. Stage IV melanoma is defined by the presence of distant metastasis. Patients with stage I melanoma have an excellent prognosis with surgical treatment alone and a cure rate of more than 85%. The 5-year postsurgical survival rates in patients with stages IIA, IIB, and IIC disease are approximately 80%, 70%, and 50%, respectively, whereas the rates for patients with stages IIIA, IIIB, and IIIC disease are 78%, 60%, and 40%, respectively.[1-3] The apparently worse prognosis of patients with IIA and IIB disease according to the AJCC data may be attributed to the lack of adequate regional lymph node staging in some patients at a time when sentinel lymph node mapping was not widely adopted as a standard of care. For patients with stage IV melanoma, an historical median survival rate of approximately 6 months has significantly improved recently to rates that approach and exceed 1 year with new molecularly targeted agents (e.g., BRAF and MEK inhibitors) and immune checkpoint inhibitors (e.g., against cytotoxic T-lymphocyte-associated protein 4 [CTLA-4] and programmed cell death protein 1 [PD-1]) that have made a real difference in the survival of these patients.[4-6]

LOCALLY AND REGIONALLY ADVANCED MELANOMA

Patients with stage III melanoma and clinically detectable regional lymph node involvement with or without in-transit metastases have a 5-year relapse rate of 68% to 89%.[7] The development of local or regional recurrence after initial surgical management portends an even poorer prognosis.[8,9] In the Melanoma Intergroup Surgical Trial, local recurrence was associated with 5-year survival rates of 9% to 11% and 10-year survival rates of 5%.[9] Surgical excision with complete regional lymph node dissection is the cornerstone of management, followed by adjuvant therapy with IFN alfa-2b, in which patients derive limited clinical benefits that are most substantial with high-dose IFN alfa (HDI).[10-13] Overall, these patients continue to experience a high risk of relapse and death despite the best available standard management approaches, and there continues to be an urgent need to improve the clinical outcome. Recent advances in the treatment of metastatic melanoma are destined to make real differences in the management of these

patients; neoadjuvant and locoregional therapeutic approaches appear to be very promising in terms of improving the surgical outcome and the risk of relapse and mortality.

NEOADJUVANT TREATMENT OF POTENTIALLY RESECTABLE LOCOREGIONAL METASTASES OF CUTANEOUS MELANOMA

Neoadjuvant therapy has improved the outcome of patients with multiple different solid tumors, including head and neck, breast, bladder, esophageal, and rectal cancers.[14-17] Benefits include improvements in survival, surgical resectability, local control, and organ preservation. Other advantages of neoadjuvant therapy are the ability to evaluate the clinical and pathologic responses and the potential to identify immunologic and histologic correlates of tumor response. Access to tumor tissue before and after neoadjuvant therapy also may allow a better understanding of the antitumor mechanisms of action that may enable more selective application of therapeutic agents to those patients who are more likely to benefit. Such findings would improve the therapeutic index and cost-effectiveness of these agents. Neoadjuvant studies of chemotherapy, BCT, and immunotherapy have been investigated in melanoma, with several important findings. Table 1 provides a summary of these studies.

Neoadjuvant Chemotherapy and Biochemotherapy Studies in Patients with Melanoma with Locoegional Metastases

A phase II study tested neoadjuvant temozolomide (TMZ) in chemotherapy-naive patients who had melanoma with surgically resectable, locoregionally advanced disease.[18] Two cycles of 75 mg/m^2/day oral TMZ were given preoperatively for 6 weeks of every 8-week cycle. The response rate, which included one partial response and two complete responses, was

---

KEY POINTS

- Patients with locoregionally advanced melanoma continue to experience a high risk of relapse and death despite the best available standard management approaches.
- Neoadjuvant biochemotherapy demonstrated high tumor response rates but was eventually abandoned after failure to deliver survival benefits in randomized trials of metastatic disease.
- Neoadjuvant immunotherapy with interferon alfa and ipilimumab have yielded several important clinical and mechanistic findings.
- In drug development, biomarker and mechanistic studies can be accelerated through neoadjuvant studies because of the access to biospecimens before and during therapy.
- Newer targeted and immunotherapeutic agents and combinations currently are being translated into the neoadjuvant setting at an accelerated pace and carry significant promise.

16%. Four patients had stable disease, and 12 experienced disease progression. Overall, the observed clinical activity with neoadjuvant TMZ was not different from what is known in metastatic melanoma.

Neoadjuvant BCT demonstrated high tumor response rates in phase II studies but eventually was abandoned because of the failure of BCT to deliver survival benefits in randomized trials of metastatic disease. A neoadjuvant phase II study of concurrent BCT was conducted in patients with resectable locoregional metastases of cutaneous melanoma (stage III; nodal, satellite/in-transit metastases and/or local recurrence).[19] In total, 65 patients were treated with two to four cycles of BCT before surgery, as summarized in Table 1. Two additional postoperative courses were given to patients who experienced tumor response after two preoperative courses. Among patients whose responses were assessed histologically, a partial response was reported in 27 patients (43.5%), and a pathologic complete remission (pCR) was reported in 6.5%; the overall response rate was 50%. Patients who experienced pCR had a significantly lower tumor burden (p = 0.02).[19] In a second phase II study that enrolled 48 patients, two cycles of BCT were administered before and after complete lymph node dissection using a BCT regimen similar to the prior study. Clinical responses were observed in 14 (38.9%) of 36 patients who had measurable disease; 13 (36.1%) experienced partial responses, and one patient (2.8%) experienced a complete response. A pCR was noted in four patients (11.1%). At a median follow-up of 31 months, 38 (79.2%) of the 48 patients were alive, and 31 patients (64.6%) remained free of disease progression.[20]

The phase II BCT studies indicated that neoadjuvant BCT is clinically active in patients who have melanoma with locoregional metastases. However, BCT has failed to demonstrate a survival advantage versus chemotherapy alone in phase III randomized trials in patients with stage IV disease.[21,22] Furthermore, chemotherapies as single agents or in combinations have not been shown to have a survival impact in patients with metastatic melanoma. IFN alfa and interleukin-2 (IL-2) used in the BCT regimens were administered at potentially suboptimal low dosages; also, in combination with chemotherapy, there is the potential for interactions of IFN alfa or IL-2 with chemotherapeutic agents, some of which have been shown to be immunosuppressive.[23] These factors may potentially antagonize or alter the immunotherapeutic effects of IFN alfa and IL-2. Of note, a phase III trial of adjuvant BCT in patients with high-risk, surgically resected melanoma (S0008) reported improved relapse-free survival but no difference in overall survival and more toxicity than HDI.[24]

Neoadjuvant Immunotherapy Studies

Several observations support the adjuvant and neoadjuvant evaluation of immunotherapeutic agents in patients with surgically resectable melanoma at high risk for death as a result of melanoma recurrence. Host immune resistance of melanoma plays a key role in disease control in the adjuvant and advanced disease settings and appears to have important implications for neoadjuvant immunotherapy of patients

TABLE 1. Neoadjuvant Studies of Resectable Locoegional Metastases of Cutaneous Melanoma

Study	No. of Patients	Design	Primary Objective	Regimen	Important Findings
Buzaid et al[19]	64	Phase II single arm	Tumor response	2-4 (3-week) cycles; days 1-4: 20 mg/m^2 IV cisplatin, 1.5 mg/m^2 IV vinblastine, 9 MIU/m^2/d continuous IV IL-2; day 1 only: 800 mg/m^2 IV dacarbazine; days 1-5: 5 MU/m^2 SC IFN alfa-2a	High tumor response rates in phase II studies but eventually abandoned, with the failure of biochemotherapy to deliver survival benefits in randomized trials of metastatic disease
Gibbs et al[20]	48	Phase II single arm	Tumor response	2 (3-week) cycles; days 1-4: 20 mg/m^2 IV cisplatin, 1.6 mg/m^2 IV vinblastine, 9 MIU/m^2/d continuous IV IL-2; day 1 only: 800 mg/m^2 IV dacarbazine; days 1-5: 5 MU/m^2 SC IFN alfa-2a	
Shah et al[18]	19	Phase II single arm	Tumor response	2 (8-week) cycles 75 mg/m^2/d temozolomide for 6 weeks then 2 weeks off	The observed clinical activity was not different from what is known in metastatic melanoma
Moschos et al[30]	20	Phase II single arm	Tumor response	20 MU/m^2 IV IFN alfa-2b 5 days a week for 4 weeks before surgery (induction) / 20 MU/m^2 SC IFN alfa-2b 3 days a week for 48 weeks starting after surgery (maintenance)	Promising clinical activity. HDI upregulated pSTAT1 and TAP2 and downregulated pSTAT3. Significant increases in endotumoral CD11c$^+$ and CD3$^+$ cells were noted after HDI. Phospho-ERK1/2 was downregulated by HDI in tumor cells but not in lymphocytes
Tarhini et al[35]	33	Phase I/II single arm	Safety, biomarker	10 mg/kg IV ipilimumab every 3 weeks for 2 doses, bracketing surgery	Promising clinical activity. Ipilimumab led to potentiation of type I CD4 and CD8 tumor-specific T cells, downregulation of MDSC, and an increase of CD8$^+$ TIL and T-cell memory (CD45RO$^+$). An immune-related gene expression signature was significantly associated with clinical benefit

Abbreviations: IV, intravenously; IL, interleukin; SC, subcutaneously; IFN, interferon; HDI, high-dose IFN alfa; MDSC, myeloid-derived suppressor cells; TIL, tumor-infiltrating lymphocytes.

with high-risk, locoregionally advanced disease.[5,10] Spontaneous regression has been reported in melanoma, which suggests a role for host immunity that is indirectly supported by the presence of lymphoid infiltrates at primary melanoma sites associated with tumor regression.[25] Host cellular immune response within melanoma has potential disease prognostic and immunotherapeutic predictive significance. T-cell infiltrates are prognostic of disease outcome in primary melanoma and in melanoma that is metastatic to regional nodes.[25-28] Furthermore, T-cell infiltrates within regional nodal metastasis are significantly associated with benefit from neoadjuvant IFN alfa therapy.[26,29,30] Further, evidence supports a difference in the quality of the host immune response of patients with earlier (operable) and more advanced (inoperable) melanoma. Although T-helper type 1 (Th1)–type CD4$^+$ antitumor T-cell function appears critical to the induction and maintenance of antitumor cytotoxic T-lymphocyte responses in vivo, and although Th2- or Th3/T regulatory-type CD4$^+$ T-cell responses may subvert Th1-type cell-mediated immunity and provide a microenvironment conducive to disease progression, patients with advanced melanoma or renal cell carcinoma have displayed strong tumor antigen-specific Th2-type polarization. Conversely, normal donors and patients who were disease free after therapy demonstrated either a weak mixed Th1-/Th2-type or a strongly polarized Th1-type response to the same epitopes.[31] Therefore, factors of host immune tolerance that seem to impede immunotherapeutic benefits in advanced disease may be less pronounced in the high-risk, operable setting. In patients with earlier-stage melanoma, the host may be more susceptible to immunologic interventions that may potentiate an antitumor T-cell response and create lasting immunity.

Neoadjuvant HDI was investigated in patients who had melanoma with palpable regional lymph node metastases presenting either with clinical AJCC stage IIIB to IIIC disease (TanyN2b,2c,3) or with recurrent regional lymphadenopathy. Patients underwent surgical biopsy at study entry and then received standard intravenous HDI (20 million units/m^2 on 5 days per week) for 4 weeks followed by complete lymphadenectomy and standard maintenance subcutaneous HDI (10 million units/m^2 3 times per week) for 48 weeks. Biopsy samples were obtained before and after intravenous HDI. Twenty patients were enrolled, and biopsy samples were informative for 17. Eleven patients (55%) demonstrated a clinical response, and three patients (15%) had a pCR. At a median follow-up of 18.5 months, 10 patients had no evidence of recurrent disease. By comparison, in the setting of inoperable metastatic disease, response rates of less than 20% were reported, although a number of patients had durable responses that ranged from 26 months to more than 30 months.[32] In the context of this neoadjuvant study, HDI was found to upregulate pSTAT1, whereas it downregulates pSTAT3 and total STAT3 levels in both tumor cells and lymphocytes. Higher pSTAT1/pSTAT3 ratios in tumor cells before treatment were associated with longer overall survival ($p = 0.032$). The pSTAT1/pSTAT3 ratios were augmented by HDI both in melanoma cells ($p = 0.005$) and in lymphocytes ($p = 0.022$). Of the immunologic mediators and markers tested, TAP2 (but not TAP1 and major histocompatibility complex [MHC] classes I/II) was augmented by HDI.[33] In

addition, HDI regulated mitogen-activated protein kinase (MAPK) signaling differentially in melanoma tumor cells and host lymphoid cells. HDI significantly downregulated pSTAT3 (p = 0.008) and phospho-MEK1/2 (p = 0.008) levels in tumor cells. Phospho-ERK1/2 was downregulated by HDI in tumor cells (p = 0.015) but not in lymphoid cells. HDI downregulated epidermal growth factor receptor (EGFR; p = 0.013), but pSTAT3 activation did not appear associated with EGFR expression and the MEK/ERK MAPK pathway, which indicates that STAT3 activation is independent of the EGFR/MEK/ERK signaling pathway.[34] Clinical responders had significantly greater increases in endotumoral CD11c+ and CD3+ cells and significantly greater decreases in endotumoral CD83+ cells than nonresponders.[30]

Neoadjuvant ipilimumab was tested in locoregionally advanced melanoma to evaluate safety and to define markers of activity and toxicity in the blood and tumor of patients at baseline and early on-treatment times.[35] Patients were treated with ipilimumab (10 mg/kg intravenously every 3 weeks for two doses) that bracketed surgery. Tumor and blood samples were obtained at baseline and at the definitive surgery time. Thirty-five patients were enrolled; diseases were stages IIIB (three patients; N2b), IIIC (32 patients; N2c, N3), and IV (two patients). The worst toxicities included grade 3 diarrhea/colitis (five patients; 14%), hepatitis (two patients; 6%), rash (one patient; 3%), and elevated lipase (three patients; 9%). The median follow-up was 19 months. Among 33 evaluable patients, the preoperative radiologic assessment by PET-CT scans at 6 to 8 weeks after the initiation of ipilimumab revealed that three patients (9%) had objective responses (two patients, complete response; one patient, partial response). Twenty-one patients (64%) had stable disease, and eight patients (24%) experienced disease progression identified with PET-CT. [18F]-fludeoxyglucose PET/CT parameters at baseline (T0) and at the first scan after two doses of ipilimumab (T1) were unable to predict recurrence after surgery (at a significance level of 0.05).[36] The number of lesions at T1 showed a trend toward predicting a higher chance of disease recurrence (p = 0.06). The median recurrence-free survival was 11 months (95% CI, 6.2 to 19.2 months). The probability of 12-month overall survival was 96%. Based on preliminary data from a study that tested HDI and tremelimumab in patients with metastatic disease and on recent data in the literature, we evaluated candidate biomarkers linked to the proinflammatory immune response and markers of immunosuppression as assessed in the tumor microenvironment (TME) and in circulation that may have therapeutic predictive roles in relation to immunotherapy for melanoma.[37] The underlying hypothesis was that our quest for a predictive biomarker signature in patients with metastatic melanoma who are treated with immunotherapy may be rewarded by evaluating candidate biomarkers in the TME and in circulation simultaneously, on the basis of the common systems of biology.[38]

Neoadjuvant ipilimumab leads to a significant potentiation of type I CD4 and CD8 tumor-specific T cells that may play a therapeutic predictive role.[35] Here, multicolor flow cytometry that used overlapping peptide pools (gp-100, MART-1, NY-ESO-1) showed baseline evidence of spontaneous in vivo cross-presentation that resulted in type I CD4+ and CD8+ antigen-specific T-cell immunity.[35] Ipilimumab induced a significant increase in type I CD4 and CD8 (fully activated and IFN gamma–producing) antigen-specific T cells. Both CD4+ and CD8+ T cells were activated (upregulated CD69) on their stimulation with individual antigen peptide pools, and a subset secreted IFN gamma. High increases (3- to 10-fold) in CD3+/CD4+/IFN gamma+ T cells were seen only in patients who were progression free at 6 months, which suggests a potential early on-treatment therapeutic predictive value. A significant modulation of circulating regulatory T cells (Treg) and myeloid-derived suppressor cells (MDSC) also was seen. A significant increase in the frequency of circulating Treg (CD4+/CD25hi+/Foxp3+ [p = 0.02] and CD4+/CD25hi+/CD39+ [p = 0.001]) from baseline to 6 weeks was observed. Significant decreases in circulating MDSC were seen. A decrease in the circulating monocyte gate MDSC Lin1-/HLA-DR-/CD33+/CD11b+ was associated with improved progression-free survival (PFS; p = 0.03). Increases in Treg were associated with improved PFS (hazard ratio = 0.57; p = 0.034). In the tumor, Treg (CD4+/CD25hi+, CD4+/CD25hi+/Foxp3+) appeared higher at week 6 in the progressive-disease group but the opposite occurred in the disease control group (p = 0.09). Tumor samples obtained at baseline and after ipilimumab were tested by immunohistochemistry and showed significant increases in CD8+ tumor-infiltrating lymphocytes after ipilimumab (p = 0.02). By flow, trends were observed in examination of the change in Treg and disease control (p = 0.09). Treg were higher at week 6 in the progressive-disease group, whereas the opposite was seen in the disease control group. This was unlike what we observed in the circulation. Ipilimumab also induced T-cell activation, as evidenced by CD69 without in vitro stimulation. There was evidence of induction/potentiation of T-cell memory (CD45RO+) but not naive status (CD45RO-) in the tumor, which also supported further testing as a predictive marker, as suggested from data by Galon et al in colorectal tumors.[39] Gene expression profiling was performed on the tumor biopsies and identified immune-related genes that were significantly differentially expressed on the basis of clinical outcome. A baseline gene signature that resulted from this analysis was significantly associated with clinical benefit of neoadjuvant ipilimumab.[40] These data have laid the groundwork for a series of subsequent studies that are evaluating potentially therapeutically predictive biomarkers of a proinflammatory immune response and of immunosuppression both in the TME and in circulating blood in patients with melanoma who are receiving immunotherapy.

Neoadjuvant Efforts Using Molecularly Targeted Agents

Driver oncogenic mutations identified in melanoma have defined clinically relevant melanoma molecular subsets that can be targeted therapeutically, leading to giant leaps in metastatic melanoma management.[41,42] Significant clinical activ-

ity in early studies of *BRAF* and MEK kinase inhibitors led to a rapid succession of phase II and III studies completed at an unprecedented pace, which prompted the regulatory approval of at least three targeted agents (i.e., vemurafenib, dabrafenib, and trametinib).[43,44] Anecdotal experiences with neoadjuvant vemurafenib and dabrafenib have been reported, and evaluations are underway in a number of clinical trials.[45,46]

FUTURE DIRECTIONS IN THE NEOADJUVANT THERAPY OF MELANOMA

Neoadjuvant therapy ideally would be applied in patients with locally advanced melanoma for whom immediate surgery is not feasible, with the goal of allowing definitive surgical resection and improvement in local and regional disease control. In these high-risk patients, neoadjuvant therapy also may target distant micrometastases that may be the source of postoperative distant relapse if systemic therapy was delayed because of surgery or complications related to surgery. Neoadjuvant therapy has improved survival in patients with multiple malignancies, including breast, bladder, cervical, and esophageal cancers.[15,17] Similarly, the rapidly expanding number of effective therapeutic agents and regimens in metastatic melanoma allow for these new agents to be evaluated in the neoadjuvant setting, where significant improvements in clinical outcome are expected. Further, in providing access to biospecimens before and after therapy, such studies are likely to provide significant mechanistic insights and biomarker findings that may have important and lasting impacts on the field of cancer.

Molecularly Targeted Combinations

Initial response rates of approximately 50%, lasting a median of 6 to 7 months, with *BRAF* inhibitor monotherapy were significantly improved to approximately 60% to 70%, and a median duration of response of approximately 9 months, with the combination of *BRAF* and MEK inhibitors.[6,42,43] Overall, *BRAF* and MEK inhibitors have been validated as effective therapies for *BRAF*-mutant metastatic melanoma. This high and unprecedented response rate with *BRAF*/MEK inhibitor therapy makes this regimen an ideal cytotoxic regimen that may improve the operability of locally advanced disease. Relevant to this hypothesis, several studies are ongoing. However, resistance ultimately develops in the majority of patients with metastatic disease, and several resistance mechanisms have been well characterized.[47] Future studies optimizing MAPK pathway inhibition (targeting ERK and CDK4/6 as monotherapy and in combinations) and combinations that target alternate pathways implicated in mediating resistance (e.g., phosphoinositide 3-kinase [PI3K] and AKT), may take advantage of the neoadjuvant approach. Combination studies with immunotherapy (including IFN, IL-2, anti-CTLA4, and anti–PD-1/PD-1 ligand [PDL-1]) that are underway in patients with metastatic disease also may be transitioned into the neoadjuvant setting, supported by the hypothesis that the high response rates seen with *BRAF*/MEK

inhibitors can be transformed into high durable response rates with immunotherapy.[48] Among ongoing targeted neoadjuvant combination studies are trials with vemurafenib/cobimetinib (NCT02303951, NCT02036086) and dabrafenib/trametinib (NCT01972347, NCT02231775).

Intralesional Immunotherapy As Neoadjuvant Therapy

Intralesional therapy of melanoma has consisted of immunotherapeutic approaches that involve cytokines, bacterial extracts, and genetically engineered viral agents. The goals of therapy consist of local tumor regression in injected metastases and induction of systemic immune responses that may affect distant noninjected tumors. Several studies tested intralesional bacillus Calmette-Guérin with promising early reports of local and distant disease control.[49,50] However, these early findings with intralesional therapy were not reproduced in later adjuvant studies, which led to a halt in development.[51] Intralesional injection of granulocyte-macrophage colony-stimulating factor (GM-CSF), IFN alfa, or IFN beta also were tested, and modest clinical activity was found.[52-54] Promising results were reported with intralesional rose bengal (PV-10).[55] A phase II study in stage III/IV melanoma reported an overall response rate of 51%. Responses were seen in both injected and bystander tumor lesions. A phase II study of coxsackievirus A21 in stage IIIC/IV melanoma reported an immune-related PFS at 6 months of 35% and a response rate (by immune-related RECIST 1.1 criteria) of 24%.[56] An intralesional approach involving plasmids coding for the HLA B7 antigen (allovectin-7) showed encouraging early results but did not meet phase III testing endpoints.[57] Talimogene laherparepvec (T-VEC) is an oncolytic immunotherapy comprising a herpes simplex virus type 1 backbone with the gene for GM-CSF. Promising early studies led to a phase III trial that tested intralesional therapy with T-VEC versus GM-CSF in stage IIIB/IV melanoma.[58] Durable and overall response rates with T-VEC were 16.3% and 26.4%, respectively. The median survival times for the study population were 23.3 months with T-VEC versus 18.9 months with GM-CSF (p = 0.051).[58] Overall, intralesional approaches have been relatively safe and well tolerated, with evidence of local and bystander/distant antitumor clinical activity that appears to be most promising with T-VEC at this time. This approach may provide a neoadjuvant therapeutic platform that can be combined with other immune-activating agents, including cytokines and checkpoint inhibitors. Combination studies of T-VEC with anti-CTLA4 and anti–PD-1 antibodies are underway in metastatic disease, and at least one neoadjuvant study with T-VEC monotherapy is planned in resectable regionally advanced melanoma (NCT02211131).

Evaluation of Newer Immune Checkpoint Inhibitors and Combinations

In a recent analysis of 1,861 patients with melanoma who were treated with ipilimumab in clinical trials, 22% were still alive at 3 years, where survival plateaued at a maximum follow-up of approximately 10 years.[59] These data illustrate the potential for cure with ipilimumab that may be more significant in patients

with earlier disease stages treated in the adjuvant and neoadjuvant settings.[31] Targeting PD-1 and PDL-1 in clinical trials has demonstrated early results of significant clinical activity, which has led to the regulatory approval of two potent and highly selective humanized monoclonal antibodies: pembrolizumab and nivolumab.[59,60] These agents have shown an unprecedented rate of durable tumor responses, exceeding 20% to 30% with single-agent immunotherapy.

Efforts in combination immunotherapy have already demonstrated significant results with the combination of ipilimumab and either nivolumab, GM-CSF, bevacizumab, or IL-2 and the combination of IFN alfa and tremelimumab; these efforts have led to subsequent randomized trials.[37,62-65] An impressive 2-year survival rate of 79% was reported recently in an update of the nivolumab/ipilimumab phase I combination trial.[66] Several other combination studies are underway that take advantage of nonredundant immune activation and T-cell differentiation mechanisms. Studies of novel immune checkpoint modulators targeting CD40, OX40, CD137, TIM3, and LAG3, among others, also are ongoing.[67] In addition, combination studies testing checkpoint inhibitors and other proinflammatory cytokines (IL-12, IL-15) are in the planning phases. These agents and combinations currently are being translated into the neoadjuvant setting; ongoing studies involve the combinations of ipilimumab and HDI (NCT01608594) and pembrolizumab and HDI (NCT02339324).

Biomarkers Predictive of Therapeutic Benefit

Aside from targeted therapy for *BRAF*-mutant melanoma, the current paradigm of systemic therapy of metastatic melanoma involves the nonselective treatment of patients with immunotherapy, despite evidence showing that only a proportion will derive significant benefits. Therefore, there is a need for predictive biomarkers that are selected on the basis of their capacity to classify patients according to the degree of benefit from treatment or the risk for significant toxicity.

Neoadjuvant studies that allow access to blood and tumor biospecimens before and after the initiation of systemic therapy provide an ideal platform for investigating such biomarkers that, ideally, can be evaluated simultaneously in the circulation and in the TME according to the common systems of biology.[35] Significant efforts in melanoma biomarker studies are underway, and preliminary data—including gene expression signatures reflective of an inflamed TME that may predict clinical benefit in patients treated with ipilimumab, tumor vaccines, and IL-2—are very promising.[35,40,69] Similarly, exome sequencing studies have elucidated a neoantigen landscape specific for tumors that respond to CTLA-4 blockade.[70] Further, immunohistochemistry studies of CD8 expression at the tumor invasive margin support the predictive value of this biomarker in relation to anti-PD1 therapeutic benefit.[71] Similar efforts are underway that may allow the prediction of patients who are more likely to experience severe immune-related toxicities. Such biomarker and mechanistic studies can be accelerated through neoadjuvant studies, given the access to biospecimens.

CONCLUSION

Neoadjuvant therapy has the potential to improve the outcomes—including survival, surgical resectability, local control, and organ preservation— of patients with locoregionally advanced melanoma. Other advantages are the ability to evaluate the clinical and pathologic responses and the potential to identify immunologic and histologic correlates of tumor response. Access to tumor tissue before and after neoadjuvant therapy may allow a better understanding of the antitumor mechanisms of action that may enable more selective application of therapeutic agents to those patients who are more likely to benefit. Neoadjuvant immunotherapy with HDI and ipilimumab has yielded several important findings, and multiple studies involving newer immunotherapeutic and targeted agents and combinations are underway. Neoadjuvant therapy in melanoma continues to be investigational and should only be pursued in the context of a clinical trial.

Achievements and Challenges of Molecular Targeted Therapy in Melanoma

Ryan Sullivan, MD, Patricia LoRusso, DO, Scott Boerner, MS, and Reinhard Dummer, MD

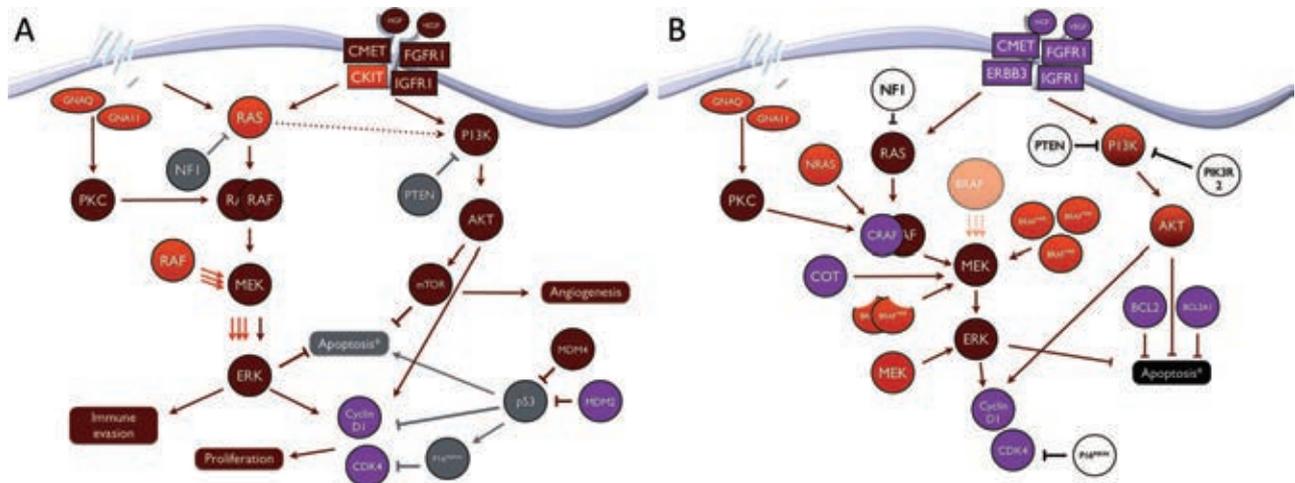
OVERVIEW

The treatment of melanoma has been revolutionized over the past decade with the development of effective molecular and immune targeted therapies. The great majority of patients with melanoma have mutations in oncogenes that predominantly drive signaling through the mitogen activated protein kinase (MAPK) pathway. Analytic tools have been developed that can effectively stratify patients into molecular subsets based on the identification of mutations in oncogenes and/or tumor suppressor genes that drive the MAPK pathway. At the same time, potent and selective inhibitors of mediators of the MAPK pathway such as RAF, MEK, and ERK have become available. The most dramatic example is the development of single-agent inhibitors of BRAF (vemurafenib, dabrafenib, encorafenib) and MEK (trametinib, cobimetinib, binimetinib) for patients with metastatic BRAF^{V600}-mutant melanoma, a subset that represents 40% to 50% of patients with metastatic melanoma. More recently, the elucidation of mechanisms underlying resistance to single-agent BRAF inhibitor therapy led to a second generation of trials that demonstrated the superiority of BRAF inhibitor/MEK inhibitor combinations (dabrafenib/trametinib; vemurafenib/cobimetinib) compared to single-agent BRAF inhibitors. Moving beyond BRAF^{V600} targeting, a number of other molecular subsets—such as mutations in *MEK*, *NRAS*, and *non-V600 BRAF* and loss of function of the tumor suppressor neurofibromatosis 1 (*NF1*)—are predicted to respond to MAPK pathway targeting by single-agent pan-RAF, MEK, or ERK inhibitors. As these strategies are being tested in clinical trials, preclinical and early clinical trial data are now emerging about which combinatorial approaches might be best for these patients.

Traditionally, melanoma has been a challenging disease to treat because chemotherapy is typically not effective and cytokine therapy, such as high-dose interleukin-2 (HD IL-2), only helps a small percentage of patients.[1] Highlighting the futility of early approaches to the development of effective therapies for melanoma, from 1976 to 2011 the U.S. Food and Drug Administration (FDA) approved only dacarbazine and HD IL-2 for the treatment of metastatic melanoma, and neither agent was demonstrated to be associated with an overall survival advantage. Over the past decade, however, great advances in immune-targeted and molecular-targeted therapies have led to a therapeutic revolution. Since 2011, six agents, including three immunotherapies (ipilimumab, pembrolizumab, nivolumab) and three molecular targeted therapies (vemurafenib, dabrafenib, trametinib), have received regulatory approval.[2] The following section summarizes genomic approaches for molecular subtyping, outlines the rationale for molecular targeted therapy in melanoma, and reviews the successes and challenges of this strategy.

Melanoma is a malignancy that arises from melanocytes, the pigment producing cells in the body that may be derived from a number of different anatomic sites including skin, mucosal surfaces, conjunctiva, and uveal structures. With the

emergence of powerful molecular diagnostic tools, a number of genetic mutations and amplifications/deletions have been identified that appear to drive tumor growth and survival signaling and render these cells sensitive to small-molecule inhibitors.[3] The great majority of these genetic aberrations lead to constitutive activation of the MAPK pathway (Fig. 1A).[4] Mutations in the serine-threonine kinase *BRAF*, particularly at the 600 position with substitution of valine with either glutamate (V600E) or lysine (V600K), drive signaling though the MAPK pathway and are present in more than 50% of patients with cutaneous melanoma, 10% to 20% of melanomas arising in mucosal or acral locations, and 0% of uveal melanomas.[5-7] Mutations upstream of BRAF, in particular activating *NRAS* mutations and loss-of-function mutations of neurofibromatosis 1 (*NF1*, a major regulator of NRAS activation), are the MAPK pathway drivers in nearly 30% of melanomas and are typically mutually exclusive of *BRAF^{V600}* mutations.[3,8,9] Interestingly, 20% to 30% of mucosal melanomas harbor either a mutation or genomic amplification of *CKIT*, which is rarely aberrant in cutaneous melanoma, and more than 80% of uveal melanomas contain a mutation in one of two G-protein subunits, *GNAQ* and *GNA11*, also rarely seen in cutaneous melanoma.[10-13] Both *CKIT* and *GNAQ/GNA11*

FIGURE 1. Relevant Signaling Cascades in Melanoma


Multiple mediators and regulators of the MAPK and PI3K pathways have been linked to melanoma. (A) Key oncogenic mutations (red), amplifications (purple), and tumor suppressor genes (gray). (B) Genetic aberrations that mediate resistance to treatment with BRAF inhibitors (driving mutation, red; genomic amplification, purple; and loss of tumor suppressor, gray).

aberrations lead to MAPK signaling.[11,12,14-16] Recently, a number of small-molecule inhibitors have been developed that inhibit many of the key mediators of the MAPK pathway including RAF (pan-RAF and BRAF-specific), MEK, and ERK, as well as upstream activators of the pathway such as CKIT.

GENOMIC APPROACHES TO MOLECULAR DIAGNOSIS AND TARGET DISCOVERY

Early in the development of potent and specific BRAF inhibitors it became clear that only patients with *BRAF* mutations

KEY POINTS

- The great majority of patients with melanoma have mutations in genes (oncogenes and/or tumor suppressor genes) that drive MAPK pathway activation.
- Potent and specific inhibitors of MAPK pathway mediators have been discovered and include BRAF inhibitors (vemurafenib, dabrafenib, encorafenib), MEK inhibitors (trametinib, selumetinib, cobimetinib, binimetinib), ERK inhibitors (BVD-523, GDC-0994), and pan-RAF inhibitors (LY3009120).
- Combination BRAF/MEK inhibition is superior to single-agent BRAF inhibition in patients with *BRAF^V600*-mutant melanoma; a number of trials of BRAF/MEK inhibition plus a third targeted agent are underway to determine whether triplet therapy is superior to BRAF/MEK doublet therapy.
- Single-agent pan-RAF, MEK, and ERK inhibitor therapies may be effective strategies for the treatment of other molecular subsets of melanoma, including uveal melanoma (typically either *GNAQ* or *GNA11* mutant), *NRAS*-mutant, *MEK*-mutant, non-V600 *BRAF* mutant, and *NF-1* loss of function.
- The use of novel molecular targeted therapies, alone or in combination, holds great promise for the treatment of melanoma, but is not without challenges.

were benefiting from these therapies. As a result, both Roche-Genentech and GlaxoSmithKline (GSK) developed companion diagnostics that were used to prescreen patients for the pivotal trials of vemurafenib and dabrafenib, respectively. Whereas the first generation of mutation detection analytics used direct sequencing, both the Roche assay (known as the cobas 4800 BRAF V600 Mutation Test) and the assay developed by GSK (THxID-BRAF test, licensed by Quest Diagnostics and bioMerieux) involve polymerase chain reaction (PCR) techniques—real-time PCR for the cobas assay and amplification refractory mutation system (ARMS)-PCR for the THxID-BRAF assay— using primers designed to quantify predominantly V600E (cobas) or both V600E and V600K (THxID-BRAF).[17,18] Both assays have been shown to be superior to Sanger sequencing, although the cobas assay only detects 70% of V600K mutations whereas the THxID-BRAF test is able to detect these with great accuracy, and both received FDA approval concurrently with vemurafenib (cobas) and dabrafenib (THxID-BRAF).[17-19] However, as described above, a number of additional mutations have been identified that might similarly be targeted with small-molecule inhibitors, including non-V600 *BRAF*, *NRAS*, *CKIT*, and *NF1* loss; thus molecular analysis platforms that can accurately and cost-effectively analyze multiple mutations are required.

A number of novel techniques to target mutant epitopes across relevant genes have been developed, including those that use mass spectrometry (Sequenom) and florescent tags (SNaPshot), but these are now being replaced by massively parallel sequencing techniques that can detect single nucleotide variants, insertions, deletions, and gene rearrangements with deep coverage.[20-22] As these assays become more widely available, the challenge for providers will be to determine how best to utilize the vast amount of information. It is expected that these types of effort will identify small subsets of patients with novel genetic aberrations that predict response to agents not previously used in melanoma.

BRAF^V600 TARGETING, RESISTANCE, AND OVERCOMING RESISTANCE

With the original observation that oncogenic mutations in BRAF were present and driving tumor growth in more than 65% of melanomas (although later the prevalence was determined to be closer to 50%), efforts to therapeutically target BRAF were undertaken.[3,5] Although the initial focus was on small molecules that blocked a wide range of kinases including RAF (sorafenib, RAF265), eventually more potent and specific inhibitors that preferentially targeted mutant isoforms of RAF (particularly at the 600 position) were tested in the clinic and have revolutionized the treatment of BRAF-mutant melanoma.[23-27] Both vemurafenib and dabrafenib were determined to be superior to chemotherapy in phase III trials, as was the MEK1/2 inhibitor trametinib, although unfortunately disease progression typically occurred within 5 to 7 months with single-agent BRAF and MEK inhibitors.[28-30] More recent strategies have demonstrated the safety of combined BRAF/MEK targeting (dabrafenib/trametinib, vemurafenib/cobimetinib, encorafenib/binimetinib), as well as the superiority of the combination with respect to response rate, progression-free survival (PFS), and overall survival (OS) in three randomized trials (COMBI-d, COMBI-v, co-BRIM).[31-36] Unfortunately, innate (primary) and acquired (secondary) resistance remain central obstacles to optimal BRAF-targeting therapy (Fig. 1B).

Tumor Heterogeneity and Innate Resistance

Melanoma primary tumors and metastases are highly heterogeneous with regard to their genomic, epigenomic, and transcriptional profiles. This heterogeneity is hard to explain by the cancer stem cell model. Moreover, many studies suggest that melanomas are not hierarchically organized, but suggest an extraordinary plasticity in several tumor subpopulations that are supported by the microenvironment. Slow-cycling tumor cell populations (such as JARID1B-positive melanoma cells) and tumor cells with an epithelial mesenchymal transition (EMT)-like phenotype (i.e., an invasive mesenchymal phenotype) contribute significantly to tumor maintenance and growth. This plasticity may facilitate a nonhierarchical organization of the tumor that supports adaptation and survival during a major stress situation as the sudden interruption of MAPK signaling.[37] This may explain why BRAF inhibitors cause only limited cell death in vitro and in vivo during targeted therapy. Pretreatment overexpression of antiapoptotic BCL2 family members, namely BCL2 and BCL2A1, has also been associated with resistance to BRAF inhibitors and may be an alternative explanation for the limited apoptosis associated with BRAF inhibitors.[38,39] Other mechanisms of primary resistance include genetic aberrations that lead to cell cycle activation (including cyclin D amplification/expression, p16 loss, and CDK4 activation) or parallel growth factor signaling (PTEN loss).[40-42]

Tumor Heterogeneity and Acquired Resistance

Even after an impressive clinical response, most patients experience progression of disease after months, and sometimes years, of successful tumor control by mono- or combination therapy with single-agent BRAF and/or MEK kinase inhibitors. The range of response duration is quite broad, ranging from weeks to years, and the resistance mechanisms causing the treatment failure have been the subject of intense scientific scrutiny. Based on high-throughput analysis of transcriptional profiles of many primary melanoma cell cultures from different laboratories worldwide, the phenotype-switching model was established.[43] In this context, the transcriptional adaptation induced by interruption of the MAPK pathway by RAF or MEK kinase inhibitors can be interpreted as a shift from the proliferative to the invasive (stem-like, EMT-like) phenotype associated with reduced glucose metabolism.[44] In doing so, melanoma cells will gain time to acquire resistance by the activation of alternative signaling pathways, such as through the selection of tumor cells with additional activating mutations.

Detailed analyses of biopsies before therapy, during tumor regression, and during relapse have provided evidence that adaptive mechanisms, as shown by elevated ERK1/2 phosphorylation levels in progressive lesions, and genomic alterations, such as activating mutations in MEK and NRAS, contribute to reactivation of the MAPK pathway.[45] The first report on this phenomenon described a de novo MEK1 mutation (P124L) in a regrowing metastasis in a patient with BRAF-mutated cancer that was successfully treated with the MEK inhibitor selumetinib.[46] This MEK1 mutation conferred strong resistance to MEK inhibitors and mild resistance to the BRAF inhibitor vemurafenib. Although less frequent, the appearance of a MEK mutation that results in resistance against both BRAF and MEK inhibitors has also been reported.[47] Several investigations have identified concomitant NRAS mutations with the persistence of V600E BRAF.[47-49] This finding is of special interest because BRAF inhibitors may cause paradoxical pathway activation in this molecular context, as demonstrated for cutaneous epithelial malignancies associated with BRAF inhibitors.[50,51] Many of these issues are reflected by the results of deep exome sequencing approaches that compare the genetic landscape before and after targeted therapy.[47] In our understanding, the presence of an NRAS mutation at the time of progression is important because, if it is active, treatment beyond progression might result in a detrimental effect as a result of paradoxical activation of the pathway.

To date, so-called gatekeeper mutations in the kinase domain of BRAF have not been identified; however, BRAF amplification and truncated BRAF variants have been reported to mediate resistance to BRAF inhibitor therapy. Initially, BRAF amplifications were preferentially seen in BRAF-mutated melanoma cell cultures.[52] However, a comparison of pre- and post-treatment biopsies by deep exome sequencing demonstrated that BRAF amplification is associated with progressive disease.[53] Additionally, alterations in BRAF splicing result in a truncated BRAF protein that lacks exons 4 to 8, a region that encompasses the RAS-binding domain and contributes to resistance to BRAF inhibitors through enhanced protein dimerization and activation of the pathway.[54]

Resistance to BRAF inhibitors also has been described to occur through upregulation of parallel signaling pathways, such as the phosphoinoside-3-kinase (PI3K) pathway, or the MAPK pathway itself through alternative kinase activation.[55-57] One example of this latter scenario is resistance mediated through activation of the kinase COT.[58] Bypass signaling can also be facilitated by the tumor microenvironment. Cells derived from the stroma of resistant tumors secrete a number of growth and viability factors that are able to rescue melanoma cells from BRAF inhibition. Among them, hepatocyte growth factor (HGF) appears to a secreted factor that is able to sustain tumor cell growth via activation of the HGF receptor MET in a paracrine manner, leading to tumor upregulation of the PI3K pathway.[59,60] Interestingly, simultaneous amplification of HGF and MET, which suggests an autocrine activation loop, was detected in melanomas with rapid progression during MEK inhibition (Reinhard Dummer, MD, unpublished data, November 2014). Other growth factor receptors can also maintain proliferation during BRAF inhibition. For example, epidermal growth factor receptor (EGFR) is expressed by melanoma cells although the expression level is quite low compared to that in colon or squamous cell carcinomas. In cases of innate or acquired resistance, melanoma cells are able to secrete EGF and activate EGFR by an autocrine loop.[61,62] These observations are convincing examples of how the microenvironment and the secretome of stromal and tumor cells cooperate to create resistance.

Reports that allow to us to link various biochemical mechanisms such as maintenance of an eIF4F complex that is associated with reactivation of MAPK signaling, persistent ERK-independent phosphorylation of the inhibitory eIF4E-binding protein 4EBP1, or increased proapoptotic BCL-2–modifying factor (BMF)-dependent degradation of eIF4G are of special interest because they open new avenues for intervention.[63] Recently, secretion of interferon beta was found to be associated with BRAF inhibition and tumor regression. In cases of resistance, PKCε-phosphorylated ATF2 downregulates interferon beta-1 expression (and signaling), which promotes the resistance of melanoma cells to chemotherapeutic agents.[64]

Strategies to Overcome Resistance

Today, the combination of BRAF and MEK inhibitors is the backbone of targeted therapy in BRAF-mutated melanoma. Depending on resistance mechanisms present in the individual patient, the addition of a third inhibitor might overcome resistance. Candidates for third agents in "triplet regimens" include a cyclin-dependent kinase inhibitor, an receptor tyrosine kinase (RTK) inhibitor (including MET, fibroblast growth factor receptor, or vascular endothelial growth factor inhibitor), an inhibitor targeting a key mediator of a parallel growth factor pathway (e.g., PI3K, AKT, mTOR inhibitors), or an agent targeting apoptosis.[65,66] A major challenge in this context is how reliably the principal mechanism of resistance can be identified in one individual and whether this mechanism is relevant for all metastases in a given patient. In addition, there

could be safety issues as the simultaneous delivery of multiple drugs might be associated with intolerable toxicity.

Moving forward, the integration of antibody therapy with targeted therapy also holds promise for overcoming resistance to current targeted therapy regimens.[67] For example, resistance to BRAF inhibition has been associated with increased MAPK signaling as well as increased expression of programmed death-ligand 1 (PD-L1), enabling melanoma cells to avoid destruction through immune suppression.[68] The combination of immunotherapy against PD-L1 with inhibitors of MAP kinase pathway targets downstream of BRAF, such as MEK, represents a promising novel strategy for overcoming such resistance and improving patient outcomes.[67-69]

Another possible approach to overcome resistance is intermittent therapy with drug holidays. In a xenograft model of primary human melanoma the proliferation of vemurafenib-resistant melanomas became drug dependent, implying that interruption of drug administration could cause regression of established drug-resistant tumors. As a consequence, intermittent dosing delayed resistance to vemurafenib.[70] It remains to be seen whether this observation is relevant for combination kinase inhibitor therapy. This strategy needs to be investigated as an approach to cope with resistance in carefully designed clinical trials.

TARGETING ANYTHING BUT BRAF

As described above, the landscape of mutations, deletions, and amplifications identified in patients with metastatic melanoma has been analyzed as part of The Cancer Genome Atlas. Although the functional significance of each specific mutation has not been determined, there are a number of relatively common mutations that appear to be critical drivers of oncogenic signaling and may be targetable (either directly or indirectly) with small-molecule inhibitors.[3] These include *NRAS* mutations, *GNAQ/GNA11* (detected in less than 1% of all melanomas but more than 80% of uveal melanomas, *CKIT* (detected in less than 6% of all melanomas but enriched in acral and mucosal melanomas), and loss of *NF1*. Not surprisingly, MEK inhibitors have been, and are currently being, studied extensively in these patients. Additionally, newer agents such as pan-RAF and ERK inhibitors have shown preclinical activity in melanoma and have now have entered the clinic and are currently being evaluated in phase I trials (NCT02014116, NCT01781429, NCT01875705).[71-78]

Targeting Uveal Melanoma

Uveal melanoma is a deadly disease that is often associated with metastatic involvement of the liver and lungs despite successful treatment of the primary tumor with surgery or stereotactic radiation techniques. Mutations in *GNAQ* and *GNA11* are present in the great majority of cases and predict signaling through protein kinase C (PKC), the MAPK pathway, and the PI3K pathway. In fact, preclinical evidence supports the use of inhibitors of MET, MEK, PKC, and PI3K/

AKT/mTOR, either as single agents or in combination.[79-87] In the clinic, single-agent MEK inhibition has been tested in a randomized phase II trial compared to chemotherapy (either dacarbazine or temozolomide) in 120 patients with metastatic uveal melanoma and was associated with an improved response rate (14 vs. 0%) and PFS (15.9 vs. 7 weeks, hazard ratio [HR] 0.46, p < 0.001) compared to chemotherapy, but showed no significant improvement in OS (11.8 vs. 9.1 months, HR 0.66, p = 0.09).[88] Building on the single-agent MEK inhibitor data, a randomized phase II trial of the MEK inhibitor trametinib and the AKT inhibitor GSK2141795 (NCT01979523) is currently ongoing. Targeting PKC signaling with the PKC inhibitor AEB071, either as a single agent (NCT01430416) or in combination with a MEK inhibitor (NCT01801358) or PI3K inhibitor (NCT02273219), is another strategy that is being testing in the clinic. Last, a number of trials of MET inhibitors are ongoing and currently enrolling patients with uveal melanoma, including the randomized phase II trial in the Alliance intergroup comparing the MET inhibitor cabozantinib with chemotherapy (NCT01835145).

Targeting CKIT

A number of inhibitors of CKIT have been tested in melanoma, with varying results. The first was a phase II trial of imatinib that enrolled 26 patients with metastatic melanoma independent of mutation or amplification status.[89] In retrospect, it is not surprising that there were no responses to therapy in this initial study; however, in three subsequent clinical trials of imatinib in patients with mucosal or acral melanoma, responses were seen in 17% to 29% of patients.[90-92] Responses were observed in nearly 30% of patients with *CKIT* mutations or amplifications, particularly in either exon 11 or 13. Phase II trials of nilotinib (NCT00788775, NCT01099514, NCT01028222), dasatinib (NCT00700882), and sunitinib (NCT00577382) have either completed accrual or are ongoing.

Targeting NRAS

Activating mutations of *NRAS* are the second most common oncogenic mutations in melanoma and are present in 20% to 30% of patients with cancer associated with MAPK activation.[3,8] As such, targeting mediators of this pathway is a logical approach that is supported by preclinical evidence; pan-RAF inhibitors, MEK inhibitors, and ERK inhibitors all have substantial preclinical activity in these tumors.[71,72,77,78] The MEK inhibitor binimetinib is associated with a 20% response rate and 4.8-month PFS in *NRAS*-mutant patients.[93] Based on these data, a randomized phase III trial comparing binimetinib with dacarbazine is underway (NCT01763164) and positive results would change the standard of care for this patient population. A randomized phase II trial of the MEK inhibitor pimasertib compared to dacarbazine has completed enrollment (NCT01693068).

Despite promising early clinical data, it is clear that the majority of patients with *NRAS*-mutant melanoma will either not benefit, or will only transiently benefit, from treatment with MEK inhibitors.[93] Thus, strategies to overcome either intrinsic or acquired resistance to MEK inhibitors are needed. In a seminal preclinical experiment, Kwong et al performed comparative analysis of *NRAS*-mutant melanoma tumors treated with vehicle, MEK inhibitor, and NRAS extinction. They determined that CDK4 was the top pathway regulator in the MEK-treated model, but not in the NRAS extinction model.[94] In other words, CDK4 expression was identified as a top candidate for mediating MEK inhibitor resistance in *NRAS*-mutant melanoma. Proving this point, dual MEK and CDK4/6 inhibitor therapy was more effective than either agent alone in multiple NRAS xenograft models.[94] Building on this work, a phase I trial of the MEK inhibitor binimetinib in combination with the CDK4/6 inhibitor LEE011 in patients with metastatic *NRAS*-mutant melanoma opened to enrollment and the preliminary data were presented at the American Society of Clinical Oncology's 2014 Annual Meeting.[95] Tumor regression was seen in most patients across all dose cohorts, responses were achieved in 7 of the 22 patients enrolled, and another 11 had stable disease. A similar trial evaluating the combination of trametinib/palbociclib is currently open for patients with all solid tumors (NCT02065063).

Targeting Angiogenesis

Tumor angiogenesis in melanoma has been well documented. Numerous molecules that promote angiogenesis are overexpressed in melanoma, including VEGF, PDGF, fibroblast growth factor (FGF), and interleukin 8.[96,97] Furthermore, their expression is associated with invasion and metastasis in preclinical models and may be associated with worse prognosis in patients with melanoma. Based on these findings and the effectiveness of angiogenesis inhibitors in other cancers (including renal cell carcinoma, breast cancer, and colon cancer), a number of antiangiogenic agents have been tested in patients with advanced melanoma. Bevacizumab, a monoclonal antibody targeting VEGF, has been evaluated in patients with melanoma with the most promising results seen for the combination of carboplatin/paclitaxel/bevacizumab. In an initial phase II trial of 53 patients, 9 (17%) patients achieved a partial response (PR) and an additional 30 (57%) had stable disease for at least 8 weeks.[98] Based on these results, a multicenter, randomized phase II trial was performed evaluating the combination of carboplatin/paclitaxel with or without bevacizumab. Specifically, 214 patients were enrolled via a 2:1 random allocation to receive carboplatin/paclitaxel plus bevacizumab (143 patients) or carboplatin/paclitaxel plus placebo (71 patients). The response rate (25.5 vs. 16.4%; p = 0.16), median PFS (5.6 vs. 4.2 months; p = 0.14), median OS (12.3 vs. 9.2 months; p = 0.19), and 1-year OS (53 vs. 39%; p = 0.06) were all better in patients receiving carboplatin/paclitaxel with bevacizumab; however, none of these findings were significant.[99] The addition of bevacizumab appeared to provide particular benefit with regard to improved OS in patients with M1c disease (HR for OS 0.64; 95% CI, 0.44 to 0.95), especially among patients who had elevated levels of lactate dehydrogenase (LDH; HR 0.53; 95% CI, 0.32 to 0.88).[99] The

TABLE 1. Clinical Trial Results of Targeted Therapy in Genetically Defined Patient Populations

benefit of VEGF pathway inhibition in patients with M1c disease and elevated LDH has been suggested in other trials of antiangiogenic agents, including a phase III trial of carboplatin/paclitaxel with or without sorafenib (E2603) in which patients in this high-risk category showed a trend toward improved PFS and OS.[23,100]

THE PROMISE AND CHALLENGES FOR FUTURE THERAPY IN MELANOMA

Although targeted therapies represent a promising weapon in the armamentarium against melanoma, their effective use in the clinic is not without challenges. As previously mentioned, multiple mechanisms of resistance to targeted therapy, including genomic and phenotypic mechanisms, are observed among different patients, as well as within or between tumors in the same individual. Advanced cancers in particular show a great deal of genetic instability, resulting in the emergence of multiple metastatic clones, each with a different genetic profile and sensitivity to specific treatments.[101-103] Tumor heterogeneity and transcriptional plasticity have been implicated as drivers of resistance to targeted therapy in melanoma and represent a significant challenge to effective treatment of this disease.[103] Increased use of novel targeted therapy combinations in the future may help to overcome both inter- and intratumor heterogeneity by broadening the targeting spectrum and potentially increasing the probability of therapeutic effectiveness.[104] Unfortunately, partial or complete overlap of toxicities is common when taking a combinatorial approach, and must be taken into account when dose escalation rules are chosen. In many cases synergistic

toxicity will result, perhaps caused by nonspecific targets, requiring substantial dose reductions. For example, the combination of the selective MEK 1/2 inhibitor binimetinib with the CDK 4/6 inhibitor LEE01 demonstrated promising antitumor activity in patients with advanced *NRAS*-mutant melanoma, but also resulted in frequent adverse events that necessitated multiple dosing reductions and interruptions.[95] In general, however, combinations that target parallel pathways are less likely to have overlapping toxicity and may be better tolerated, as are agents with greater specificity.[105] For example, the combination of the BRAF inhibitor dabrafenib with the MEK inhibitor trametinib in patients with *BRAF*-mutant melanoma showed a decrease in many class-related toxicities associated with BRAF inhibitors compared to dabrafenib monotherapy.[31,105,106]

As novel targeted therapies continue through development, the translation of preclinical data into the clinical setting is often difficult. Cell lines and animal models may not effectively mimic human tumors, the tumor microenvironment, or immune responses, and may not demonstrate the same mechanisms of resistance. For novel drug combinations, this translation can be fraught with complications if laboratory and animal models used for one class of agents differ from those used for another.

Identifying appropriate biomarkers is critical for the detection, treatment, and monitoring of targeted therapies. Biomarker identification and analysis has typically relied on the use of tumor tissue, which involves a great cost, logistical difficulties, and risk to the patient. The continued development of noninvasive tools such as circulating tumor DNA (ctDNA) will be important for use as a tissue surrogate for a

variety of different solid tumor types and clinical indications, in addition to opening the possibility of regular monitoring of patients and changing treatments as necessary.[108] However, even if clinically relevant biomarkers and actionable mutations are discovered, there may not be a matched agent in development that effectively targets them.

The use of novel targeted combinations is also complicated by the many different motivations of the various stakeholders involved in drug development, including pharmaceutical companies, academic researchers, and regulatory agencies.[105,109,110] All too often, these stakeholders have different priorities, such as intellectual property, conflict of interest, incentives for academics, and publication policies. Different views on these priorities can lead to distrust, a decision not to collaborate, and eventual failure of a project. Lack of collaboration can lead to duplication of efforts and lack of progress, resulting in inefficient use of limited patient and financial resources.[105] Finding a way to satisfy these different priorities is critical in order to move therapies forward in the most efficient manner possible.

CONCLUSION

Although not without challenges, the use of novel targeted therapies in the context of molecular testing has opened new avenues for a precision medicine approach for metastatic melanoma, including a significant benefit already realized for this patient population. In some cases impressive tumor regressions have been demonstrated (Table 1); however, responses are not seen in the majority of patients with non-*BRAF* mutated cancer who are treated with targeted therapy and relapse is frequent in such cases despite combination therapy with BRAF and MEK inhibitors. Intensive translational research has highlighted the complexity of the resistance mechanisms involved and offers opportunities for interventions and improved patient outcomes. There is a need for additional clinical trials accompanied by high-throughput biomarker analyses to further improve these outcomes. Overcoming the scientific challenges, as well as satisfying the priorities of the various stakeholders involved in the development of novel therapies, will be critical for improving the treatment of patients with melanoma.

Treating Older Adults with Cancer: Geriatric Perspectives

Heidi D. Klepin, MD, MS, Miriam Rodin, MD, PhD, and Arti Hurria, MD

OVERVIEW

The proportion of older adults (age 65 and older) in oncology practices continues to increase. Older adults present with unique issues that complicate management decisions and evidence from randomized clinical trials to inform management of these patients is lacking. Despite this, principles of geriatric medicine need to be incorporated into oncology practice to provide optimal individualized care to patients. There is increasing evidence from observational studies that geriatric assessment (GA) strategies can be applied in oncology, can help predict treatment outcomes, and can inform supportive care management for older adults. In this review, we discuss the principles of GA and their use in older adults with cancer. In addition, considerations on when to refer to a geriatrician and issues related to management of vulnerable older adults will be addressed.

The baby boomers began turning age 65 in 2011, leading to a doubling in the U.S. population age 65 and older by 2030.[1] At the same time, life expectancy is increasing. By 2030, the largest growth in the U.S. population will occur among individuals aged 80 and older. This demographic shift correlates with a rise in age-related diseases, such as cancer. The majority of cancer diagnoses and cancer deaths occur in individuals aged 65 and older. A 67% increase in cancer incidence among individuals age 65 and older is predicted to occur from 2010 to 2030.[2] Furthermore, most cancer survivors are older adults, who live with the sequelae of a cancer diagnosis and its treatment in the setting of aging and age-related diseases.

The growth in the number of older adults with cancer and cancer survivors occurs at a time when there is also an anticipated physician workforce shortage. The number of physicians who are specializing in geriatric medicine is decreasing.[3] Furthermore, there are not enough oncologists to care for this growing population of older adults in need.[4] The Institute of Medicine (IOM) report *Retooling for an Aging America: Building the Health Care Workforce* stated: "The health care workforce in general receives very little geriatric training and is not prepared to deliver the best possible care to older patients."[3] Currently, 1% to 2% of physicians and less than 1% of nurses, physician assistants, and pharmacists have geriatric specialization or certification. The IOM report highlighted that "… to meet the health care needs of the next generation of older adults, the geriatric competence of the entire workforce needs to be enhanced … innovative models need to be developed and implemented." This article will review some of the key considerations in caring for an older adult with cancer, including individualizing care for older adults with cancer through utilization of a GA and considerations on when to refer to a geriatrician.

INCORPORATING GERIATRIC ASSESSMENT INTO DECISION MAKING

Care of the geriatric patient (like the pediatric patient) requires a unique skill set. For both the pediatric and geriatric patient, there are age-related changes in physiology that increase vulnerability to toxicity, highlighting the concern regarding long-term effects of therapy. However, there is a unique difference between the geriatric and pediatric populations. For the pediatric patient, chronological age closely mirrors functional age. In contrast, there is a wide heterogeneity in chronological age and functional age in the geriatric patient.

A key part of decision making in the geriatric patient with cancer is to understand the individual's functional age in order to personalize care. A GA is a tool that can be utilized to achieve this goal through an evaluation of key domains predictive of morbidity and mortality risk in older adults, including functional status, comorbid medical conditions, cognition, psychological state, social support, nutritional status, and a review of medications.[5-11] This type of assessment can predict an older adult's life expectancy[8,12-15] and risk for chemotherapy toxicity.[16-20] Importantly, brief GA tools that are primarily survey based can be performed in oncology clinics. Useful chemotherapy toxicity risk scores have been developed from observational studies that can be applied in practice.[17,20] These studies highlighted specific patient char-

acteristics that are independently associated with toxicity and show that the cumulative burden of impairments is prognostic (Table 1). Most importantly, a GA can identify areas of vulnerability and can be utilized to guide interventions. The domains of a GA are reviewed below, with a focus on specific pertinence to the care of older adults with cancer.

Functional Status

A functional status assessment focuses on the need for assistance with daily activities to maintain independence in the home (Activities of Daily Living [ADL]) and in the community (Instrumental Activities of Daily Living [IADL]). Activities of Daily Living include basic self-care skills such as bathing, dressing, toileting, transferring, and maintaining continence. IADL are activities needed to maintain independence in the community such as shopping, taking transportation, preparing meals, doing housework, taking medications, and managing personal finances. Among the geriatric population, the need for assistance with these activities is predictive of overall life expectancy and resource requirement (such as nursing home placement).[21] For the older patient with cancer, understanding the need for assistance with these activities is critical for treatment planning. For example, an integral part of cancer treatment is the use of sup-

portive care medications that are taken at home to minimize treatment side effects. A key part of a geriatric assessment is to evaluate whether the patient can take their medication at the right doses and at the right time. If not, then interventions can be implemented such as engaging family or a visiting nurse to assist. In addition, before prescribing chemotherapy, a transportation plan needs to be discussed. Some chemotherapy side effects, such as fever and neutropenia, can be life-threatening and require immediate attention. Key questions include whether the patient has transportation to clinic visits and whether they have a caregiver to provide transportation if they are not feeling well.

A part of functional assessment is to evaluate for the risk for falls. Falls in older adults account for many hospital admissions and, even without apparent injury, are a warning sign for impending functional decline. Falls can result in immobilization and disablement even if the patient does not sustain a fracture. These risks are even greater in older adults with cancer, especially if there is metastatic disease to bone or use of cancer treatments that accelerate bone loss. Furthermore, cancer or cancer treatments can be associated with platelet disorders and thrombocytopenia. Older adults with cardiovascular disease may already be on anticoagulants, further compounding risk. A fall can cause disastrous intracranial bleeding. Falls are predictable by any of the short directly observed tests of gait and balance that typically take less than 2 minutes and can be built into the patient check-in procedure.[22]

Comorbidity

An assessment of comorbidity is an integral part of cancer treatment planning. It is particularly important for older adults, due to the increased prevalence of multiple chronic conditions with age and the variability of comorbidity burden among similarly aged older adults. First, it can be utilized to assess overall life expectancy and to weigh competing causes of morbidity and mortality.[23] Second, it can be utilized to tailor cancer treatment. Key questions include whether the patient's other medical problems affect the ability to tolerate cancer treatments. For example, in a patient with diabetes, supportive care medications, such as steroids, may exacerbate diabetes. If steroids will be used, education and blood sugar management need to be considered. Furthermore, the choice of chemotherapy may be influenced by diabetic com-

KEY POINTS

- Oncologists need to be familiar with practical strategies to assess physiologic and functional capacity in older patients to inform optimal management.
- Geriatric assessment can predict treatment outcomes.
- Incorporation of geriatric assessment strategies and geriatric medicine consultation can help individualize initial treatment decisions and inform management strategies during the course of treatment and survivorship.
- Dose modification for vulnerable older adults reviewing palliative therapy is common and may optimize therapeutic benefit for some patients.
- Consideration of patient-centered outcomes inclusive of functional independence, health care utilization, and psychosocial health are critical for clinical trial design and to inform management of older adults receiving chemotherapy.

plications. For example, one may choose to avoid chemotherapy drugs that increase the risk for neuropathy (such as taxanes).

Cognition

With aging, there is an increased prevalence of cognitive impairment that poses distinct risks when considering cancer therapy.[24] The findings of cognitive impairment can be subtle and easily missed, but may be unmasked during a stressor such as cancer treatment. Studies suggest that the prevalence of cognitive impairment among older adults receiving chemotherapy may be 20% or greater.[25-27] Even mild cognitive impairment increases the risk for delirium, the risk for being unable to follow instructions for self-management of toxicities, the risk for nutritional depletion, and the ability to communicate important personal information to caregivers. A key component of assessing cognitive function is evaluating capacity for decision making. Even in the setting of cognitive impairment, individuals could have the capacity to make medical decisions if they meet the following four criteria: (1) understands the relevant information, (2) appreciates the situation, (3) uses reason to make a decision, and (4) communicates their choices.[28] Careful attention to cognitive status should be given at every clinical contact. Any abnormality on any of the short screening tools warrants further attention and referral.

It is important to recognize that screening for cognitive impairment may help identify delirium among older patients with cancer, especially during acute illness and treatment stress. Delirium is an acute, fluctuating disorder of attention that is common among acutely ill and postoperative older adults including those on inpatient oncology units.[29,30] Presence of delirium increases the risk for mortality. The agitated form is easily recognized, but the hypoactive form is easily overlooked if there is not a concerted effort to screen. There is some evidence that delirium is preventable with specialized acute care for the elderly teams.[31] Recognition of delirium provides an opportunity to identify and treat underlying causes (commonly infection, medications, or stress) and, potentially, prevent common complications including falls, malnutrition, aspiration, decubitus ulcers, and deconditioning.

Nutrition

Poor nutrition has been identified as a risk factor for chemotherapy toxicity.[17] Some simple screening questions for nutrition can include whether the patient has a low body mass index (less than 22 kg/m^2) or whether they had unintentional weight loss (greater than 5%). Patients with either a low body mass index or unintentional weight loss should be referred for a nutrition consult. Other standardized screening tools such as the Mini Nutritional Assessment can be readily implemented in routine practice.[17] If an older adult with cancer is fatigued or sick, they will need additional family or friend support to prepare meals. Therefore, assessing social support is an important part of the GA.[32,33] National programs such as the Meals On Wheels Association of America could also be implemented for those with inadequate social support.

Psychological State and Social Support

The psychological assessment includes an evaluation for depression, anxiety, and distress. These symptoms can be under-appreciated in older adults and sometimes present in unique ways with more somatic symptoms. Depression is, unfortunately, underdiagnosed in patients with cancer. Older adults were historically reluctant to admit to depression for fear of the social stigma associated with the diagnosis. However, the current generation of older adults was brought up in a different era in which the discussion of emotional states is far more permissive. Nonetheless, depression can go unnoticed in an office or bedside visit focused on somatic symptoms. Short validated tools such as the National Comprehensive Cancer Network Distress Thermometer or the question, "Do you feel depressed?" can facilitate screening and identification of those in distress.[34]

Gauging social support is a critical part of cancer treatment planning.[35,36] Key questions include evaluating whether the patient has both emotional support and tangible support. An example of emotional support is whether the patient has someone to listen to their problems and provide advice. An example of tangible support is whether the patient has someone to take them to the doctor if needed. In addition, one must assess if the patient is a caregiver for someone else, and who in turn will take on that caregiving role if the patient is too ill to do so.

Medication Review

Medication review and reconciliation are a key part of a GA. Older adults often take several medications prescribed by different health care providers, increasing the risk for medication duplications, dosing errors, and drugs inappropriate for older patients.[37-39] Older patients with cancer are taking an average of five medications or more.[25,40,41] Use of multiple medications at the time of chemotherapy treatment may increase the risk for toxicity because of adverse drug events or interactions. Studies investigating the prognostic significance of polypharmacy on treatment outcomes among older patients with cancer have shown mixed results. Most studies that incorporated polypharmacy as a risk factor in the context of a GA have not shown a clear association between number of medications and treatment toxicity.[17,26,42] These study cohorts are typically heterogeneous and include mixed cancer types and varied treatments. In a study of older women with advanced ovarian cancer, use of six or more medications at chemotherapy initiation was associated with decreased survival.[18] A study of older women with advanced breast cancer receiving chemotherapy showed use of five or more medications was independently associated with treatment toxicity.[19] Finally, among older adults with acute myeloid leukemia use of four or more medications at the time of induction chemotherapy was associated with increased early death, lower remission rates, and shorter survival.[43] Taken together, the current data suggest that the implications of polypharmacy may be specific to the clinical scenario and most evident in patients at high risk for toxicity.

Although polypharmacy may be a surrogate marker for unmeasured vulnerability, it also increases the risk for drug interactions during treatment. One study of older patients with cancer identified potential drug problems in 62% of patients with 50% of these rated as moderate or severe.[41] Another study of older adults receiving chemotherapy identified a potential drug interaction among 75% of patients (244 patients) and found an association between potential drug interaction and nonhematologic toxicity.[44] Although much more research needs to be done on this topic, proactive management strategies can be advocated to minimize risks for patients. Careful review of medications, including consideration of discontinuation of any medications without clear indication, may benefit many older adults. This is frequently an overlooked opportunity in oncology practice and may be facilitated by communication with a primary care physician or geriatrician. Use of available drug interaction software can help avoid initiation of new high-risk medications.

COLLABORATION WITH GERIATRIC MEDICINE
Who
There is a referral bias for the healthiest older adults to be referred for cancer treatment. Few clinical trials enroll older adults and those that do preselect for the fittest patients.[45] Until there is sufficient observational experience with a protocol or there are trials specifically designed for older adults, clinical oncologists will have to base judgments on individualized assessments.[46] Most physicians will be able to recognize the frailest patients without special tools. At first presentation these patients may report feeling weak, having little physical activity, and tiring easily. They may report poor appetite and some weight loss that cannot be attributed to the cancer or the cancer treatment.[47-49] The frail phenotype portends loss of organ reserve and loss of homeostatic capacity because of multiple accumulated deficits in many organ systems. In other words, it is not one organ, it is the integration of the systems of organs. Frailty manifests itself, therefore, in syndromes such as delirium, falls, and incontinence.[50]

Under the rubric of patient safety and quality improvement many U.S. hospitals and clinics now use rapid screens built into their electronic health records intake forms that ask straight forward functional questions to identify patients at risk for adverse hospital events, notably falls, delirium, early readmission and functional decline. Questions include: Do you have any visual or hearing problems? Have you fallen? Do you need help getting dressed, bathing, or getting your meals? Do you need help making decisions about your health care or finances? There are several population-validated short geriatric screening tools that have been piloted in geriatric patients with cancer with good predictive value when compared with a GA.[51-53] A screening questionnaire such as the VES-13 or G8 is usually self-administered in 5 minutes. These standardized questionnaires accurately identify older adults who would benefit from a more thorough assessment, coupled with targeted interventions, as part of treatment planning.

The GA has been shown repeatedly to identify older adults at high risk for unexpected treatment toxicity.[20,54,55] By and large, however, it turns out that all of the screening questions are not necessary to identify those at risk. Certain items seem to carry more weight, specifically those focusing on functional limitations in performing higher order activities. These include IADLs, which are those that are required to live alone.[20] In part, this is evidence for the referral bias that prevents the oldest, sickest, frailest patients from presenting to oncology practice. Many of the geriatric tools are designed to make fine distinctions among very frail older adults who may never be referred for cancer treatment. Therefore, the tools that work the best are those that can identify older adults who are functioning well at baseline, but they are doing so by compensating for an underlying deficit, the so-called vulnerable elderly. One study found that only 20% of older adults with a Karnofsky Performance Score (KPS) of 80 or higher performed perfectly on a 3- to 4-minute directly observed test of gait and balance.[56] A similar short observational tool predicted falls in older men attending a prostate cancer clinic.[57] Directly observed performance predicted disability and survival among older adults living in the community with a cancer diagnosis.[58] GA accurately predicted which of 68 older adults enrolled in a dose-escalation study were able to complete the regimen (fit), did not tolerate full-dose therapy (vulnerable), or were unable to complete the study because of excess toxicity (frail.) As expected GA did not predict which specific toxicity was limiting treatment, only that patients had predictable intolerance of symptoms.[59]

When
At present, most studies report on GA or other assessments shortly after diagnosis to predict how older patients will tolerate first-line therapy. However, we would argue that some aspects of the GA should be repeated at each visit. Toxicity is cumulative, and patients often minimize discomfort unless they are directly asked. This is a major part of the rationale for having supportive and palliative care for symptom control and for help in disclosing bad news.[60] Some toxicities, however, may be less obvious, such as delirium, neuropathy affecting gait and balance, drug interactions, depression, and bowel or bladder dysfunction. Very little has been published about the functional trajectory of older adults with cancer even though KPS or Eastern Cooperative Oncology Group (ECOG) Performance Status scores are routinely recorded. As demonstrated in several studies, these scales are global, impressionistic assessments that may miss key items of relevance to the geriatric population.

Where
Several research reports now show that gathering GA data on all older adults and following it with a routine or unsolicited consultation has an effect on cancer treatment decisions; however, several questions remain regarding how to best integrate GA and consultation into oncology care. In a recent systematic review summarizing the effect of geriatric evaluations on treatment decisions, a modification in treatment

plan was prescribed in almost 40% of patients, with less intensive treatment accounting for two-thirds of these plans.[61] In one French study, GA followed tumor board deliberation for the initial treatment of 191 patients older than 70. There was a slight tendency to decrease the intensity of treatment after reviewing the GA findings, but it is not clear from this report how the geriatric consultation was integrated into the final treatment plan.[62] A second French study introduced inpatient GA for hospitalized older adults with cancer.[63] Of 107 patients, the geriatric consultant agreed with the oncology treatment plan 68% of the time. When there was disagreement, approximately half of the time the oncology team ignored the geriatrics recommendations, whereas, the other half of the time the oncology team stepped down the treatment or changed to palliative care in concordance with geriatrics recommendations. Interestingly, a recent meta-analysis of the effect of inpatient geriatric consultation in a general hospital population concluded that the main benefit was to be seen in decreased mortality 6 to 8 months after discharge, not necessarily during the index admission.[64] In other words, it seems that geriatric inpatient consultation can help oncologists identify and plan care for the frailest and sickest patients on the one hand, and help with postacute care and planning as they do with any other hospitalized older adult.

In the outpatient setting, where most cancer treatment is delivered, GA has followed oncology assessment in two recently published reports. One clinic planned to refer all patients with gastrointestinal and lung cancer older than age 70 to the geriatrician for a GA. However, the actual referral rate was only 29%, and only 25% actually completed the appointment. The GA information affected only those patients for whom the oncologist had not decided what to do.[65] We see a different result in a report of geriatric consultation in an outpatient oncology setting in which patients were already receiving their first-line therapy.[66] Of 161 patients older than age 70, 49% had their treatment changed based on the geriatricians' assessment of ADLs, cognitive function, depression, and malnutrition: 34 had less intense treatment and 45 had more intensive treatment after consultation.

Why

Geriatricians anticipate, diagnose, and manage syndromes that do not necessarily involve only one organ, for which there is no diagnostic test, and for which there is ample evidence of increased morbidity, mortality, and disablement. Older patients who have these syndromes, whether at home or in the hospital, may end their lives in nursing homes or suffer other preventable losses in dignity and quality of life.

Current evidence supports the value of geriatric medicine consultation for at least some older adults with cancer. Consultation should be sought when validated screening tools indicate a problem with performing daily activities required for self-care (ADLs) and maintaining a household independently (IADLs). Consultation should be considered for older adults with polypharmacy, particularly in the setting of multimorbidity, frequent falls, and any change in mental status

that could indicate delirium or depression. Before treatment, older adults can be assessed for decisional capacity formally or informally. A rapid gait screening should be performed initially for risk stratification and, subsequently, to monitor risk for falls.

The timing of consultation remains in the hands of the primary oncology team. When oncologists have hesitation to treat and geriatric consultation is easily available, cancer treatment plans may be adjusted, more often toward less aggressive treatment. Hospital-based geriatric consultation can also be beneficial. The assessment of functional status, cognitive status, decisional capacity, physical performance, and emotional well-being should be considered vital signs to be followed throughout cancer treatment. Involving a geriatrician can help lessen the demands on the oncology team and potentially improve treatment outcomes.

THE EVIDENCE GAP BETWEEN RISK ASSESSMENT AND MANAGEMENT

Although there is increasing evidence that vulnerability to treatment toxicity can be predicted for older adults receiving chemotherapy,[17,20,27] there remains an evidence gap between identification of vulnerability and knowledge of how to best manage vulnerable older adults. Unfortunately, most randomized clinical trials are not yet incorporating measurement of vulnerability or frailty to inform which treatment modifications, if any, would optimize outcomes for a given older adult. The remaining sections of this chapter will highlight issues related to chemotherapy dosing and toxicity assessments among older patients in practice.

DOSE MODIFICATION FOR OLDER ADULTS RECEIVING CHEMOTHERAPY

Most published models to predict chemotherapy toxicity among older adults have shown that the risk of grade 3 to grade 5 toxicity for older adults is approximately 50%,[20] with vulnerable and frailer patients likely exceeding these estimates. When considering a treatment decision, the balance between the risk of treatment and its potential benefits often poses a major challenge. Treatment characteristics that have been shown to influence toxicity risk include use of standard-dose chemotherapy and polychemotherapy.[20] Therefore, dose modification is often considered to minimize the negative consequences of therapy on symptoms and quality of life. Because of a scarcity of clinical trial data there remain more questions than answers regarding the benefits and risks of dose modification strategies, particularly in the setting of first-line treatment for advanced cancer.

DOSE MODIFICATION IS COMMON AMONG OLDER PATIENTS WITH CANCER

Available evidence suggests that dose modification is common among older adults treated for cancer. Data from com-

munity practices have shown that increased age is associated with lower relative-dose intensity during adjuvant chemotherapy.[67,68] An analysis of a multisite cohort study enrolling older adults starting a new chemotherapy regimen showed that almost one-third (29%) of the 319 patients with advanced cancer had a dose reduction with the first cycle of chemotherapy. Factors associated with primary dose reduction included older age, a primary diagnosis of lung cancer, and comorbid conditions.[69]

INDICATIONS FOR UP-FRONT DOSE ADJUSTMENT

Physiologic changes associated with aging have implications for chemotherapy toxicity among older adults. Aging is associated with decreased intestinal absorption, changes in volume of distribution, decreased hepatic metabolism, and impaired renal excretion. The degree to which any of these changes occur in an individual and have clinical significance varies among patients of the same chronologic age. Among these, a decline in renal function needs to be considered in dosing. Many chemotherapy drugs are cleared renally and it is well documented that relying on serum creatinine alone will greatly underestimate renal function in older adults. Creatinine clearance should be calculated for all older adults starting chemotherapy treatment to inform dose adjustment for renally cleared drugs. Guidelines exist for recommendations on renal dose adjustment including a position paper published by the International Society of Geriatric Oncology.[70]

Current guidelines do not recommend up-front dose adjustment in the adjuvant setting for older adults because of the potential negative consequences on cancer outcomes and the goals of therapy. In this setting, the treatment decision should be framed around the question, "Do I think my patient can tolerate a standard dose regimen?" Mitigation of toxicity risk in the adjuvant setting may include a choice between standard-dose, single-agent chemotherapy compared with polychemotherapy in certain settings (i.e., colorectal cancer) or two-drug compared with three-drug combinations (i.e., breast cancer). Tailoring choice of regimen and supportive care to the patient's comorbidity profile may also minimize adverse events. For those patients considered unfit for standard-dose treatments, no adjuvant therapy is likely the best alternative. However, in the metastatic setting, our goals of treatment are to balance disease control and quality of life. Alterations in dosing and scheduling of treatments become an important strategy for the management of patients.

CLINICAL TRIAL EVIDENCE FOR DOSE MODIFICATION IN ADVANCED CANCER

Few randomized controlled trials have addressed the risks and benefits of up-front dose modification or treatment schedule modifications (i.e., treatment holidays) for non-fit older adults with advanced cancer, resulting in a paucity of guideline-based recommendations. However, several colon cancer trials directly or indirectly provide some insights into these approaches.

A novel randomized trial published by Seymour et al addressed, in part, the issue of dose reduction in first-line treatment for older adults with advanced stage colorectal cancer. This study used a 2-by-2 factorial design to randomize 459 frail (considered not fit for full-dose combination chemotherapy by their physician) older adults with metastatic colorectal cancer to one of four first-line systemic therapies using an attenuated starting dose (80% of standard).[71] The study design allowed for escalation to full-dose therapy after 6 weeks, if tolerated. Patients (median age 74) were randomly assigned to one of the following arms: (1) 48-hour intravenous fluorouracil (5-FU), (2) oxaliplatin/5-FU, (3) capecitabine, or (4) oxaliplatin/capecitabine. In addition to a quality-of-life questionnaire, a composite outcome termed overall treatment utility was incorporated in an attempt to capture patient and physician satisfaction with the outcome of each treatment decision. Several lessons can be learned from this study. First, recruiting unfit patients to a randomized trial was feasible. Second, few patients achieved dose escalation, with almost half (49%) requiring additional dose reductions. Third, the unique trial design, inclusive of patient-centered endpoints, provided relevant information suggesting that use of oxaliplatin in this attenuated dosing schedule may provide a palliative benefit, whereas, capecitabine may be associated with more toxicity compared with 5-FU. This study provides evidence for considering up-front dose attenuation when treating non-fit older adults with metastatic colorectal cancer, and introduces additional outcome measures to help quantify the palliative benefit of therapy.

Questions regarding optimal dosing schedules, including treatment breaks, for older patients are also common. Again, few studies specifically have addressed this issue in older patients, yet, older patients are most likely to suffer debilitating consequences from ongoing therapy. For colorectal cancer, some data can be extrapolated from existing studies investigating chemotherapy-free intervals (CFI).[72-75] For patients fit enough to initiate combination chemotherapy, evidence would suggest that CFI have minimal effect on overall survival with some potential benefits in quality of life. Although only a fraction of patients enrolled in these studies were older than 75, there is suggestion of similar outcomes among older compared with younger patients when using this strategy.[74] It is reasonable to incorporate these data into treatment planning for older patients in an attempt to minimize the negative consequences of therapy on functional independence and quality of life.

TOXICITY ASSESSMENT: WHAT ARE WE MISSING?

Prediction of treatment outcomes for older adults is hindered not only by the limited number of older adults enrolled in clinical trials, but also by the lack of routine collection of endpoints that better describes the patient experience. Outcomes such as functional independence, health care utilization, psychosocial health, and well-being are typically not measured in trials. In a review of 127 older

patient–specific palliative chemotherapy trials, functional outcomes, health care utilization, cognitive function, and quality of life were reported in 6%, 3%, 6%, and 31%, respectively.[76] Yet many of these outcomes are of concern to patients. Use of GA measures during treatment can provide useful information to inform risk prediction and supportive care. For example, an observational study of 364 adults age 70 or older (77% with ECOG 0 to 1) starting first-line chemotherapy showed that almost 17% experienced a loss of independence defined by a decrease in the ability to complete ADLs after the first treatment.[77] Incorporation of simple assessment measures during treatment in clinical trials and in practice may better inform

management of complications to ultimately improve treatment efficacy and tolerance.

CONCLUSION
Caring for older patients with cancer presents unique challenges. Incorporation of GA strategies can help individualize initial treatment decisions and inform management strategies during the course of treatment and survivorship. Incorporation of GA strategies into clinical trial design will provide needed evidence to optimize therapy for vulnerable and frail older adults.

Chemotherapy-Induced Peripheral Neurotoxicity in Cancer Survivors: An Underdiagnosed Clinical Entity?

Guido Cavaletti, MD, Paola Alberti, MD, and Paola Marmiroli, MD

OVERVIEW

Systemic chemotherapy is a cornerstone of the modern medical management of cancer, although its use is limited by toxicity on normal tissues and organs, including the nervous system. Long-surviving or cured people strongly require a high level of wellness in addition to prolongation of life (the concept of the quality of survival), but neurologic dysfunction can severely affect daily life activities. Chemotherapy-related peripheral neurotoxicity is becoming one of the most worrisome long-term side effects in patients affected by a neoplasm. The central nervous system has a limited capacity to recover from injuries, and it is not surprising that severe damage can determine long-term or permanent neurologic dysfunction. However, the peripheral nervous system also can be permanently damaged by anticancer treatments despite its better regeneration capacities, and the effect on patients' daily life activities might be extremely severe. However, only recently, the paradigms of peripheral neurotoxicity reversibility have been scientifically challenged, and studies have been performed to capture the patients' perspectives on this issue and to measure the effect of peripheral neurotoxicity on their daily life activities. Despite these efforts, knowledge about this problem is still largely incomplete, and further studies are necessary to clarify the several still-unsettled aspects of long-term peripheral neurotoxicity of conventional and targeted anticancer chemotherapy.

Over the last decades, improvement in early diagnosis, precise subtype characterization, and more effective treatment plans allowed clinicians to achieve complete cures or remarkable increases in long-term survival in patients living with cancer in developed countries. For instance, in the period from 1950 to 2010, overall cancer-related mortality adjusted for age decreased in the United States by more than two-thirds in young patients (i.e., younger than age 14), by more than 50% in patients through age 44, and by at least 25% through age 64.[1]

This improvement highlighted an emerging issue in cancer survivors, represented by the persistent side effects of cancer treatment. Among several cancer treatment–related side effects, neurotoxicity can be particularly severe and long lasting and can affect the quality of life (QoL) as well as the daily life activities of cancer survivors.[2,3] The peculiar characteristics and biology of neurons (e.g., high specialization, selective metabolism, incapacity to replicate) and the very limited possibility of the central nervous system (CNS) to effectively recover from severe and extensive damage make CNS neurotoxicity a well-known, critical medical problem. However, despite the better regeneration capacity of the peripheral nervous system (PNS), PNS neurotoxicity also can be severe and permanent.

Although physicians and patients are now well aware of chemotherapy-related PNS neurotoxicity, and although its occurrence generally can be easily recognized, several unset-

tled issue are still present in this field. First, the precise clinical manifestations and their incidence and severity are not always properly assessed, and the several tools used so far have very rarely been validated for this specific use. Second, the pathogenesis of the clinical signs of PNS damage is unknown for most chemotherapy-related conditions. Third, the available pharmacologic and nonpharmacologic strategies designed to limit the incidence and severity of chemotherapy-induced neurotoxicity are not particularly effective in most instances. Finally, the long-term course and reversibility of symptoms and signs have very rarely been investigated so far.[4-9]

Overall, the importance of chemotherapy-related toxicity caused by PNS damage is underestimated. This aspect is becoming increasingly important, and the National Comprehensive Cancer Network has recently expanded its survivorship guidelines to include long-term chemotherapy-induced peripheral neurotoxicity (CIPN).

PATHOGENETIC AND CLINICAL FEATURES OF CHEMOTHERAPY-INDUCED PERIPHERAL NEUROTOXICITY

To achieve a proper understanding of the long-term effects of CIPN, knowledge of the basic pathogenetic and clinical features related to the use of the different neurotoxic dugs is necessary.

The PNS is a common target for the neurotoxicity of several conventional chemotherapy drugs. This is mostly because of the less efficient blood–nervous system barrier in the PNS, namely at the dorsal root ganglia (DRG) level, which allows easy access to nerve fibers and neurons. However, the most recent cancer-targeted drugs also are not completely safe.[6] The peripheral neurotoxicity of both conventional and targeted compounds will be treated separately.

In most cases, CIPN ensuing after conventional treatments consists of dose-dependent, predominantly sensory, length-dependent neuropathies/neuronopathies. More rarely, motor, autonomic, or cranial nerve involvement also can be observed. The conventional drugs associated with CIPN are platinum compounds, taxanes, vinca alkaloids, epothilones, proteasome inhibitors, and thalidomide.

Patients with CIPN can experience negative (i.e., impairment in touch, pin and vibration perception, sensory ataxia with imbalance and falls) as well as positive (i.e., paresthesias/dysesthesias, neuropathic pain) symptoms. All of these symptoms generally develop at limb extremities and then show a distal-to-proximal progression. The frequency, severity, and time course of CIPN can be very variable. In patients with CIPN who are treated with platinum drugs, a peculiar temporal pattern can be observed, which is represented by symptoms that worsen months after chemotherapy suspension—the so-called coasting phenomenon. As it will be discussed later in more detail, it is now clear that CIPN-related signs and symptoms may be long lasting or even permanent. The typical clinical features of CIPN have been extensively reviewed (Table 1).[10-13]

The epidemiology of CIPN is still unclear, and one of the main reasons for this uncertainty is the lack of a gold standard in its assessment.[5] In fact, the reliability and reproducibility of a CIPN assessment in patients with cancer are still unmet clinical and scientific needs. In the past, several methodological issues were not clearly recognized, and different nonvalidated scales were used, which led to conflicting results. Despite these challenges, the proper design of a reliable assessment plan is now easier for patients with CIPN. In this clinical setting, a formal trial (the CI-PeriNomS study) demonstrated the actual reliability of physician-assessed and patient-reported outcome measures in patients with stable CIPN. However, the same demonstration is still missing for the responsiveness to changes during treatment and the clinical meaningfulness of these changes.

Moreover, the markedly different perception of CIPN severity using physician-assessed measures (e.g., the widely used National Cancer Institute Common Toxicity Criteria [NCI-CTC] adverse events scale and the more comprehensive Total Neuropathy Score, clinical version) or patient-reported outcome measures (e.g., the European Organisation for Research and Treatment of Cancer [EORTC] QLQ-C30 and CIPN20 modules) is emerging very clearly. The first methodological study designed to address this relevant issue has been reported recently,[4] and marked differences in perceptions of CIPN by patients versus by treating physicians have been demonstrated.[14] These apparently conflicting results actually represent two sides of the same coin, and they should always be coupled in the planning and interpretation of any study devoted to CIPN investigation or treatment.

CIPN pathogenesis is still unclear for many aspects, and most of the available information relies on the results of preclinical models.

The DRG are the main target of platinum drugs.[11] These drugs cause intrastrand adduct and interstrand crosslink formation with a subsequent alteration of the tertiary structure of the DNA in DRG neurons. They also cause cell-cycle kinetics alterations: postmitotic DRG neurons would reenter into the cell cycle and be induced into apoptosis.[15] Other pathogenetic hypotheses have been proposed, which involve oxidative stress, mitochondrial dysfunction, reduction in the activity of enzymes involved in DNA base excision, repair of oxidative damage, redox regulation, and cellular transport.[16-18]

The most obvious mechanism of PNS damage by taxanes is related to their hyper-polymerizing action on microtubules. In the axons, microtubule disruption can lead to interference in axonal transport, which eventually affects the integrity of sensory neurons. A dying-back process that starts from distal nerve endings and is followed by disturbed axonal flow has been demonstrated in models of CIPN associated with taxanes.[19] However, macrophage activation in both the DRG and the peripheral nerve, and microglial activation within the spinal cord, also have been demonstrated.[20] In an animal study, paclitaxel-induced swelling and vacuolation of axonal mitochondria in A and C fibers was demonstrated.[21]

Competition studies with paclitaxel demonstrated that epothilones might act on the same or on an overlapping binding site on tubulin. Kinetic experiments revealed that epothilones are competitive inhibitors of paclitaxel binding to the tubulin polymer. On this basis, it is likely that taxanes and epothilones share the same mechanism of damage.[11]

Vinca alkaloid neurotoxicity is probably related to their ability to inhibit microtubule functions and disrupt the cytoskeleton.[11] In neurons, vinca alkaloids prevent tubulin polymerization

KEY POINTS

- Anticancer chemotherapy can permanently damage both the central and the peripheral nervous systems, but the mechanism(s) of this toxicity is largely unknown.
- The recognition of chemotherapy-induced peripheral neurotoxicity is simple, if education is provided and a high level of attention is maintained.
- Chemotherapy-induced peripheral neurotoxicity is probably an underestimated clinical problem in cancer survivors.
- Patients' and health-care providers' perceptions of the severity of chemotherapy-induced peripheral neurotoxicity may be very different, as demonstrated by recent studies focused on this highly relevant issue.
- No effective treatments are available for alleviating persistent symptoms of chemotherapy-induced peripheral neurotoxicity.

TABLE 1. Typical Clinical Features of Chemotherapy-Induced Peripheral Neurotoxicity Associated with Standard Chemotherapeutic Agents

Drug	Typical Symptoms/Signs
Platinum	
Cisplatin	Early reduction/loss of DTR
	Distal, symmetric, upper- and lower-limb impairment/loss of all sensory modalities
	Sensory ataxia and gait imbalance are frequent
	Neuropathic pain can be present, but it is not frequent
	Coasting* phenomenon is frequent
Carboplatin	Similar to cisplatin but milder
Oxalipatin	Acute
	Cold-induced transient paresthesias in mouth, throat, and limb extremities
	Cramps/muscle spasm in throat muscle, jaw spasm
	Chronic
	Very similar to cisplatin
Bortezomib	Reduction/loss of DTR
	Mild to moderate, distal, symmetric loss of all sensory modalities occurs. Small myelinated and unmyelinated fibers are markedly affected, leading to severe neuropathic pain.
	Mild distal weakness in lower limbs is possible
Taxanes (paclitaxel, docetaxel)	Reduction/loss of DTR
	Myalgia syndrome is frequent (as an atypical neuropathic pain?)
	Distal, symmetric, upper and lower limb impairment/loss of all sensory modalities
	Gait unsteadiness is possible because of proprioceptive loss
	Distal, symmetric weakness in lower limbs is generally mild
Epothilones (ixabepilone, sagopilone)	Signs and symptoms are similar to taxanes, but neuropathic pain is less frequent, and recovery is reportedly faster
Vinca alkaloids (vincristine, other compounds with similar but much lower neurotoxicity)	Reduction/loss of DTR
	Neuropathic pain/paresthesia at limb extremities is relatively frequent
	Distal, symmetric, upper and lower limb impairment/loss of all sensory modalities
	Distal, symmetric weakness in lower limbs progressing to foot drop
	Autonomic symptoms (eg, orthostatic hypotension, constipation) may be severe
Thalidomide	Reduction/loss of DTR
	Relatively frequent neuropathic pain at limb extremities
	Mild to moderate, distal, symmetric loss of all sensory modalities
	Weakness is rare

Abbreviations: DTR, deep tendon reflexes.
*Coasting = worsening of signs/symptoms of neuropathy over months after drug withdrawal.

from soluble dimers into microtubules, which leads to axonal swelling and alteration of the axonal transport.[22] The different affinity for tubulin shown by vinca alkaloid compounds (vincristine affinity > vinblastine > vinorelbine > vinflunine) might explain the distinct neurotoxic profile of these drugs.[11]

DRG neurons, satellite cells, and nerve fibers also are targets of bortezomib toxicity.[23,24] In animal models, bortezomib causes a severe DRG neuronal dysfunction that not only inhibits proteasome activity but also alters transcription, nuclear processing and transport, and cytoplasmic translation of mRNA.[25] In the peripheral nerves, histopathologic and neurophysiologic findings demonstrate a dose-dependent damage of B and C fibers with abnormal vesicular inclusion bodies in unmyelinated axons.[23,24] Mitochondrial and endoplasmic reticulum damage and dysregulation of

neurotrophins, caused by either activation of the mitochondrial-based apoptotic pathway or inhibition of the transcription of factors necessary for neuron survival, also have been reported.[26] Recently, increased tubulin polymeration has been demonstrated in cultured DRG neurons and in animal models.[27,28]

Despite the evident neurotoxic effects of thalidomide,[29] no convincing pathogenetic explanation for thalidomide neurotoxicity has been provided, and its more recent and highly active derivatives lenalidomide and pomalidomide are definitely less neurotoxic.[30]

At the moment, no effective preventive or curative strategy is available for the treatment of CIPN, as documented by a systematic Cochrane review of platinum drugs.[31] A focused American Society for Clinical Oncology (ASCO) expert panel extended this review substantially to the

other neurotoxic drugs, with the same disappointing results.[32]

Conventional chemotherapy has limitations in its effectiveness, and it is associated with potentially severe side effects as a result of damage to normal tissues, as shown for CIPN. To overcome some of these problems, a transition to rationally designed, molecularly targeted drugs, which aims at a much more specific effect on cancer cells and a sparing of normal tissues, has occurred in chemotherapy. Several of these targeted drugs are now used routinely. Different from chemotherapy with curative intent, cancer-targeted drugs also are used as continuous administration after treatment response, and maintenance therapy can be continued in cases of tumor progression to prevent uncontrolled growth. Although these drugs are generally considered safer and less toxic than conventional chemotherapy, off-target toxicities (e.g., neurotoxicity) may emerge, particularly during prolonged use.

Although the literature evidence is still limited and data are somewhat inconsistent, PNS toxicity has been described. Moreover, because cancer-targeted therapies frequently are used after or in combination with conventional chemotherapy, the possibility that their use could worsen the toxicity profile of standard neurotoxic chemotherapy drugs also should be considered. In Table 2, examples regarding the possible peripheral neurotoxic effect of cancer-targeted drugs are reported.

Also, the pathogenesis of cancer-targeted drugs effects on the PNS is largely unknown. It has been suggested that some of their neurotoxic effects are a result of the capacity to interact with the immune system. For instance, five of a series of 85 patients treated with alemtuzumab developed a progressive sensorimotor radiculoneuropathy and/or a myelitis.[33] Moreover, in 2010, another case of acute inflammatory polyradiculoneuropathy (Guillain-Barré syndrome) was reported in an alemtuzumab-treated patient.[34] In these cases, it has been hypothesized that alemtuzumab may trigger an autoimmune cascade that results from indiscriminate dysregulation of regulatory T cells or from a molecular mimicry.

In addition to the immune-mediated effect on the PNS, clinical pictures compatible with classical CIPN also have been described with cancer-targeted drugs. The administration of brentuximab vedotin can be associated with a dose-dependent peripheral neuropathy that can limit prolonged administration of the drug. In phase I studies, cumulative dose-related peripheral neuropathy, probably associated with unconjugated microtubule inhibitor monomethyl auristatin E (i.e., the active part of the molecule acting as the classical chemotherapy drugs) was clinically relevant; 37% of patients showed persistent symptoms, which led to drug discontinuation in 25% of patients.[35] In another study, 73% of patients treated with brentuximab vedotin developed peripheral neuropathy, mostly mild to moderate, and similar data were replicated in phase II studies.[36] However, dramatic motor neuropathy also has been associated with brentuximab vedotin use.[37]

It can be concluded that careful monitoring that is based on a formal neurologic assessment of the possible PNS toxicity of all of these new drugs is mandatory to ascertain in prospective clinical trials their real toxicity profiles, alone or in combination treatments.

EVIDENCE OF LONG-TERM PERSISTENCE OF CHEMOTHERAPY-INDUCED PERIPHERAL NEUROTOXICITY

The previously accepted paradigm that CIPN, in nearly all cases, is a reversible clinical condition has recently been challenged by several studies performed mainly in patients with breast, colorectal, and ovarian cancer, in which the use of neurotoxic drugs is frequent and survival for greater than 5 years is increasingly frequent.

TABLE 2. Examples of Peripheral Neurotoxicity of Targeted Agents Used in Cancer Therapy

Drug	Reported Previous Neurotoxic Treatment	Description of Peripheral Nervous System Toxicity
Alemtuzumab	None	Progressive peripheral sensorimotor radiculoneuropathy and/or myelitis
Brentuximab vedotin	Previous chemotherapy (undefined)	Peripheral sensory neuropathy: any grade in up to 66%; grade 3 in up to 8%
		Peripheral motor neuropathy: any grade in up to 11%, grade 3 in up to 7%
Carfilzomib	Lenalidomide or thalidomide	Treatment-related neuropathy: any grade in up to 17%; rarely grade 3
Ibritumomab	CVP or COP or CHOP	Paresthesias: grade 1 in up to 13%
Imatinib	Cytarabine	"Pain in limbs": any grade in up to 11%; grades 3-4 in up to 1%
Ipilipumab	Carboplatin	Guillain-Barré syndrome
Lapatinib	Taxanes, vinorelbine	"Pain in extremities": any grade in up to 13%; grade 3 in < 1%
Regorafenib	Oxaliplatin	Sensory neuropathy: any grade in up to 7%; grade 3 in < 1%
Rituximab	CHOP (first-line), ProMACE CytaBOM (second-line)	Guillain-Barré syndrome
	None	Guillain-Barré syndrome
Sorafenib	Previous chemotherapy (undefined)	Treatment-emergent sensory neuropathy: grades 1-2 in up to 20%
Vemurafenib	Previous chemotherapy (undefined)	Peripheral neuropathy: any grade in up to 10%; grade 3 in 1%
Vorinostat	Previous chemotherapy (undefined)	Cutaneous polyneuropathy (tingling) was reported as leading to discontinuation

Abbreviations: CVP, cyclophosphamide, vincristine, prednisone; COP, cyclophosphamide, vincristine, prednisone; CHOP, cyclophosphamide, doxorubicin, vincristine, prednisone; ProMACE CytaBOM, cyclophosphamide, doxorubicin, etoposide cytozar, bleomycin, vincristine, methotrexate, prednisone.

The availability of large registries of patients with cancer who were carefully observed—such as the Patient-Reported Outcomes Following Initial Treatment and Long-Term Evaluation of Survivorship (PROFILES) registry—has allowed investigations on the persistence of CIPN-related long-term effects in several cancer types and, therefore, on the relationship existing with different treatments.

In patients with colorectal cancer treated with oxaliplatin, Park et al reported the persistence of CIPN symptoms in 79% of patients after a median follow-up of 29 months; after a similar period, in a different study, Gramont et al reported more than one-fourth of the patients with NCI-CTC grade 3 CIPN still had symptoms.[38,39] The prevalence of NCI-CTC grades 1 to 3 CIPN was 24% after 18 months in the Multicenter International Study of Oxaliplatin/Fluorouracil/Leucovorin in the Adjuvant Treatment of Colon Cancer (MOSAIC) clinical trial.[40] Analyzing the PROFILES data, Mols et al evaluated the features of long-term CIPN-related symptoms in 500 survivors of colorectal cancer treated with chemotherapy assessed with the EORTC CIPN20 scale,[41] a patient-reported outcome that is based on separate instrument reporting for sensory, motor, and autonomic symptoms. In the study, the persistence of CIPN-related symptoms was demonstrated for up to 11 years after treatment. A different analysis confirmed that symptoms more frequently reported were tingling in toes and feet (30%), numbness in toes and feet (19%), tingling hands or fingers (15%), and burning or shooting pain in toes or feet (13%).[42] Dose-intensity was not associated with a worse neurologic outcome, although it was related to the oxaliplatin cumulative dose, and this association also occurred for trouble in standing or walking.

Improvement in surgery and the use of multimodal therapies in patients with ovarian cancer has allowed clinicians to achieve a 5-year survival rate of greater than 40% in this population.[43] In a study performed with a cohort of 116 patients with ovarian cancer, investigated at a median of 501 days after the end of treatment, 62% of the 100 responders reported the presence of peripheral neuropathy (according to EORTC questionnaires), and 29% defined them as significant intensity.[44]

EFFECT OF CHEMOTHERAPY-INDUCED PERIPHERAL NEUROTOXICITY ON THE QUALITY OF LIFE OF CANCER SURVIVORS

The number of cancer survivors and of patients in whom cancer has become a chronic disease is increasing in Western countries, and these people strongly require considerations about the effect of long-term toxicities on QoL. From this perspective, CIPN is likely to be one of the main survivorship issue.

However, only a few well-conducted analyses have been performed to quantify the real extent of the problem, and different methodological approaches have been used, which make a reliable comparison very difficult. Mols et al performed a systematic review of the available literature and found 11 studies that assessed the relationship that exists between CIPN and QoL.[45] Eight of these studies reported an association, whereas three failed to observe any association be-

tween CIPN and QoL. Because at least two of the three negative studies had substantial methodological flaws, the overall conclusion drawn from the review is that CIPN is very likely to be negatively associated with QoL in cancer survivors.

In a study that was not included in the previous review by Mols et al, Tofthagen et al investigated a cohort of patients treated with oxaliplatin up to 7 years after treatment and observed that 89% of them reported at least one symptom of neuropathy;[45,46] among these patients, 24% had difficulties in driving and 60% in exercising. All of the subscales of the short-form (SF)-36 were significantly associated with the presence and severity of CIPN, but no objective assessment of CIPN presence was included in the study design.

Another study was reported in 2014 by Ezendam et al,[47] who investigated a cohort of patients with ovarian cancer by using two EORTC QoL scales; the results demonstrated that CIPN symptoms were significantly associated with QoL impairment. However, because a quarter of the women who did not receive neurotoxic chemotherapy were affected by peripheral neuropathy symptoms, this result, in the absence of any objective evaluation, raises some concern about the validity of the selected assessment tool to really detect CIPN.

A specific and underestimated aspect of long-term CIPN is the possibility that neurologic impairment might cause an increased propensity to fall. This concern was raised originally by Tofthagen et al in 2012 in a small series of patients with cancer and CIPN; 20% of them had fallen recently.[48] An increased incidence of falls had already been reported in patients with cancer and in older populations.[49] Gewandter et al investigated a cohort of 471 patients with CIPN; 27% of participants reported functional impairment (e.g., difficulty in shopping or in doing common tasks necessary to live in their home independently), whereas 12% had a fall in the 3-month period preceding enrollment on the study.[50] When these results were analyzed in relation to the type of CIPN, motor neuropathy was significantly associated with falls, which suggests that, in the study cohort, taxanes used as breast cancer treatment were responsible for these events.[50]

HEALTH CARE PROVIDERS AND LONG-TERM CHEMOTHERAPY-INDUCED PERIPHERAL NEUROTOXICITY

The relationship existing between patients with cancer and their health-care providers is somewhat complex. Patients experience several different side effects, and an accurate discrimination of the contribution of CIPN to overall toxicity might be difficult. Moreover, patients often are worried by the possibility that effective treatment could be modified because of side effects. A study of 1,425 patients with cancer who had different malignancies demonstrated that patients often underreported their symptoms to health-care providers;[51] when a comparison was performed between the hospital notes and the patient interviews, the data did not correspond for the majority of the patients.[44] With specific reference to CIPN, moderate/severe symptoms were re-

ported by 29% of patients, whereas symptoms of any severity were reported by only 12% of patients according to the hospital notes that referred to follow-up visits. Conversely, health-care providers sometimes are insufficiently educated and trained to recognize the earliest evidence of CIPN. Moreover, with reference to this specific aspect, the possibility that long-term CIPN might be managed by primary care physicians and not only by oncologists should be considered. A survey fielded in 2009 and recently published revealed that long-term CIPN induced by paclitaxel was recognized by only 27% of primary care physician and the percentage was even lower (22%) for oxaliplatin-treated cancer survivors.[52] These results are not surprising, because no specific education and training are provided outside the oncology and neurology fields to recognize CIPN. However, with the aging population, cancer (and treatment-related toxicities) in the primary care setting are very likely to increase in the future.

Recent studies report a desire among patients for better information and support related to long-term/persistent treatment-related toxicities as well as greater awareness of these side effects among health care providers.[53]

CONCLUSION

The cure of cancer frequently is based on complex, hazardous, and toxic treatments, which are accepted because of their potential life-saving effects. However, cancer survivors deserve and ask for the best possible quality of survival after cancer treatment, particularly over the long term. Unfortunately, in several instances, this need is still unmet. Among the reasons for this situation, the insufficient knowledge of the pathogenesis of cancer treatment–related neurotoxicity is definitely one of the most important issues.

To achieve a better understanding of chemotherapy-induced neurotoxicity, accurate preclinical studies might provide very useful suggestions, but the translation of their results into the clinical setting is sometimes difficult. On the clinical side, a very important contribution to better knowledge of cancer treatment–related neurotoxicity could come from a more homogeneous, reliable, and systematic collection of the clinical data of treated patients. This will highlight similarities and differences between treatments to identify early predictors and to clarify individual susceptibilities to neurotoxicity that might represent invaluable clues to drive research into the proper direction and, eventually, provide reliable guidelines to manage CIPN.

The final aim of these investigations is to offer patients with cancer the possibility to be treated with affordable neurotoxicity or, at least, to provide them effective treatments. To this aim, a virtuous alliance among patients and treating physicians is needed. In fact, physicians should be trained not only at the use of treatments but also at the recognition and proper assessment of the first signs of neurotoxicity, and patients should be made aware of it to report early symptoms with the common goal of preventing irreversible damage.

Challenges to Standardizing the Care for Adult Cancer Survivors: Highlighting ASCO's Fatigue and Anxiety and Depression Guidelines

Ann H. Partridge, MD, MPH, Paul B. Jacobsen, PhD, and Barbara L. Andersen, PhD

OVERVIEW

There are over 14 million survivors of cancer living in the United States alone and tens of millions more worldwide, with this population expected to nearly double in the next decade. The successes of prevention, early detection, and better therapies have lead to an emerging understanding of the substantial medical and psychosocial issues for this growing population that must be tackled for individuals and from the health care system and societal perspectives.

There are over 14 million survivors of cancer living in the United States alone and tens of millions more worldwide, with this population expected to nearly double in the next decade. The successes of prevention, early detection, and better therapies have lead to an emerging understanding of the substantial medical and psychosocial issues for this growing population that must be tackled for individuals and from the health care system and societal perspectives.

The major components of survivorship care include (1) surveillance for recurrence and new primary cancers, including consideration of genetic risk predisposition; (2) prevention, monitoring for, and management of long-term and late effects of cancer and cancer treatment, including medical and psychosocial issues; (3) counseling and assistance for optimizing health behaviors; and (4) coordination of care to assure that patients receive the appropriate evidence-based follow-up care from the appropriate provider at the right times.[2,3] Increasing awareness and delivery of this care in a patient-centered, proactive manner in our already overburdened health system has proven to be quite a challenge. This is, in part, because standardizing the care for survivors of cancer poses unique and substantial hurdles. Although individual patients have varying and diverse needs in all medical settings, cancer comprises myriad diseases necessitating a wide range of therapeutic interventions and associated risks in follow-up with diverse recommendations for care. Tailored proactive survivorship care planning is one potential solution to this issue, yet the resources, efforts, changes in standard conventions of care required, and the limited data demonstrating their value have limited their uptake to date.[4-6]

Another major and related issue is that cancer research to date has predominantly focused on improving disease control and cure rates. Relatively little dedicated research has centered on survivorship concerns. And much of the available data to inform the care of survivors has been observational from therapeutic clinical trials without patient-reported outcomes or from large databases with little granularity. Further, there have been few prospective studies, limited intervention research, and even fewer randomized trials of interventions to improve care and outcomes for survivors. Thus, the sparse evidence base to guide the care of survivors has generally led to heterogeneous follow-up and care concerning most issues for cancer survivors. And even in the few settings where enough data exists to inform evidence-based, systematic guidelines, they are not routinely followed.[7]

Finally, survivorship care in its infancy has suffered from a prior lack of prioritization.[8] Just like the treatment of most cancers, a one size fits all approach does not work for cancer survivorship care. Most recently, risk-based care has been advocated for targeting the appropriate care to individual patients, from the appropriate provider, at the most optimal times in the cancer care trajectory.[9] To address these needs, researchers, clinicians, and advocates worldwide have been working to define cancer survivors' needs and determine how to optimally deliver the care to meet them. Formalized in 2011, the American Society of Clinical Oncology's (ASCO's) Survivorship Committee aims to deliver high-quality survivorship care to enhance patients' long-term health by managing concerns related to cancer treatment and survivorship.[10] The committee offers educational opportunities and clinical guidance on survivorship care, including an array of guidelines focused on specific survivorship concerns,

Corresponding author: Ann H. Partridge, MD, MPH, Dana-Farber Cancer Institute, 450 Brookline Ave., Boston, MA 02215; email: ahpartridge@partners.org.

including anxiety, depression, and fatigue. In addition to this growing body of guidelines, the ASCO Cancer Survivorship Compendium is a repository of tools and resources to enable oncology providers to implement or improve survivorship care within their practices. This manuscript highlights two of the first guidelines that have emerged from the dedicated work of ASCO's Survivorship and Clinical Practice Guidelines Committees, surrounding fatigue, anxiety, and depression as targetable, treatable symptoms that are highly prevalent in cancer survivors.

CANCER-RELATED FATIGUE GUIDELINES

Fatigue is one of the most common and distressing symptoms of people undergoing cancer treatment.[11] In addition to fatigue during treatment, approximately one-third of patients will go on to experience persistent fatigue for months or years following the completion of their treatment.[12] As part of a larger effort to address symptom management and quality-of-life issues in post-treatment cancer survivors, ASCO's Cancer Survivorship Committee organized an expert panel charged with formulating a new clinical practice guideline or endorsing or adapting an existing guideline for screening, assessment, and management of post-treatment fatigue in survivors of adult-onset cancers.

The panel began by searching literature to determine whether guidelines existed that it could endorse or adapt. Based on the search and prespecified evaluation criteria,[13] the panel chose to adapt a 2011 pan-Canadian practice guideline for screening, assessment, and care of cancer-related fatigue.[14] This guideline was also informed by recommendations from the Oncology Nursing Society (ONS) and the National Comprehensive Cancer Network (NCCN).[15,16] The panel also considered two NCCN guidelines that had been created or updated since 2009.[17,18] The resulting adapted guideline was published in the *Journal of Clinical Oncology* in 2014.[13] The ASCO-adapted guideline is organized into an algorithm that specifies recommendations for screening, comprehensive and focused assessment, laboratory evaluation, treatment care options, and ongoing monitoring and follow-up.

KEY POINTS

- Standardizing survivorship care poses unique challenges.
- Increased awareness and prioritization of survivors' issues is necessary.
- A growing array of recommendations and tools are becoming available to improve survivorship care.
- Fatigue is a common effect that should be screened for and managed.
- Routine anxiety and depression screening in cancer survivors should lead to improved psychosocial outcomes.

Overview of the Clinical Algorithm for Cancer-Related Fatigue

Screening. The primary recommendations for screening are to screen all patients for fatigue at their initial visit, at appropriate intervals during and following treatment, and as clinically indicated; and to screen using brief self-report measures with established cutoff scores. One recommended way to screen is through use of a simple 0-to-10 numeric rating scale (0, no fatigue; 10, worst fatigue imaginable), where mild fatigue is indicated by scores of 1 to 3, moderate fatigue is indicated by scores of 4 to 6, and severe fatigue is indicated by scores of 7 to 10. The guideline further recommends that patients who report moderate to severe fatigue undergo a comprehensive and focused assessment.

Comprehensive and focused assessment. The primary recommendations for comprehensive and focused assessment are to conduct a focused fatigue history that evaluates the various features of the patient's experience of fatigue (e.g., associated or alleviating factors); to consider the possibility of disease recurrence; and, in the absence of disease recurrence, to assess treatable factors that may be contributing to fatigue (e.g., comorbidities, medications, nutritional issues). When conducting this assessment, the primary clinical team must decide when referral to an appropriately trained professional (e.g., cardiologist) is needed. Laboratory evaluations may also play a role in a comprehensive and focused assessment based on the presence of other symptoms and the onset and severity of fatigue. Possible laboratory evaluations include a complete blood cell count with differential and a comprehensive metabolic panel.

Treatment and care options. Regardless of the reported level of fatigue, the guideline recommends that all patients be offered education about fatigue after treatment (e.g., information about the difference between fatigue that is normal in most individuals following exertion or lack of sleep and cancer-related fatigue) and advice about general strategies to help manage fatigue (e.g., self-monitoring of fatigue). These issues may be further confounded in our aging population, including patients with cancer, and therefore cancer survivors as well. For patients reporting moderate or severe fatigue, the guideline first recommends treating contributing factors identified as part of the comprehensive and focused assessment. For example, the assessment may suggest that the patient's fatigue can be addressed by treating their sleep problem or pain problem. Beyond this action, the guideline indicates that patients with moderate to severe fatigue may benefit from physical activity, psychosocial, mind-body, or pharmacologic interventions. At present, there are no clear standards for selecting among these interventions to treat an individual patient, and research is needed about how best to prioritize, sequence, and link the available treatment options. The guideline contains specific recommendations for each type of intervention based on a review of existing guidelines and a re-

cent literature review. Readers may also wish to review a recent ONS update on evidence-based interventions for cancer-related fatigue.[19]

Ongoing monitoring and follow-up. For patients who received treatment for fatigue, the guideline recommends that they be observed and re-evaluated regularly to determine whether treatment has been effective or needs to be readdressed. For patients who did not receive treatment for fatigue, the guideline recommends promotion of ongoing self-monitoring and screening at follow-up visits since fatigue can still emerge as a late effect.

Challenges and Opportunities for Implementing the Cancer-Related Fatigue Guideline

Many of the challenges in implementing this guideline will be similar to those identified for the broader challenge of implementing survivorship care plans. One important issue is the significant time and resources required to develop care plans.[10] Proposed solutions for this problem included development of automated, programmable applications to expedite the process.[10] Another important issue is health care providers' concern that they possess insufficient knowledge of cancer survivor issues to adequately address them.[20] Efforts to address this issue should include dissemination of the guideline and related information in formats and forums desired by providers. With regard to the current guideline, ASCO University recently posted a brief web-based educational program summarizing the recommendations.[21] Other challenges more specific to fatigue include the lack of documentation about fatigue levels and the lack of supportive care referrals for providing interventions for fatigue. Documentation can potentially be improved by introducing routine symptom screening using electronic methods (e.g., computer kiosks or tablets) that deliver the information collected immediately to clinicians for review and action.[22] Finally, referrals can be facilitated by identifying in-house or community resources that can provide relevant interventions. Also, it may be possible to deliver certain interventions to patients remotely via the Internet.[23]

ANXIETY AND DEPRESSION GUIDELINES

ASCO provided practice recommendations adapted from the Pan-Canadian guideline on Screening, Assessment, and Care of Psychosocial Distress (Depression, Anxiety) in Adults with Cancer,[24] which addressed the optimum screening, assessment, and psychosocial-supportive care interventions for adults with cancer who are identified as experiencing symptoms of depression and/or anxiety.

The ASCO panel underscores that health care practitioners implementing the guideline recommendations should first identify the available resources in their institution and community for the treatment of anxiety and depressive anxiety

symptoms. The availability and accessibility of supportive care services for all are important in preventing or reducing the severity of symptoms of psychopathology. As a minimum, practitioners should verify with their institution or local hospital the preferred pathway for care of an individual who may present with a psychologic or psychiatric emergency. Presented first are the recommendations applicable to both anxiety and depressive symptom presentations, followed by the considerations unique to each.

General Recommendations

Screening. All patients should be screened for psychologic symptoms at their initial visit, at appropriate intervals, and as clinically indicated, especially with changes in disease status (e.g., post-treatment, recurrence, progression) and when there is a transition to palliative and end-of-life care. Screening should be done using valid and reliable measures of anxiety or depressive symptoms that feature reportable scores (dimensions) that are clinically meaningful (established cutoffs). A phased screening and assessment that does not rely simply on a symptom count from the screening measure is recommended. Consider the need to use culturally sensitive measures. Tailor further assessment or treatment for those with learning disabilities or cognitive impairments.

Identification or determination of the presence or absence of pertinent history or risk factors is important for interpretation of the screen and decision making for subsequent follow-up assessment. Other concerns that may become evident with screening, such as risk of harm to self and/or others, severe anxiety or agitation, or the presence of psychosis or confusion (delirium) requires referral to a psychiatrist, psychologist, physician, or equivalently trained professional for emergency evaluation. Facilitate a safe environment and one-to-one observation, and initiate appropriate harm-reduction interventions to reduce risk of harm to self and/or others.

Follow-up assessment. When moderate-to-severe or severe symptomatology is detected through screening, individuals should have a diagnostic assessment to identify the nature and extent of the symptoms and the presence or absence of anxiety disorder(s) or mood disorders. The clinical team must decide when referral to a psychiatrist, psychologist, or equivalently trained professional is needed for diagnostic assessment. The clinical team should share responsibility for assessments, designating those who are expected to conduct assessments as per scope of practice. If a patient needs a referral for the treatment of anxiety or depression, discuss with the patient the reason(s) for and anticipated benefits from the referral. Further, the clinical team should subsequently determine the patient's compliance with the referral.

Treatment. Medical (e.g., unrelieved symptoms such as pain and fatigue, or delirium brought on by infection or electrolyte imbalance) or substance abuse causes of anxiety or

depression should be treated first. Offer support and provide education and information about anxiety or depression and its management to all patients and their families, and explain the specific symptoms or symptom worsening that warrant a call to the physician or nurse.

Psychologic and psychosocial interventions should derive from relevant treatment manuals of empirically supported treatments specifying the content and guiding the structure, delivery mode, and duration. Use of treatment outcome measures should be routine (minimally pre- and post-treatment) to (1) gauge the efficacy of treatment for the individual patient, (2) monitor treatment adherence, and (3) evaluate practitioner competence.

Special Considerations: Depressive Symptoms and Mood Disorders

Screening for symptoms. The Patient Health Questionnaire-9 (PHQ-9) is recommended for depression screening. The first two items assess for the classic symptoms of low mood and anhedonia. If a patient endorses either item (or both) as occurring for more than half of the time or nearly every day within the past 2 weeks (i.e., a score of ≥ 2), he or she should complete the remaining items of the PHQ-9.[25,26] It is estimated that 25% to 30% of patients would need to complete the remaining items. The traditional cutoff for the PHQ-9 is 10 or greater. The panel's recommended cutoff score of 8 or greater is based on study of the diagnostic accuracy of the PHQ-9 with cancer outpatients. A meta-analysis by Manea et al also supports the 8 or greater cutoff score.[27] As suggested for screening, it is important to determine the associated sociodemographic, psychiatric or health comorbidities, or social impairments, if any, and the duration that depressive symptoms have been present.

Follow-up assessment. If moderate-to-severe or severe symptomatology is detected, individuals should have a diagnostic assessment to identify the nature and extent of the depressive symptoms and the presence or absence of a mood disorder. The assessment should also identify the severity of cancer symptoms (e.g., fatigue), possible stressors, and risk factors for depression.

Treatment for mood disorders. It is recommended to use a stepped care model and tailor intervention recommendations based on variables such as the following:
- Current symptomatology level and presence or absence of *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5) diagnosis.
- Level of functional impairment in major life areas.
- Presence or absence of risk factors.
- History of and response to previous treatments for depression.
- Patient preference.
- Persistence of symptoms following receipt of an initial course of depression treatment.

For severe levels of depressive symptoms or a diagnosed mood disorder, use pharmacologic, psychologic (e.g., psychotherapy, psychoeducational therapy, cognitive-behavioral therapy, and exercise) or combined treatment delivered by appropriately trained individuals.[28-38] Depressive disorders have special characteristics.[34,35] Many individuals (50% to 60%) with a diagnosed depressive disorder will have a comorbid anxiety disorder, with generalized anxiety being the most prevalent.[39] If an individual has comorbid anxiety symptoms or disorder(s), the route is usually to treat the depression first. Also, some people have depression that does not respond to an initial course of treatment.

Follow-up and reassessment. Persons with depressive symptoms commonly lack the motivation necessary to follow through on referrals and/or to comply with treatment recommendations. With this in mind, on a biweekly or monthly basis until symptoms have remitted, consider the following:
- Assess follow through and compliance with individual or group psychologic or psychosocial referrals, as well as satisfaction with these services.
- Assess compliance with any pharmacologic treatment, patient concerns about side effects, and satisfaction with the treatment's symptom relief.
- If compliance is poor, assess and construct a plan to circumvent obstacles to compliance or discuss alternative interventions that present fewer obstacles.
- After 8 weeks of treatment, if symptom reduction and satisfaction with treatment are poor despite good compliance, alter the treatment course (e.g., add a pharmacologic intervention to a psychologic, change the specific medication, refer to individual psychotherapy if group therapy has not proved helpful).[34,35,40]

Special Considerations: Anxiety Symptoms and Disorders

Screening for symptoms. Anxiety disorders include specific phobias and social phobia, panic and agoraphobia, generalized anxiety disorder (GAD), obsessive compulsive disorder, and post-traumatic stress disorder. It is recommended that patients be assessed for generalized anxiety disorder, as it is the most prevalent of all anxiety disorders and commonly comorbid with others, primarily mood disorders or other anxiety disorders (e.g., social anxiety disorder).[39]

The GAD-7 scale is also recommended. Patients with GAD do not necessarily present with symptoms of anxiety. The pathognomonic GAD symptom—multiple excessive worries—may present as concerns or fears. Whereas cancer worries may be common for many, GAD worry or fear may be disproportionate to actual cancer-related risk (e.g., excessive fear of recurrence, worry about multiple symptoms, or symptoms not associated with current disease or treatments). Importantly, an individual with GAD has

worries about a range of other noncancer topics and areas of his or her life.

Follow-up assessment. The assessment should identify signs and symptoms of anxiety (e.g., panic attacks, trembling, sweating, tachypnea, tachycardia, palpitations, sweaty palms), severity of symptoms, possible stressors (e.g., impaired daily living), risk factors, and times of vulnerability and should also explore underlying problems or causes. If a patient has severe symptoms of anxiety following the further assessment, when possible, confirm an anxiety disorder diagnosis before initiating any treatment options (e.g., DSM-5, which may require making a referral).

Treatment for anxiety disorders. For a patient with moderate anxiety, the primary oncology team may choose to manage the concerns using typical supportive care management. In addition, the team can use a stepped care model to tailor any additional intervention recommendations based on variables such as the following:

- Current symptomatology level and presence or absence of DSM-5 diagnoses.
- Level of functional impairment in major life areas.
- Presence or absence of risk factors.
- Chronicity of GAD and response to previous treatments, if any.
- Patient preference.

If anxiolytic therapy is used, patients should be informed of the side effect profiles of the medications, tolerability of treatment (including the potential for interaction with other current medications), response to prior treatment, and patient preference. Patients should be warned of any potential harm or adverse effects—particularly about the long-term use of benzodiazepines in the treatment of anxiety. These medications carry an increased risk of abuse and dependence and are associated with side effects including cognitive impairment. As a consequence, use of these medications should be time limited in accordance with established psychiatric guidelines.[41]

Follow-up and reassessment. Because cautiousness and a tendency to avoid threatening stimuli are cardinal features of anxiety pathology, persons with symptoms of anxiety commonly do not follow through on referrals or treatment recommendations. With this in mind, the mental health professional or other member of the clinical team managing the patient's anxiety should assess the following on a monthly basis or until symptoms have subsided:

- Follow through and compliance with individual or group psychologic or psychosocial referrals, as well as satisfaction with the treatment.
- Compliance with and pharmacologic treatment, patient's concerns about side effects, and satisfaction with the symptom relief provided by the treatment.[2,34,42]

If medications are used, consider tapering if symptoms are under control and if the primary environmental sources of anxiety are no longer present. Longer periods of tapering are often necessary with benzodiazepines, particularly with potent or rapidly eliminated medications.

If compliance is poor, assess and construct a plan to circumvent obstacles to compliance, or discuss alternative interventions that present fewer obstacles. After 8 weeks of treatment, if symptom reduction and satisfaction with treatment are poor despite good compliance, alter the treatment course.

SUMMARY OF ANXIETY AND DEPRESSION GUIDELINES

As noted in the 2008 Institute of Medicine report, *Cancer Care for the Whole Patient: Meeting Psychosocial Health Needs*, and confirmed in a recent report,[43] the psychologic needs of patients with cancer are not being addressed, posing a serious problem for U.S. health care. If psychologic needs are not addressed, regardless of when they arise, they then predict later stress and anxiety,[44,45] depressive symptoms,[46] low quality of life,[47] and increased side effects with treatment and more physical symptoms.[48-51] Alternatively, treatment for either anxiety or depression can successfully address issues such as these[31,52] and has the potential to reduce the risk of recurrence[53] or cancer death.[48-50,54]

Overall, mood disorders are associated with lower quality of life and soaring health care costs.[55,56] Patients with cancer who are depressed worry about their disease (70%), relationships with friends (77%), the well-being of family members (74%), and finances (63%),[57] and the sequelae of this includes more symptom distress[58-60] and maladaptive coping,[61] among others. Depression in particular is associated with heightened risk for premature mortality (recurrence risk = 1.22–1.39) and cancer death (recurrence risk = 1.18).[50,62] Two studies have now documented increased rates of suicide among populations of long-term survivors of breast and testicular cancer.[63,64]

Anxiety is the most common mental health issue for long-term cancer survivors.[65] Heightened anxiety is associated with increased side effects and symptoms[66] and poorer physical functioning.[67] Worry, the hallmark of GAD, can be multifocal[68] with content shifting over time from treatment concerns to physical symptoms and limitations.[69] Be it stress, anxiety, or worry, all are related to important neuroendocrine changes,[70] which may account, in part, for the poorer survival among patients with cancer who have heightened stress.[71]

The majority of patients with cancer do well, manifesting remarkable resilience at diagnosis, treatment, and thereafter. Regardless of the timing and circumstances by which any psychiatric comorbidity may arise, patients can experience enormous emotional, interpersonal, and financial costs, and providers and the health care system alike can encounter economic consequences when depressive and anxiety disorders are not treated. Screening and early, efficacious treatment for those manifesting significant symptoms of anxiety or depression holds the potential to reduce the human cost of cancer, not only for patients and survivors but also for those who care for and about them.

Sexual Healing in Patients with Prostate Cancer on Hormone Therapy

Leslie R. Schover, PhD

OVERVIEW

Since prostate cancer becomes more common with age, at least one-third of men have sexual problems at diagnosis. All localized treatments for prostate cancer greatly increase the prevalence of sexual dysfunction, which include loss of desire, erectile dysfunction, and changes in orgasm. Even men on active surveillance have a higher rate of problems than matched peers without prostate cancer. However, men given androgen deprivation therapy (ADT) have the worst rates of sexual dysfunction. Even after 3 to 4 months of ADT, men's desire for sex is decreased and irreversible damage may occur to the erectile tissue in the penis. Erections do not recover in about one-half of men, even if ADT is discontinued. Although intermittent ADT allows some recovery of sexual function, serum testosterone requires 9 to 12 months off ADT to recover. Again, one-half of men have permanent erectile dysfunction. If ADT causes atrophy of the erectile tissue, blood leaks out of the venous system during erection. This syndrome is difficult to treat except with surgery to implant a penile prosthesis. Despite the high rate of sexual problems in men on ADT, a small group stays sexually active and is able to have reliable erections. To improve men's sexual satisfaction on ADT, it may be important to educate them about getting extra mental and physical sexual stimulation, as well as using penile rehabilitation during hormone therapy. Information on reaching orgasm and coping with problems such as dry orgasm, pain with orgasm, and urinary incontinence during sex also should be provided.

In 1998 I spoke about sexuality for men with prostate cancer and their partners at a large symposium at the University of Michigan. Only about 5 minutes of my 25-minute talk was devoted to sexual function and androgen deprivation therapy. I acknowledged that most men noticed a decrease in their desire for sex, had difficulty getting and keeping erections, and required more effort to reach an orgasm. However, I pointed out that as many as 20% of men had satisfying sex with a partner at times, although it took more mental and physical stimulation to get aroused and have an orgasm. Men with erection problems also might still enjoy sex enough to get medical or surgical treatment to improve their erections. The next day, a woman told me how important my presentation was to her and her husband. During his 3 years on hormone therapy, they never had sex. His oncologist said it would not be possible. My talk inspired them to go back to the hotel and try. The result was a very satisfying session of lovemaking that included intercourse with a firm erection and orgasms for both partners.

Such instant cures have not been common during my career, but this incident highlights the importance of providing men and their partners more optimistic, though accurate, expectations about sexuality during hormone therapy. Our culture tends to believe that hormones have absolute power to control sexual desire and function instead of seeing them as one factor in the complex interaction of sexual beliefs and experiences, relationship issues, and skills in coping with a chronic illness.

This article summarizes what is known about men's sexual function during androgen deprivation therapy for prostate cancer and suggests options to help men and their partners maintain more active sex lives if desired.

SEXUAL FUNCTION IN MEN WITH PROSTATE CANCER

One-third to one-half of men already have sexual dysfunction at the time of prostate cancer diagnosis. Prevalence increases with aging and comorbid disease.[1-3] In addition, all current treatments for localized prostate cancer, including active surveillance, greatly increase rates of sexual dysfunction. Men randomly assigned to active surveillance or radical prostatectomy in the Scandinavian Prostate Cancer Group Study were compared to matched controls.[4] At 12-year follow-up, 84% of men who had a prostatectomy, and 80% of men on active surveillance, but only 43% of controls had erectile dysfunction (ED). Although 28% of men on surveillance began androgen deprivation therapy (ADT) in the interim, and others had progressive disease, ED may increase with damage to the neurovascular bundles from repeated

Corresponding author: Leslie R. Schover, PhD, Department of Behavioral Science, The University of Texas MD Anderson Cancer Center, Unit 1330, PO Box 301439, Houston, TX 77230-1439; email: lschover@mdanderson.org.

prostate biopsies.[5] Similarly, ED rates a year after diagnosis of localized prostate cancer in 771 Norwegian men were 76% in those on surveillance, 89% after radical prostatectomy, 83% after radiotherapy, and 84% after combined radiotherapy and hormone therapy.[6]

Sexual and urinary function in men diagnosed with prostate cancer were significantly worse than in healthy controls in the Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial in the United States (p < 0.001).[7,8] Side effects persisted across 10 years of follow-up. More than 95% of men in each cancer treatment group reported sexual dysfunction and 50% had urinary or bowel dysfunction. Diagnosis by prostate-specific antigen (PSA) screening theoretically could downstage the cancer, but screening reduced neither long-term mortality nor rates of sexual, urinary, or bowel complications.

ANDROGEN DEPRIVATION FOR PROSTATE CANCER AND ITS EFFECT ON SEXUAL FUNCTION

Androgen deprivation therapy has been used in a variety of ways to treat patients with prostate cancer over the past 70 years, ever since the discovery that signaling from androgen receptors in prostate cancer cells is responsible for at least some of the proliferation and recurrence of disease.[9] However, even when ADT succeeds in controlling cancer cells that are sensitive to hormones, cancer progression may take place because of clones of cells that are less dependent on androgens. Second-line hormone treatment with drugs such as abiraterone or the androgen blocker enzalutamide also has been shown to be beneficial even when first-line ADT has failed.[9]

Androgen deprivation therapy, whether with bilateral orchiectomy, luteinizing hormone-releasing hormone agonists or antagonists, helps treat prostate cancer symptoms in men

KEY POINTS

- Men with prostate cancer have a high prevalence of sexual dysfunction because of age, comorbidities, and damage from definitive treatment for localized disease.
- Androgen deprivation therapy adds to the problem because of the loss of hormone stimulation in the brain and direct damage to the erectile tissue.
- Men who have good sexual function at the time of prostate cancer diagnosis and who are in a sexual relationship with a partner who wants to stay active are more bothered by the sexual dysfunction.
- Preventing and treating problems may involve counseling the man or couple on how to achieve more intense sexual stimulation, how to improve sexual communication and avoid performance anxiety, and how to decide whether to try a treatment to restore better erections.
- Men who have sex with men have some special issues, including a greater emphasis on the sensual qualities of semen at ejaculation and sometimes a need for a more rigid erection to allow anal penetration.

with metastatic disease and may prolong survival,[10] but it also increases the risks of cardiovascular disease, osteoporosis, and sexual dysfunction.[10] It remains unclear if using ADT as neoadjuvant treatment before radical prostatectomy prevents recurrence in men with high-risk disease, although benefits in survival have been demonstrated from combining ADT with external beam radiation therapy in this patient subgroup.[10] It has become increasingly clear, however, that ADT as a monotherapy is inferior to active surveillance in older men with organ-confined prostate cancer, causing morbidity but not prolonging survival.[11,12]

Rates of sexual problems are high among men on ADT. These problems include a decreased desire for sex, difficulty getting and keeping erections, reduced semen volume, trouble reaching orgasm, and distress about gynecomastia and feminization of fat distribution.[13] Many men surveyed already had definitive local treatment with radical prostatectomy or radiation therapy. Their sexual function was severely damaged before the onset of ADT, making it difficult to attribute additional problems to hormone therapy.[4,6,8,14-16] Nevertheless, sexual function is poorer in men who had past or current ADT when compared to men only treated with surgery or radiation therapy.[17-19] Even after 3 or 4 months of ADT, damage to erectile function is likely to be permanent because of alterations to the smooth muscle in the cavernous bodies of the penis. During erection, despite adequate arterial inflow of blood, the veins draining blood from the erectile tissue are not occluded and penile rigidity cannot be maintained.[19] ADT also impairs nocturnal erections, which may be important sources of oxygenated blood to the penis after localized prostate cancer treatment by helping nerves to heal and maintaining the health of endothelial cells in the erectile tissue.

Men who rate their degree of distress or "bother" about sexual dysfunction as greater also report more depression and poorer quality of life.[16] Not surprisingly, men are more bothered by sexual problems if they are younger and have better sexual function when diagnosed with prostate cancer or starting ADT, and if their relationship is more satisfying (i.e., they have more to lose).[2,3,16] Distress about sexual problems also is associated with more caregiving stress and poorer quality of life in the spouses of men diagnosed 3 years previously with prostate cancer.[20]

Some men are given double-blockade therapy by adding an androgen blocker to ADT. Although survival benefits of double blockade are dubious,[10,21] drugs such as finasteride or bicalutamide may directly damage the smooth muscle inside the cavernous bodies, increasing the risk of venous leak and irreversible erectile dysfunction.[22]

INTERMITTENT ANDROGEN DEPRIVATION THERAPY

Another issue is whether intermittent hormone therapy is as effective as continuous ADT in prolonging survival while maintaining better quality of life, including recovery of sexual function during time off ADT.[23] Two recent, large phase III trials suggest that intermittent ADT is equivalent to con-

tinuous ADT in prolonging survival in men who have a rising PSA after definitive treatment for local disease, while allowing somewhat better quality of life.[22] In men with metastatic disease, mean survival was slightly longer (5.8 vs. 5.1 years) when continuous ADT was used, but the clinical significance of the results is not very convincing.[23]

Men often remain profoundly hypogonadal for months after ADT is withdrawn, especially if they are older or have had several cycles on and off ADT.[22] Not surprisingly, recovery of quality of life, including sexual function, is correlated with serum testosterone levels. Typically, about one-half of men recover better erections when off ADT, but only a minority remains sexually active after several months. The rate of sexual inactivity may be even greater for men who have metastatic disease.[24] The structural changes in the erectile tissue of the penis related to ADT or androgen-blocking drugs may contribute to men's discouragement about sexual function. Continuing impairment of sexual desire and arousability related to central nervous system effects undoubtedly also play a role.[25]

One of the largest prospective trials to measure sexual function during intermittent ADT was a phase II cohort study of 250 men treated with a combination of flutamide and leuprolide for 9 months, with subsequent times off treatment over 2 years if the PSA was 4 ng/mL or less.[26] About one-half had biochemic recurrence after definitive localized treatment; others had locally advanced or metastatic disease at diagnosis. As expected, sexual function already was impaired at baseline, with 57% reporting erection problems, 47% low desire, and 46% sexual inactivity. All self-report measures deteriorated over the 9 months of ADT and only 13% remained sexually active. During their time off ADT, 52% of men sexually active at baseline resumed sex and all reported improved erectile function. However, 9 to 12 months off ADT was necessary to reach optimal recovery. Although desire for sex and feeling masculine improved during time off ADT, these outcomes remained poorer than at baseline. Approximately 15% of men who continued having sex during ADT reported adequate erections. The authors did not report factors that may identify the subgroup of men who maintain fairly normal sex lives during ADT, but the author's clinical experience suggests that younger age, a strong desire for sex at prostate cancer diagnosis, and being in a relationship with good sexual communication are all good prognostic factors.

INTERVENTIONS TO MAINTAIN SEXUAL SATISFACTION IN MEN ON ANDROGEN DEPRIVATION THERAPY

As the anecdote at the beginning of this article suggests, an important factor in helping men maintain sexual activity and satisfaction during ADT is to provide positive, although realistic, expectations. Not all men or their partners have a strong desire to stay sexually active, especially if ADT that began after definitive therapy for localized disease already impaired erections.

For those who want a sex life, I often cite a classic study demonstrating that hypogonadal men have more trouble than men with normal hormone levels in getting subjectively aroused or achieving erections if they are asked to generate their own sexual fantasy.[27] However, when shown an erotic film, their arousal and erections are similar to those of eugonadal men. Thus, it is likely to take both extra physical caressing and mental sexual stimulation for a man to experience arousal or to get the best possible erection when on ADT. I counsel men and their partners to put a priority on time for intimate touching, rather than waiting for spontaneous desire. A sensate focus framework helps partners regard sexual caressing as a time to share intimacy rather than an occasion to demonstrate sexual performance.[28]

Men who begin with good erectile function may benefit from penile rehabilitation using medical treatments for erectile dysfunction, such as oral medication, vacuum erection devices, or penile injections several times a week to ensure a regular supply of oxygenated blood to the erectile tissue.[29] The utility of penile rehabilitation during ADT has not been studied yet in a randomized trial.

Some men are not able to maintain firm erections even if they want to be sexually active, and can get subjectively aroused, because of damage to the smooth muscle and venous occlusion mechanism in the erectile tissue. This erection problem is unlikely to be treated successfully with oral, phosphodiesterase-5 inhibitors, a vacuum erection device, or penile injection therapy. It may require surgery to implant an inflatable penile prosthesis.[30] Motivation to have surgery is often related to the importance sexuality is in a man's life and his current relationships status. Men who have sex with men may need a more rigid erection to achieve anal penetration, which also could make a penile prosthesis attractive.[31] Some men switch from preferring to be the partner who penetrates anally to being the anal receptive partner as a way to get sexual pleasure despite erectile dysfunction.

With or without firm and reliable erections, men can still experience the sensation of orgasm during or after ADT, but it may require more intense sexual stimulation over a longer period of time than before. For partners, the effort to help a man reach orgasm can turn sex from a pleasurable sharing of intimacy into a work session. I often encourage couples to incorporate vibrator stimulation into their sexual caressing. A vibrator provides a different and intense type of sexual pleasure with less effort than prolonged manual or oral stimulation of the penis. For men who enjoy vaginal or anal penetration, vibrators that mimic the sensation are available. Other options include the Viberect, a medical-grade vibrator that can vary the frequency and intensity of stimulation, or high-tech vibrators that provide a range of types of physical sensations. If partners are open to watching erotic videos during sex, the extra mental stimulation may help a man to get as aroused as possible. If the couple finds that the use of erotic films has a negative effect on their intimacy, the man can watch a video just before starting sexual activity with a partner.

Since the prostate and seminal vesicles produce the liquid components of semen, men who have had radical prostatectomy have dry orgasms that include pleasurable sensations and muscle contractions, but without semen coming out of

the penis.[32] After external beam radiotherapy or brachytherapy, semen volume is often greatly reduced. Since dihydrotestosterone in the prostate regulates semen production, even men who begin ADT without prior definitive treatment of local prostate cancer usually have greatly reduced semen volume. Men often believe that women can feel semen spurting into the vagina during intercourse. In fact, most women do not miss having semen at ejaculation. Some women feel more comfortable giving a man oral stimulation if he has dry orgasms. In gay couples, however, loss of semen volume is more often viewed as making sex less sensual and enjoyable.[31] Other changes in orgasm after prostate cancer treatment may include less intensity and pleasure, pain at the moment of orgasm, or after radical prostatectomy, leaking urine during sexual arousal or orgasm.[32] Putting a tension ring at the base of the penis that occludes the urethra during sex can be helpful when leaking urine bothers a man or his partner.[33]

THE ROLE OF EXERCISE IN MAINTAINING SEXUAL SATISFACTION

The focus on energy balance in preventing prostate cancer and in promoting better quality of life after prostate cancer has led to randomized trials that add aerobic/strength training exercise for men starting ADT. Despite the well-documented morbidities of ADT on cardiovascular metabolism, fat distribution, and bone density, trials have often failed to prove a significant effect of exercise on quality of life in men on ADT.[34] A well-designed study that randomly assigned men to usual care versus exercise for 6 months after radical prostatectomy found improvements in physical fitness in the intervention group, but no impact on recovery of erectile function.[35] Recently a pilot study of only 57 men on ADT compared usual care to an exercise intervention group. The study found that the exercise group was significantly more likely to be sexually active after a 12-week program (p = 0.024).[36] However, only 21% of the exercise group men were sexually active at baseline compared to 17% at the end of the brief treatment. In the usual care group, rates of sexual activity were 22% at baseline and 0% post-treatment.

A review of the literature on prostate cancer and sexual function suggests that the best outcomes occur with multidisciplinary care that addresses physiologic damage to the sexual response as well as a man's coping skills and relationships.[28] If he is in a committed relationship, including the partner is also helpful.

Bone Health in Adults Treated with Endocrine Therapy for Early Breast or Prostate Cancer

Catherine H. Van Poznak, MD

OVERVIEW

Bone is a hormonally responsive organ. Sex hormones and calcium regulating hormones, including parathyroid hormone, 1–25 dihydroxy vitamin D, and calcitonin, have effects on bone resorption and bone deposition. These hormones affect both bone quality and bone quantity. The sex hormone estrogen inhibits bone resorption, and estrogen therapy has been developed to prevent and treat osteoporosis. Androgens are an important source of estrogen through the action of the enzyme aromatase and may themselves stimulate bone formation. Hence, the sex steroids play a role in bone metabolism. Breast cancer and prostate cancer are frequently hormonally responsive and may be treated with antiestrogens or antiandrogens respectfully. In addition, chemotherapy and supportive medications may alter the patient's endocrine system. In general, the suppression of sex hormones has a predictable affect on bone health, as seen by loss of bone mineral density and increased risk of fragility fractures. The bone toxicity of cancer-directed endocrine therapy can be mitigated through screening, counseling on optimization of calcium and vitamin D intake, exercise, and other lifestyle/behavioral actions, as well as the use of medications when the fracture risk is high. Maintaining bone health in patients who are treated with endocrine therapy for breast and prostate cancer is the focus of this review.

In the United States, approximately one in eight women will be affected by breast cancer and one in seven men will be affected by prostate cancer. Screening techniques and excellent therapies exist for both of these cancers. Although there remains room for improvement, the cure and survival rates for both of these cancers are high. It is estimated that there are more than 2.8 million breast cancer survivors and more than 2.7 million prostate cancer survivors alive today in the United States.[1,2] Breast cancer and prostate cancer are frequently hormonally responsive and may be treated with antiestrogens or antiandrogens. In general, the suppression of sex hormones during cancer therapy has a predictable affect on bone health, as seen by loss of bone mineral density and increased risk of fragility fractures. Hence, in terms of survivorship of these patients, long-term bone health issues, including osteoporosis, are a public health concern.

When treating breast and prostate cancer in the adjuvant setting, the goals of care are curative. For metastatic breast or prostate cancer, the goals of care are palliative. Metastatic breast and prostate cancers typically affect life expectancy and often cause bone metastases. Although the following discussion of bone health includes much that is applicable to both adjuvant and metastatic care, the focus is on the non-metastatic setting.

OSTEOPENIA AND OSTEOPOROSIS IN THE OLDER ADULT POPULATION

In the United States, approximately 10 million people have osteoporosis and an additional 43 million have low bone density.[3,4] Low bone mass correlates with an increased risk for fracture, and fractures are associated with substantial morbidity and mortality. Approximately one in two women and one in five men in the United States will experience an osteoporotic fracture.[3] A particularly disconcerting fact is that a hip fracture is associated with 8% to 36% excess mortality within 1 year. In addition, 20% of patients with a fracture of the hip require long-term nursing home care, and 60% will not regain their prefracture level of independence.[3] In addition to the pain and suffering associated with fractures, they are also is a substantial burden to health care expenditure.

A standard technique for measuring bone mineral density (BMD) is dual energy X-ray absorptiometry (DXA). The World Health Organization[5] has defined conditions of low bone mass using BMD as outlined in Table 1. The T score represents the standard deviation from an ideal bone mass. The BMD measurement provides the diagnostic criteria of osteoporosis as well as a threshold for pharmaceutical intervention.[4] Although the T score provides the operational definition of osteoporosis, the underlying health concern is the risk for fracture, not simply having a low DXA T score. There

TABLE 1. World Health Organization Diagnostic Thresholds for Low Bone Mass Using DXA Results for Men and Women[44,52,53]

	Interpretation of DXA Measurement	T Score
Normal	BMD more than 1 SD below the young adult female reference mean	≥ 1
Osteopenia	BMD more than 1 SD but less than 2.5 SD below the young adult mean	< 1 and > 2.5
Osteoporosis	BMD 2.5 SD or more below the young adult female mean	≤ 2.5
Severe Osteoporosis	BMD 2.5 SD or more below the young female adult mean in the presence of one or more fragility fractures	≤ 2.5 and clinical fragility fracture

Abbreviations: WHO, World Health Organization; DXA, dual energy x-ray absorptiometry; BMD, bone mineral density; SD, standard deviation.

is a movement by the National Bone Health Alliance to revise the working definition of osteoporosis such that it captures more than simply the DXA result and more fully reflects the risk of fracture.[6] Risk factors for fracture include increased age, low bone mass, prior fragility fracture, falls, impaired vision, low body weight, neuromuscular deficits, vitamin D deficiency, and a variety of medications.[7]

BONE HEALTH CARE FOR THE GENERAL POPULATION

Osteoporotic fractures are a public health concern and a wide range of free multilingual educational resources addressing bone health are publically available to address this issue. These high-quality, data-driven patient educational materials are available through the National Institutes of Health,[8]

Center for Disease Control,[9] Agency for Healthcare Research and Quality,[10] and other nongovernmental organizations such as the National Osteoporosis Foundation.[11] Similarly, numerous organizations, foundations, and government agencies have generated clinical practice guidelines on the management of bone health. Two selected guidelines on the recommendations for screening and treatment of bone health are summarized in Table 2.

BONE AS A HORMONALLY RESPONSIVE ORGAN

Bone is a dynamic organ and is constantly remodeling. Bone remodeling is the process of removal and replacement of bone mass at the same site. The remodeling process is critical to maintain mineral homeostasis and bone strength and to repair microdamage. The calcium level of extracellular fluid is tightly regulated through coordination of the gastrointestinal tract, kidneys, and bone. Systemic hormones that regulate these minerals are calcitonin, calcitriol (active vitamin D), and parathyroid hormone. Other critical systemic hormones for bone include growth hormone, insulin like growth factor, cortisol, estrogens, and androgens. These hormones play different roles throughout the life span of an individual as the skeleton changes with the aging process.[12,13]

The ratio of bone resorption to bone deposition fluctuates throughout life and is affected by steroid hormones. During youth the skeleton acquires bone mass, which reaches a plateau in young adulthood to middle age. In women, bone resorption accelerates at the onset of natural menopause and typically outpaces bone formation. During menopause, bone loss from the lumbar spine is 2 to 3% per year for approximately 5 years. Subsequently, the rate of bone loss is 0.5 to 1.0% per year, and is similar in both older men and women.[12,14] Deficiency of either estrogen or androgen promotes an increase in the number of osteoclasts and osteoclast activation, leading to an increased rate of bone resorption that outpaces bone formation.

ENDOCRINE THERAPIES AND BONE HEALTH

There is a possibility of low bone mass and/or fragility fractures as comorbid conditions at the time of cancer diagnosis and a pre-existing metabolic bone condition may influence the plan of care. Breast cancer and prostate cancer are frequently treated with adjuvant antiestrogens or antiandrogens respectively. These endocrine therapies can be considered risk factors for osteoporosis or fracture when assessing bone health in this patient population. If a fracture occurs in someone with a diagnosis of breast or prostate cancer, it is prudent to assess whether the fracture is pathologic in nature. Therapies for osteoporotic and pathologic fractures have many similarities, but there are also differences in treatment and fundamental differences in the goals of care.

Breast and Prostate Cancer Therapies That Increase the Risk of Bone Loss and Fracture

It has been known for many years that oophorectomy and orchiectomy can improve outcomes of patients with meta-

TABLE 2. Overview of Two Prominent Bone Health Screening and Treatment Guidelines[5]

	Vitamin D Screening	Vitamin D and Calcium Intake	Osteoporosis BMD Screening	BMD Threshold for Pharmacologic Intervention	Monitoring
USPSTF	Evidence is insufficient to assess the benefit/harm in Asymptomatic adults	Evidence is insufficient to assess the benefit/harm in premenopausal women and in men	Recommends screening in women age 65 and older and in younger women with significant fracture risk	Not specifically addressed; drug therapy may be considered in the primary (no previous osteoporotic fracture) or in the secondary (prior osteoporotic fracture) setting	Evidence is lacking on intervals of repeat screening
		Evidence is insufficient to assess the benefit/harm of daily supplements with >400 IU of vitamin D and >1,000 mg of calcium in noninstitutionalized postmenopausal women	Evidence is insufficient to assess the benefit/harm in men; men most likely to benefit from screening have a 10-yr risk for osteoporotic fracture greater than a 65-year-old white woman without risk factors		
NOF Advises universal counseling on risks, nutrition, exercise, and behaviors	Not specifically addressed	Women under the age of 50 • 1,000 mg of calcium from all sources daily	• Postmenopausal women and men over the age of 50 with an adult age fracture • Postmenopausal woman and men above age 50-69 based on risk factor profile • Women age 65 and older • Men age 70 and older	• Clinical or asymptomatic hip or vertebral fracture • T score ≤ -2.5 in femoral neck, total hip or lumbar spine by DXA • Postmenopausal women and men age 50 and older with low bone mass (-1.0 to -2.5) and a high-risk FRAX score (*)	BMD 1-2 years after initiating therapy & every 2 years thereafter
		Women age 50 and older • 1,200 mg calcium daily Men age 70 and younger • 1,000 mg calcium daily Men age 71 and older • 1,200 mg calcium daily Adults under the age of 50 • 400-800 IU vitamin D Adults age 50 and older • 800-1,000 IU vitamin D			

Abbreviations: USPSTF, U.S. Preventive Services Task Force; NOF, National Osteoporosis Foundation; BMD, bone mineral density.
*FRAX: Fracture Risk Algorithm; High-risk scores: 10-year hip fracture probability ≥ 3% or 10-year major osteoporosis-related fracture probability ≥ 20% based on the USA adapted World Health Organization fracture risk model.

static breast cancer and prostate cancer, respectively. Great advances have been made in understanding the molecular mechanisms of the sex hormones and hormonal influences on cancer and bone. Refinements in targeted endocrine therapy and cancer care have moved endocrine therapy into the (neo-)adjuvant setting. The goals of (neo-)adjuvant endocrine therapy are to improve disease-free and overall survival. With the use of endocrine systemic therapy to eradicate occult residual tumor cells, the skeleton is also exposed to endocrine intervention. The resulting deprivation of estrogen and androgen accelerate bone loss and increases the risk for fracture. Managing these risks are important aspects of cancer survivorship care. The effects of antiestrogen and antiandrogen cancer therapies on bone have been a subject of study for more than 20 years.[15,16] Much has been published on the effects of cancer therapy on BMD and the increased risk of fracture. Components of that literature will be reviewed here, but this is not an exhaustive review.

Breast Cancer Endocrine Therapies

Approximately 75% of breast cancers express the estrogen receptor or progesterone receptor and are considered hormone receptor positive (HR+).[17] Use of antiestrogen adjuvant therapies reduces the risk of breast cancer recurrence by approximately 30% to 50%.[18] Current guidelines recommending the use of targeted antiestrogen therapy for early-stage HR+ breast cancer include those published by the American Society of Clinical Oncology (ASCO).[19] The ASCO guideline supports the use of adjuvant tamoxifen in premenopausal and perimenopausal women with HR+ breast cancer. For women with HR+ early breast cancer who are postmenopausal, the use of an aromatase inhibitor (AI) is favored either as the sole adjuvant endocrine therapy or in sequence with tamoxifen. The menopausal status of the patient, the drug used, and the duration of treatment all affect how adjuvant breast cancer endocrine therapy will affect bone and may influence treatment decisions.

Tamoxifen is a selective estrogen receptor modulator (SERM) with both agonist and antagonist effects. In postmenopausal women, tamoxifen acts as a partial estrogen agonist on bone, stabilizing or even increasing bone mass. In a randomized placebo-controlled study 20 mg tamoxifen administered daily increased the lumbar spine BMD by 0.61% per year, whereas treatment with the placebo was associated with a 1% decrease in BMD per year (p < 0.001).[14] With longer follow-up of these patients the sample size dwindled; at 5 years there was a trend for the tamoxifen-treated group to have a higher BMD, but the difference was not significant

(tamoxifen, 0.8% increase in BMD; placebo, 0.7% decrease in BMD; p = 0.06).[20] The bone data for 10-year treatment with tamoxifen are limited. The ATLAS trial enrolled both premenopausal and postmenopausal women and randomly assigned them to either stopping tamoxifen at 5 years or continuing tamoxifen for 10 years. There were 62 fractures in the 10-year tamoxifen group and 70 fractures in the 5-year tamoxifen group. This difference did not reach statistical significance (event rate ratio 0.86; 95% CI, 0.61 to 1.21, p = 0.39) and was not analyzed based on menopausal status.[21]

In premenopausal women, tamoxifen is associated with loss of BMD. A prospective study serially monitored BMD in premenopausal women with breast cancer who were treated with chemotherapy. Women with HR+ tumors received tamoxifen and women with HR− cancers were observed as controls. At 3 years, women in the tamoxifen-treated group who retained menstrual function lost 4.6% of lumbar spine BMD whereas the controls who similarly retained menstrual function after chemotherapy had a modest gain of 0.6% in lumbar spine BMD.[22] A similar trend in BMD was seen in a randomized controlled study of healthy women treated with a chemoprevention regimen of 20 mg tamoxifen daily or placebo. In this trial the premenopausal women lost 1.44% in lumbar spine BMD per year over 3 years whereas those on placebo gained 0.24% of BMD (p < 0.001).[23]

The aromatase inhibitors (AIs) anastrozole, exemestane, and letrozole prevent the conversion of androgens to estrogens by reversibly or irreversibly inhibiting the aromatase enzyme. They are indicated for use in HR+ breast cancer in postmenopausal women and may be considered an option in women undergoing chemical ovarian ablation.[18,19] The AI-induced decrease in serum estrogen is associated with a decrease in risk of breast cancer recurrence and occurrence of new breast cancer, but is also associated with accelerated loss of BMD and an increased risk for fracture. These bone toxicities have been seen irrespective of the particular AI studied.[19,24-26] The effect of AIs on BMD contrasts with that of tamoxifen, which may have a stabilizing or positive effect on postmenopausal BMD. In a systematic review and meta-analysis, 5 years of AI therapy was associated with a 47% increase in the odds of bone fracture compared to tamoxifen (odds ratio [OR] 1.47; 95% CI, 1.34 to 1.61, p < 0.001). The absolute fracture risk was 7.5% in the AI group and 5.2% in the tamoxifen group.[27]

There has been interest in whether exemestane may not have the same magnitude of bone toxicity as the nonsteroidal AIs. The bone substudy within the phase III MA.27 study investigated whether exemestane has a superior bone sparing affect compared with anastrozole. At 2 years of follow-up, the changes in BMD did not differ between treatment arms, regardless of baseline BMD. In addition, the rates of fractures were similarly low in both arms.[28] BMD was assessed in a substudy of MAP.3, a randomized placebo-controlled study of exemestane versus placebo for the prevention of breast cancer in which 351 postmenopausal women (176 on exemestane, 175 on placebo) underwent serial BMD measure-ments. At 2 years of treatment, exemestane was associated with statistically greater bone loss in lumbar spine, hip, radius, and tibia.[29]

Ovarian ablation by chemical, radiation, or surgical means results in lower circulating levels of serum estrogens in premenopausal women with breast cancer and may be considered an adjuvant endocrine therapy.[18,30] Surgery and radiation create a permanent menopausal state whereas use of GnRH agonists (goserelin or leuprolide) provides a temporary chemically-induced menopausal state. The use of ovarian suppression in the adjuvant setting has recently been informed by the reports of two large phase III studies[31,32] and the role for ovarian ablation in adjuvant breast cancer care is still being defined.

Acute cessation of ovarian function with its sudden drop in circulating estrogen levels correlates with rapid acceleration of bone resorption and ultimately a decrease in BMD. The rate of loss is greatest initially and decreases over time. In a small study of serial BMD measurements after oophorectomy, the women had lost 18% to 19% of spine BMD at 2 years.[33] In premenopausal women participating in a randomized clinical trial comparing goserelin, goserelin/tamoxifen, tamoxifen alone or no endocrine therapy, women treated with goserelin alone experienced a 5% decrease in total body BMD at 2 years. Those treated with goserelin/tamoxifen experienced 1.4% loss, tamoxifen alone resulted in a 1.5% loss, and the control group showed a 0.3% loss.[34] These findings from small older studies are consistent with BMD changes noted in the phase III study ABCSG-12, in which premenopausal women with breast cancer were randomly assigned to goserelin/tamoxifen versus goserelin/anastrozole. There was a second randomization to zoledronic acid or not, and, as expected, treatment with 4 mg zoledronic acid every 6 months preserved BMD. At 3 years the women who were not treated with zoledronic acid but received goserelin/tamoxifen lost 9.0% of lumbar spine BMD whereas those who were treated with goserelin/anastrozole without zoledronic acid lost 13.6% of lumbar spine BMD.[35]

Chemotherapy-induced ovarian dysfunction may be temporary or permanent and is influenced by the chemotherapeutic regimen and the age of the patient. Because of the inherent difficulties in assessing residual ovarian function, chemotherapy-induced ovarian dysfunction should not be mistaken for menopause. A reference for the definition of menopause in the setting of breast cancer therapy can be found within the National Comprehensive Cancer Network breast cancer guidelines. Chemotherapy-induced ovarian dysfunction is associated with loss of BMD. The rate and duration of bone loss has not been thoroughly categorized because of differences in the definition of ovarian dysfunction, duration of study, and frequent inclusions of interventions such as bisphosphonates. The most comprehensive analysis of chemotherapy-induced ovarian dysfunction BMD studies was performed in the Cancer and Leukemia Group B (CALGB) trial 79809, which enrolled 439 premenopausal women over the age of 40 who were receiving adjuvant breast

cancer chemotherapy. Women were randomly assigned to treatment with zoledronic acid, to be given up front or in the second year of the study. Women were serially monitored for ovarian function and BMD. A total of 150 women met the study definition for chemotherapy-induced ovarian failure and completed lumbar spine BMD assessments at baseline and 1 year; 80 women in the delay zoledronic acid arm and 70 women in the up-front zoledronic acid arm. Women who were treated with zoledronic acid gained 1.2% in lumbar spine BMD whereas the untreated group lost 6.7% of lumbar spine BMD at 1 year (p < 0.001).[36]

Prostate Cancer Endocrine Therapies

The androgen receptor is expressed on prostate cancer[37] and the majority of prostate cancers are androgen-dependent and respond to endocrine therapy.[38] Androgen deprivation therapy (ADT) may be permanently induced with bilateral orchiectomy or temporarily induced by chemical ablation with GnRH agonists (leuprolide, goserlin, triporeline, or histrelin) or GnRH antagonists (degarelix).

ADT may be used in earlier stage prostate cancers that are deemed to be at high risk of recurrence. ADT may be used as neoadjuvant therapy, concurrently with radiation therapy, or as adjuvant therapy following radiation. In addition, ADT may be used in the setting of biochemical recurrence. This discussion will not cover metastatic disease or combined androgen blockage.

The hypogonadal state induced by ADT is associated with an accelerated rate of bone resorption. In general, in an older man the normal rate of loss of BMD is approximately 0.5 to 1.0% per year. With bilateral orchiectomy the rate of loss in BMD is estimated at approximately 8% to 10% over the first 1 to 2 years,[39] whereas the rate of BMD loss with ADT is 3% to 7% per year.[26] The rate of BMD loss is greatest when first starting ADT and decreases over time.

ADT is associated with an increased risk for fracture. An analysis of SEER-Medicare records of more than 50,000 men with a diagnosis of prostate cancer demonstrated a dose-dependent association between the use of GnRH agonists and the risk of fracture.[40] Nineteen percent of men who received ADT for 12 to 60 months experienced a fracture whereas only 12.6% without ADT had fractures in the same time period (p < 0.001). Men treated with one to four doses of GnRH had a fracture risk similar to those with no ADT, and those treated with nine or more doses had a fracture risk similar to that of men who underwent orchiectomy, which was associated with the highest rate of fractures. This study could not rule out pathologic fractures; however, the risk of fracture with ADT was not significantly altered when the analysis was restricted to early-stage disease. Similarly, another large database analysis of men with prostate cancer treated with or without GnRH demonstrated a significantly increased risk for fracture in those treated with GnRH; the relative risk for hip fracture with ADT was 1.76 (95% CI, 1.33 to 2.33).[41]

BONE HEALTH CARE IN THE SETTING OF ENDOCRINE THERAPY FOR BREAST OR PROSTATE CANCER

Low bone mass may be a pre-existing comorbid condition when breast or prostate cancer is diagnosed or may be induced secondary to cancer therapies. When prescribing cancer therapies that might increase the risk of fracture, counseling on the potential bone toxicity and means to mitigate that risk should be provided. Universal counseling on bone health includes providing advice on calcium and vitamin D intake, exercise, behavior (no tobacco, limit alcohol), the risk of falling, and certain medications such as steroids. These risk factors can be modified in many situations and should not be neglected as they are opportunities to optimize bone health. The management of bone health can be shared with the patient's primary care provider, as well as other medical providers such as endocrinologists. Bone health guidelines for the general public and for those affected by cancer have been published and serve as references. Examples of such guidelines include documents produced by the USPSTF,[42] National Osteoporosis Foundation,[11] American College of Physicians,[43] and European Society of Medical Oncology.[44]

Screening for risk of fracture includes obtaining a bone health history, assessing loss in height as an indicator of prior vertebral compression fractures, obtaining a personal and family history of fragility fractures, assessing calcium and vitamin D intake, and reviewing prior BMD assessments. Using information obtained by history and physical examination, the clinical team may consult the free online World Health Organization Fracture Risk Assessment Tool (FRAX), which can be used with or without BMD data.[45] This tool has similarities to Adjuvant! OnLine in that it calculates estimated risk of specific outcomes, but it does not replace additional evaluations and clinical judgment. The outcomes estimated by FRAX are the 10-year risk of either a major osteoporotic fracture or a hip fracture. Suggested thresholds for pharmacologic intervention include a 20% or greater risk of major osteoporotic fracture risk in 10 years or a 3% or greater risk of hip fracture in 10 years; however, treatment decisions must be made based on the individual's situation. FRAX is not applicable to patients on antiresorptive therapy.

The result of BMD testing may provide the diagnosis of osteoporosis or osteopenia. A low BMD is associated with a high risk of fracture and DXA is the gold standard for measuring BMD. If low bone mass is identified, consideration should be given to secondary causes of osteoporosis such as primary hyperparathyroidism or vitamin D deficiency, which may be common in women with breast cancer.[46] It is estimated that for each standard deviation drop in BMD the risk of fracture increases by 1.5- to 2.5-fold, thus making the measurement of BMD for fracture risk assessment similar to that of blood pressure for stroke.[13] DXA results can be serially monitored in treated or untreated patients. The interval between DXA scans is typically 1 to 2 years[13,26] although a longer duration may be appropriate, particularly for those on

TABLE 3. FDA-Approved Pharmacologic Therapies for the Prevention and/or Treatment of Osteoporosis*

Drug Class	Drug Name	Indications for Women	Indications for Men	Concerns/Warnings
Bisphosphonates	Alendronate	Treat or prevent postmenopausal osteoporosis	Increase bone mass in osteoporosis	Uncommon risks include hypocalcemia, osteonecrosis of the jaw, and atypical fractures. Intravenous formulations may cause acute phase reactions and renal dysfunction
	Ibandronate	Treat or prevent postmenopausal osteoporosis		
	Risedronate	Treat or prevent postmenopausal osteoporosis	Increase bone mass in osteoporosis	
	Zoledronic acid (5 mg)	Treat or prevent postmenopausal osteoporosis	Increase bone mass in osteoporosis	
Monoclonal Antibody	Denosumab (60 mg)	Treatment of postmenopausal osteoporosis with high risk for fracture. Treatment to increase bone mass in women at high risk for fracture who are receiving adjuvant AI for breast cancer	Treatment to increase bone mass in osteoporosis at high risk for fracture. Treatment to increase bone mass in men at high risk for fracture receiving ADT for non-metastatic prostate cancer	Uncommon risks include hypocalcemia, osteonecrosis of the jaw, and atypical fractures
Hormonal	Raloxifene	Treat or prevent postmenopausal osteoporosis		In the ATAC trial,[54] the combination of SERM (tamoxifen) and AI did not have the same efficacy as the AI alone
	Menopausal hormonal therapy, estrogen and estrogen-progestin combination Duavee (estrogen combined with bazedoxifene)	Prevent postmenopausal osteoporosis		Exogenous estrogen use is generally to be avoided because of concern for an increased risk of breast cancer recurrence
	Teriparatide (parathyroid hormone)	Postmenopausal osteoporosis with high risk for fracture	Primary or hypogonadal osteoporosis at high risk for fracture	Not to be used by those who have received external beam or implant radiation because of increased risk for osteosarcoma. Not to be used by those with bone metastases

Abbreviations: ATAC, Arimidex, Tamoxifen, alone or in combination.
*Indications for glucocorticoid-induced osteoporosis are not presented here.

antiresorptive therapy or those with low risk of fracture. Interesting data generated from the Study of Osteoporotic Fractures demonstrated that postmenopausal women with normal BMD at baseline transition to osteoporosis at a slower rate than postmenopausal women with severe osteopenia (T score -2.0 to -2.49).[47] These data suggest that the interval of monitoring BMD might be influenced by the baseline DXA result. However, the data do not lend themselves directly to patients with breast cancer or prostate cancer receiving endocrine therapy.

Osteoporosis may be underdiagnosed.[6] A SEER-Medicare study of health care utilization of DXA in women over the age of 65 with a history of nonmetastatic breast cancer revealed that less than 10% of the study population underwent BMD testing.[48] Another SEER-Medicare study suggests that the frequency of BMD screening was less than 20% in the year 2002.[49] Screening of men for osteoporosis is also occurring at a low rate. A SEER-Medicare study of men on ADT for non-metastatic prostate cancer revealed fewer than 10% of patients with BMD measurements.[50]

BMD thresholds for pharmacologic intervention typically include osteoporosis (T score ≤ -2.5) or low bone mass and additional risk factors for fracture. Once the risk for a fragility fracture is sufficiently high to warrant pharmacologic in-

tervention in a patient with early-stage breast or prostate cancer, there are data supporting the use of bisphosphonates or denosumab at FDA-approved dosing and intervals. Discussion of the use of bisphosphonate therapy as an anticancer therapy is outside the scope of this discussion. Clinical trials ranging from phase II to phase IV have demonstrated the ability of bisphosphonates or denosumab to preserve or improve BMD in the setting of endocrine therapy for breast or prostate cancer. Options for pharmacologic intervention, including therapies to avoid, are outlined in Table 3. Published cancer and bone health guidelines produced by cancer organizations include the ESMO bone health guideline[44] and the NCCN Task Force Report, Bone Health in Cancer Care.[51] The duration of antiresorptive therapy will be influenced by the response obtained, the duration of endocrine therapy, and the fracture risk. It is of note that the FDA recommends periodic re-evaluation of the need for continued bisphosphonate therapy, particularly in patients who have been treated for over 5 years. This reflects concern for long-term toxicities such as subtrochanteric and diaphyseal femur fractures. Patients receiving bisphosphonates or denosumab in the setting of endocrine therapy for early-stage breast or prostate cancer are at risk of experiencing toxicities from antiresorptive therapy per packet insert warnings and precautions.

FUTURE DIRECTIONS

With our aging population, it is expected that the number of people affected by osteoporosis and with cancer will increase. The need to co-manage these diagnoses will continue into the foreseeable future. Areas of osteoporosis research include targeting sclerostin and thereby potentially inducing osteo-anabolic activity, which may or may not be appropriate for use in patients with a history of breast or prostate cancer. As novel bone signaling pathways are targeted, the effect on cancer signaling must also be considered. Likewise, as novel anticancer therapies are developed, their effects on bone health should be investigated.

There are insufficient data to guide all possible clinically relevant bone and endocrine situations faced in the medical oncology clinic. Indeed, there are many questions that have not been formally studied, most notably where fractures are the primary endpoint. A fundamental goal of bone health care is to prevent fractures. BMD is a surrogate measurement used in risk assessment for fracture but is not the endgame. It can be challenging to study rates of fractures because of the large number of patients and the long duration of follow-up needed. Thankfully, it is very likely that in the future of "Big Data" and the ASCO program CancerLinQ, knowledge of the bone health of every patient will provide answers to fracture-related and other questions. There is reason to be optimistic that CancerLinQ and future research will reveal patterns of events and patterns of care that will inform future guidelines to improve bone outcomes.

Endocrine Therapy and Its Effect on Sexual Function

Shari Goldfarb, MD

Breast cancer is the most common malignancy in women and it is estimated that more than 230,000 invasive cancers will be diagnosed this year.[1] Approximately three-quarters of all invasive breast cancers are estrogen and/or progesterone receptor–positive. Endocrine therapy is the mainstay of treatment for both prevention and treatment of hormone receptor–positive breast cancers. Hormone therapy is the oldest targeted therapy and was initially described by both Sir George Beatson[2] and Albert Schinzinger more than 100 years ago when they noted that bilateral oophorectomies resulted in tumor regression in premenopausal women with advanced breast cancer.[3] A key therapeutic approach for treatment of both metastatic and adjuvant hormone receptor–positive breast cancer is estrogen deprivation. This can be achieved by suppressing ovaries, decreasing estrogen production, blocking estrogen at the level of the receptor, or by degrading estrogen receptors. Endocrine therapy is also used for the treatment of some hormone receptor–positive endometrial cancers. Commonly used endocrine therapies can have extensive sexual side effects that affect quality of life (QoL).[4-6] This article will discuss different endocrine therapies, their effect on sexual function, and treatment options to improve sexual health.

ENDOCRINE THERAPY

Tamoxifen

Tamoxifen is a selective estrogen receptor modulator (SERM), which has both partial estrogen agonist and antagonist activity. It competitively binds to the estrogen receptor (ER), which leads to interrupted cell proliferation and ultimately cell death by causing cells to remain in the G1 phase of the cell cycle.[7] Tamoxifen mimics estrogen in certain tissues, such as the bone and uterus, which has both beneficial and adverse effects. For example, tamoxifen improves lipid profiles and prevents bone demineralization, increasing bone density. However, it also increases the risk of uterine cancer by 2.5 times and the risk of a thromboembolic event by 1.9 times.[8] In breast tissue, tamoxifen antagonizes the action of estrogen, which both treats breast cancer and decreases the risk of a new primary breast cancer. The U.S. Food and Drug Administration (FDA) initially approved tamoxifen for the treatment of metastatic breast cancer in 1977 and for adju-

vant therapy in 1990. Tamoxifen was subsequently approved in 1999 by the FDA for the primary prevention of breast cancer.

Aromatase Inhibitors

Aromatase is an enzyme of the cytochrome P450 (CYP) family and the product of the CYP19 gene, which is the primary enzyme used for the synthesis of estrogen in postmenopausal women. It is found in peripheral tissues including muscle, normal breast tissue, breast cancer tissue, fat, liver, and brain.[9] Aromatase inhibitors (AIs) decrease estrogen production by blocking aromatase and thus decrease peripheral conversion of testosterone to estradiol and androstenedione to estrone. Third generation AIs decrease estrogen production by over 95%, resulting in subphysiologic levels of estrogen. AIs are only effective in postmenopausal women because they are unable to overcome ovarian aromatase activity.

Classification of the Aromatase Inhibitors: Nonsteroidal and Steroidal Agents

AIs are classified into two different types (1) nonsteroidal or (2) steroidal, which differ in their mechanism of interaction with the enzyme aromatase.[10] Nonsteroidal AIs bind reversibly to the heme portion of the CYP aromatase enzyme, resulting in competitive inhibition.[11] These type II inhibitors include the imidazole, fadrozole, and the imide, aminoglutethimide, as well as the triazoles including letrozole, anastrozole, and vorozole. Steroidal AIs are similar in structure to the true enzyme substrate, androstenedione, and bind irreversibly to the substrate binding domain of the aromatase enzyme, which results in a permanent inactivation of the aromatase enzyme.[12] These type I inhibitors include exemestane, formestane, and atamestane. There is no clinical evidence that demonstrates one mechanism of inhibition is superior to the other.

There are first, second, and third generation AIs based on their specificity and potency for aromatase enzyme inhibition.[13] The third generation AIs are the most potent and specific and include anastrozole, letrozole, and exemestane. They are widely used because they have improved tolerability and efficacy compared with prior generations. The third generation AIs have long half lives (anastrozole and letrozole ap-

From the Departments of Medicine and Epidemiology and Biostatistics, Memorial Sloan Kettering Cancer Center, and Department of Medicine, Weill Cornell Medical College.

proach 48 hours and exemestane 27 hours) allowing for daily dosing.

Fulvestrant

Fulvestrant is a selective estrogen receptor degrader that was FDA approved in April 2002 for the treatment of hormone receptor–positive metastatic breast cancer. Fulvestrant downregulates the ER by binding to it and inducing a change in conformational shape that prevents ER dimerization, resulting in the loss of cellular ER.[14,15]

OVARIAN SUPPRESSION

In premenopausal women with hormone receptor–positive metastatic breast cancer, estrogen deprivation is a key therapeutic strategy. Since the ovaries are the predominant sites of estrogen synthesis in premenopausal women, a patient's ovaries must be medically suppressed or surgically ablated via bilateral oophorectomies as part of her breast cancer treatment.[16,17] Estrogen levels are immediately and permanently reduced to the postmenopausal range in all women after surgical castration, whereas medical ablation is slower and may take several weeks before estrogen is fully suppressed. Medical ablation is performed by using a luteinizing hormone-releasing hormone (LHRH) analog, which acts on the hypothalamic-pituitary-ovarian axis and suppresses circulating estrogen levels.[18] LHRH analogs include goserelin, buserelin, triptorelin, and leuprolide and are administered as either monthly or every 3 month injections.[18] Medical suppression is reversible once the LHRH agonist is discontinued. After the initial administration of an LHRH analog, there is a surge in both estrogen and gonadotropin levels, which may cause a tumor flare phenomenon.

More recently with the presentation and publication of data from the Suppression of Ovarian Function Trial (SOFT) and Tamoxifen and Exemestane trial (TEXT) studies, ovarian suppression is being considered as adjuvant therapy for some young premenopausal women with high-risk early-stage disease.[19] The TEXT trial randomly assigned premenopausal women with early-stage hormone receptor–positive breast cancer to receive either 5 years of adjuvant therapy with triptorelin in combination with tamoxifen or triptorelin in combination with exemestane. The SOFT trial randomly assigned premenopausal women with early-stage hormone receptor–positive breast cancer to receive either ovarian suppression with exemestane, ovarian suppression with tamoxifen, or tamoxifen alone for 5 years. In the SOFT trial, ovarian suppression could be achieved with either triptorelin, ovarian irradiation, or bilateral oophorectomy.

The original plan was for separate statistical analyses for the TEXT and SOFT studies followed by a planned combined analysis of the ovarian suppression plus tamoxifen versus ovarian suppression plus exemestane cohorts.[19] However, as a result of low recurrence rates, in 2011 the studies were amended to make the primary analysis a combined analysis. The combined analysis had a median follow-up of 68 months. In the ovarian suppression plus exemestane cohort, disease-free survival at 5 years was 91.1% compared with 87.3% in the ovarian suppression plus tamoxifen arm (hazard ratio [HR] for disease recurrence, second invasive cancer, or death, 0.72; 95% CI, 0.60 to 0.85; $p < 0.001$). There was no significant difference in overall survival between the two treatment groups (HR for death in the exemestane plus ovarian suppression group, 1.14; 95% CI, 0.86 to 1.51; $p = 0.37$).

SEXUAL SIDE EFFECTS OF ENDOCRINE THERAPY

In premenopausal women, the primary site of both estrogen and testosterone synthesis is the ovaries. However, hormones play essential roles in central and peripheral aspects of female sexual function, sexuality, and integrity of the urogenital tract. When premenopausal women undergo either medical or surgical ovarian ablation for the treatment of breast cancer, they are abruptly put into menopause. This can also occur with chemotherapy-induced amenorrhea and menopause, which may be transient or permanent. Premature menopause often causes greater intensity and duration of symptoms than women undergoing natural menopause. Hot flashes, vaginal dryness, urogenital atrophy, dyspareunia, decreased libido, and changes in sexual response have been shown to negatively affect QoL, compliance with medication, and overall outcome. Iatrogenic menopause often causes lower steroid levels than natural menopause. For example, testosterone levels in natural menopause are around 290 pg/mL, but are 110 pg/mL in iatrogenic menopause, which substantially worsens sexual function. Likewise, estradiol, androstenedione, and dehydroepiandrosterone (DHEA) are present at lower levels as a result of iatrogenic menopause compared with natural menopause.

Treatment with endocrine therapy can have substantial sexual side effects, even in women who are already in menopause.[13] In postmenopausal women treated with AIs, marked alteration of the vulvar anatomy has been seen clinically in combination with vaginal dryness and dyspareunia that can lead to a change in the physical capacity for sex.[20] It is unclear why some women are more sensitive to endocrine therapy than others, but it may be secondary to polymorphisms in the ER and androgen receptors that cause a differential ability to utilize the small amount of available estrogen that is present.[21]

Tamoxifen, AIs, and fulvestrant all have sexual side effects. Tamoxifen can cause a clear vaginal discharge, vaginal and/or endometrial bleeding, vaginal dryness, vaginitis, dyspareunia, lowered orgasmic intensity, hot flashes, and decreased libido.[22,23] AIs suppress estrogen to subphysiologic levels, which causes worse vaginal dryness, dyspareunia, urogenital atrophy, decreased libido, lowered orgasmic intensity, and changes in sexual response compared with tamoxifen. In women with breast cancer on AIs for extended periods of time, gynecologists have also seen more extreme sexual side effects of therapy such as severe narrowing or stenosis of the vaginal introitus, clitoral atrophy, adhesions, phimosis, and decrease in vaginal length that may be a result of a loss of collagen, glycogen, and other proteins in the hypoestrogenic urogenital epithelium.[24,25] Since baseline gynecologic examinations are rarely performed before the initiation of AIs, the extent of architectural changes and stenosis attributable to the medication is difficult to quantify. It is unknown if these changes are reversible after discontinuing AI therapy or if they persist or worsen over time. Fulvestrant tends to have fewer sexual side effects than tamoxifen and AIs; however, fulvestrant can cause vaginal dryness, hot flashes, dyspareunia, and/or decreased libido.

Breast cancer and its treatment can also cause body image concerns including alopecia, surgical scars, change in weight, loss of femininity, decreased nipple sensation, and chest wall numbness, which all affect a woman's sexuality. Libido and sexual function is further impaired by hormonal changes, amenorrhea, anxiety, a change in relationship with a partner, depression, family distress, neuropathy, impaired immune response, and fatigue.[26,27]

ASSESSMENT OF SEXUAL FUNCTION IN WOMEN WITH BREAST CANCER

Clinicians should discuss sexual health with all women with breast cancer and survivors of the disease, including those who are single and older. Counseling for prevention and treatment of sexual problems will vary based on the time at which the patient presents for care. It would be helpful to have a baseline assessment of sexual function before or at the time of a cancer diagnosis to have a better understanding of the effect of a breast cancer diagnosis and each subsequent treatment (surgery, chemotherapy, radiation therapy, and endocrine therapy) on sexual function. However, gynecologists, medical oncologists, breast surgeons, radiation oncologists, and plastic surgeons do not routinely assess and document a woman's sexual function. Ideally, it should be a part of a routine annual gynecologic exam.

It would improve patient care and research by having an accurate assessment of baseline sexual function. This can be assessed on a patient review of systems form briefly with one question or in greater depth with several questions. For example, sexual concerns can be added to a check-box review of systems form and patients can answer yes or no. This can be the starting point to stimulate a discussion, to prompt more in-depth questioning, or to refer to a sexual health provider. If there is more time or room on the form, other questions can be added to assess hot flashes, vaginal lubrication, dyspareunia, postmenopausal bleeding, decreased libido, and recurrent urinary tract infections. It has been shown that patients will not initiate sexuality discussions, but want health care providers to discuss this topic. If clinicians neglect to discuss sexual problems, they will often go unaddressed.

INTERVENTIONS TO IMPROVE SEXUAL FUNCTION

Sexual problems in women with breast cancer can be especially challenging to treat and often requires a multidisciplinary approach. Treatment and prevention of sexual dysfunction from cancer and its therapy is best addressed with a team including a gynecologist, sex therapist, psychologist, and physical therapist who all work together and in collaboration with the patient's oncologist and/or primary care physician.

Vaginal atrophy and lubrication problems in breast cancer survivors are prevalent and its management is complex.[24] Although the most effective agent for menopause-induced vaginal atrophy is estrogen,[28] women with breast cancer are discouraged from using systemic estrogens because of an increased risk of disease recurrence.[29-31] Some safe and potential nonhormonal treatments include moisturizers, lubricants, counseling, sex therapy, physical therapy for pelvic floor disorders, altering contributing medications (e.g., selective serotonin reuptake inhibitors [SSRIs]), and mechanical devices/vibrators.[32] The standard of care for the treatment of vaginal atrophy in women with hormone receptor–positive cancers is currently moisturizers. At this time, the use of intravaginal estrogen, testosterone, and DHEA is controversial and further studies must be conducted to evaluate its safety in women with breast cancer who are receiving endocrine therapy, especially AIs. Randomized control data are lacking and are required to develop evidence-based treatment for sexual dysfunction in patients with cancer and to ultimately improve patient outcomes and QoL.

Lubricants

Lubricants are recommended to reduce friction and pain during vaginal penetration for women with vaginal atrophy and/or dryness. They are used on the woman and her partner (or sexual device) as needed before penetration. There are three different classes of lubricants: water-based, oil-based, and silicone-based. Water-based lubricants decrease pain

and friction with vaginal and anal intercourse and improve the sensation of dryness, but are shorter-acting and tend to dry quickly. Silicone-based lubricants tend to work better than water-based lubricants for anal intercourse because they are longer lasting and give a lusher feel. However, they can not be used with silicone vibrators, dilators, or other silicone toys. Both water- and silicone-based lubricants are safe to use with latex condoms, but oil-based lubricants may render latex condoms ineffective. Oil-based lubricants such as olive oil and vegetable oil tend to be the lubricant of choice for oral sex, but can increase risk of vaginal infections. Parabens and glycerines in lubricants can cause contact dermatitis, skin irritation, or a burning sensation. There are hundreds of lubricants available and each woman can chose the one that works best for her. Lubricants can also be used in combination with moisturizers.

Moisturizers

For postmenopausal women taking an AI with subphysiologic levels of estrogen, chronic vaginal dryness (e.g., genitals feel dry, irritated, pruritic, and/or painful during intercourse, gynecologic exams, and even with walking or sitting) is common and lubricants are often not enough to treat it.[33] Nonhormonal moisturizers are a safe treatment for vaginal dryness and atrophy in both pre- and postmenopausal women with breast cancer.[34-36] Intravaginal moisturizers (gels, creams, suppositories, or ovules) should be used every two to three nights to hydrate the vulvo-vaginal tissues, achieve optimal absorption, and minimize leakage. They also improve vaginal pH, dryness, elasticity, irritation, discomfort, and pruritus and are not solely used for sexual contact.[33,37] Regular treatment for 8 to 12 weeks is needed to see maximum benefit. The most commonly used moisturizer in the United States and Canada is Replens.

Replens is a polycarbophil-based gel that binds to the vaginal epithelium and delivers water and electrolytes to the underlying cells.[37] It normalizes vaginal pH, improves morphology of epithelial cells in vaginal smears, and alleviates vaginal symptoms.[37,38] Patients should be educated about the differences between lubricants and moisturizers to ensure proper usage of both types of treatment. In women with hormone receptor–positive breast cancer receiving endocrine therapy, there is currently limited information regarding the efficacy of moisturizers and if benefits can be maintained over time. Several small clinical trials performed in postmenopausal women with vaginal atrophy evaluated the efficacy of Replens, but did not follow patients long enough to determine effectiveness over time.[34,37] Clinical trial results with Replens are variable. Two small studies in postmenopausal women showed an improvement in vaginal discomfort, pruritus, and dyspareunia equivalent to the relief seen with intravaginal estrogen creams.[34,39] Two other small double-blind studies (one in women with breast cancer) did not show better efficacy with Replens compared with lubricants.[40,41] Replens has also been used as part of a multifaceted intervention to alleviate menopausal symptoms in women

with breast cancer, but the independent effect of Replens was not analyzed.[42]

Hyaluronic Acid

Hyaluronic acid is the main component of other moisturizers such as Hyalogyn and Hyalofemme. It is a high molecular weight glycosaminoglycan that moisturizes the vaginal epithelium by retaining high amounts of water and creating an extracellular water film with swelling.[43,44] By delivering water and electrolytes into underlying cells, hyaluronic acid improves epithelial elasticity and hydration.[45] In a group of postmenopausal women without cancer, an intravaginal gel containing hyaluronic acid was compared with vaginal 17-β estradiol tablets. Both treatments demonstrated an improvement in vaginal pH and atrophy with relief of vaginal symptoms. Two small pilot studies suggest possible benefits of hyaluronic acid in women with endometrial or breast cancer.[45] Further research on the efficacy of hyaluronic acid in the breast cancer population is needed.

Ospemifene

Ospemifene, a SERM with tissue-selective effects, was FDA approved on February 26, 2013 for the treatment of dyspareunia in postmenopausal women. Two phase III clinical trials showed that the efficacy of ospemifene was substantially greater than placebo in terms of improving dyspareunia, vaginal pH, and increasing superficial cells.[46,47] The most frequently reported treatment-related adverse event was hot flashes, which were reported in 6.6% of study participants in the ospemifene cohort compared with 3.6% in the placebo treatment group. Ospemifene can also increase the risk of endometrial cancer and blood clots, including deep vein thrombosis, pulmonary emboli, and cerebrovascular events. The effect of ospemifene on breast tissue has never been studied clinically and until it is evaluated, it should not be given to women with a history of breast cancer.

Dilators

AIs can cause marked alteration of the vulvar and vaginal anatomy causing vaginal stenosis from loss of rugae, which transforms the vaginal canal into a smooth, inflexible tube. Stenosis causes the vagina to feel stretched, painful, or taut during vaginal penetration. Vaginal stenosis is best treated with a multimodal approach using dilators, moisturizers, lubricants, pelvic floor physical therapy, and patient education. Dilators are available in sets of increasing size and are used for a gradual stretching process starting with the smallest dilator. They alleviate anxiety and improve a woman's confidence that something can comfortably be placed into the vagina without discomfort.[33] Dilators are essential for maintaining vaginal health if a patient is not sexually active or lacks a partner, treating vaginal pain, and improving tolerability of pelvic examinations.[33] Compliance with dilators is poor, but women are more likely to be compliant if they believe dilators will make their pelvic exams more comfortable[48] or if they are using vaginal health promotion strategies, such as lubricants (p = 0.029) or vaginal moisturizers (p <

0.001).[49] In conjunction with pelvic floor physical therapy, dilator therapy appears to be most effective.

Pelvic Floor Exercises

Strengthening the pelvic floor may have restorative effects and improve arousal.[33,50] Pelvic floor exercises, such as contraction and relaxation of vaginal and pelvic muscles, improve sexual function by helping pelvic muscles relax during penetration, thereby improving dyspareunia from pain associated with reflexively tightening. Improving blood flow to the pelvic floor from exercises, self-stimulation, and/or vibrator use also benefits sexual function by using the arousal response.[33] Pelvic floor physical therapy and/or biofeedback may be useful for treating vaginal pain, strengthening pelvic floor muscles, improving circulation for arousal, and providing feedback regarding these issues.[33,50,51]

Antidepressants

Women with breast cancer are frequently treated with antidepressants for depression, anxiety, and management of their hot flashes. Many SSRIs are extremely helpful in treating psychologic difficulties, but cause sexual side effects.[52,53] Therefore, a conversation about the risk and benefits of SSRIs should occur before prescribing these medications. A study in patients with cancer showed that up to 79% of patients were receiving one or more psychotropic medications.[54] SSRI-induced sexual dysfunction may improve with phosphodiesterase type 5 inhibitor treatment, but this therapy has never been studied in patients with cancer and the medications are not FDA approved for this indication.[55] Bupropion is an antidepressant that does not have the adverse sexual side effect profile of most SSRIs and has been shown to actually improve overall sexual satisfaction, arousal, orgasm intensity, and desire.[55] An effective treatment strategy is to change a patient to bupropion from a different SSRI, if they are experiencing sexual side effects.

Psychologic Treatment

During endocrine therapy, patients with cancer often experience persistent sexual difficulties (e.g., dyspareunia, difficulty with lubrication, decreased libido) and attention to their effect on QoL should be an essential part of their clinical care. Sexual function and a person's sexual self-schema can also be adversely affected by depression and distress that often accompany a breast cancer diagnosis.[56,57] Therefore, it is essential to screen for psychologic problems and intervene early to improve a patient's confidence, psychologic well-being, and self-perception during and after treatment. Counseling and/or sex therapy can be effective treatment options to help patient's cope and adjust to changes, especially when performed in combination with other treatment strategies. Therapy can help a woman understand the effect of breast cancer and its treatment on sexuality, reduce fear about intimacy, learn strategies to address pain (i.e., intravaginal moisturizers and dilator therapy), promote vaginal health, increase sexual knowledge, expand the sexual repertoire, and promote positive sexual identity. Psychologic and physical consequences of cancer that affect sexuality and sexual function should be addressed proactively with all patients with cancer. Therapy can also help a patient cope with an altered body image, decreased self-esteem, depression, anxiety, and fatigue.

Sensate Focus is a technique used for women experiencing dyspareunia that helps to reduce anxiety associated with sexual touch. Sexual function for women is often multifactorial in nature with both a physical and mental component. This is evident when an individual overcomes sexual challenges despite physical impairments through adaptation. For example, a recent mindfulness intervention demonstrated improvement in the perception of arousal, even when no physical improvements in engorgement were noted.[58] In female patients with cancer, decrease distress was associated with increased sexual satisfaction.[59] Psychologic interventions appear to be effective, but additional randomized controlled trials are necessary to develop a standardized evidence-based approach to treatment.[60]

Hormone Replacement Therapy

The use of intravaginal estrogens, testosterone, and DHEA in women with hormone receptor–positive breast cancer is controversial. Several small studies have been performed and are ongoing, but it is unlikely that a large randomized study evaluating safety will ever be performed.[61-64] At this time, intravaginal hormone therapy should only be considered as a last resort after the failure of all nonhormonal options. A discussion of the risks, benefits, side effects, and alternatives to hormone therapy is required before initiating treatment so patients can make informed decisions. It is a balance between the perceived need for treatment and concerns about the therapy.

Investigational Treatments

Currently there are no FDA-approved medications for decreased libido, arousal, or orgasmic difficulties in women. However, this is an area of active drug development by pharmaceutical companies and both investigational nonhormonal and hormonal treatments are being studied. Bremelanotide or PT 141 is a promising nonhormonal agent for female sexual interest/arousal disorder. It is a melanocortin 1 and 4 receptor agonist that binds to the melanocortin 4 receptor in the hypothalamus. Flibanserin, a 5-HT1A receptor agonist and 5-HT2A receptor antagonist, is another nonhormonal drug being studied for treatment of hypoactive sexual desire disorder. The combined formulation of sildenafil plus testosterone, as well as buspirone plus testosterone, are two hormonal agents that are being studied for hypoactive sexual desire disorder, low sexual motivation, and insensitivity to sexual cues.

CONCLUSION

As women live longer after a breast cancer diagnosis and treatment, attention to QoL and symptoms are of increasing

importance both during treatment and throughout survivorship. Well-conducted research is needed to improve prevention, diagnosis, and treatment of female sexual dysfunction throughout breast cancer treatment and survivorship. In addition, more evidence about the short and long-term sexual side effects of endocrine therapy is needed to appropriately counsel patients about the relative morbidity of cancer treatment strategies. Clinical trials are needed to identify safe and effective interventions to ameliorate sexual dysfunction and ultimately improve patient outcomes through evidence based treatment. There are currently no FDA approved medications for decreased libido, arousal, or orgasmic difficulties in women. Pharmacologic medications for treating female sexual dysfunction lag behind male therapies, but there are many drugs in development that will hopefully benefit women in the future.

Disclosures of Potential Conflicts of Interest

Assuring Quality Cancer Survivorship Care: We've Only Just Begun

Deborah K. Mayer, PhD, RN, AOCN, FAAN, Charles L. Shapiro, MD, Paul Jacobson, MD, and Mary S. McCabe, RN, BA, BS, MA

OVERVIEW

Clinical practice guidelines, quality metrics, and performance improvement projects are the key tools of the national movement to improve and assure quality cancer care. Each of these evaluation instruments is intended to assess quality from a unique perspective, including that of the individual provider, the practice/hospital, and the health care system. A number of organizations have developed or endorsed quality measures specific to cancer, however, these have not formally included survivorship measures. Fortunately, the American Society of Clinical Oncology (ASCO), the National Comprehensive Cancer Network, the American Cancer Society, and the American College of Surgeons (ACoS) have taken a leadership role in developing survivorship guidelines and quality metrics. Both ASCO and ACoS have focused their efforts on the treatment summary and care plan, a document that was proposed in the 2006 Institute of Medicine report on cancer survivorship. ASCO has proposed a care plan template for implementation and incorporation into the electronic health records (EHR), which will lend itself to structure, process, and outcome measurement. ACoS, conversely, has included the care plan in its cancer program standards with annual evaluation metrics. In addition, ASCO has developed a number of key survivorship-relevant metrics as part of its Quality Oncology Practice Initiative (QOPI), a tool developed to measure quality cancer care and assess adherence to guidelines across academic and community practices. Together, these efforts will direct us to more effective ways to disseminate guideline recommendations and to better methods of assessing quality survivorship care nationally.

Increasingly, the field of oncology is focused on the implementation of strategies to improve care with an emphasis on evaluation. However, this process of implementation and evaluation is not linear; rather, it is a cyclical process in which, ideally, evidence is translated into practice and practice is reviewed and improved on the basis of evaluation, which in turn leads to new research hypotheses. Clinical practice guidelines (CPGs), quality metrics, and performance improvement projects are the key tools of this national movement to improve and assure quality cancer care. As identified in the 2013 Institute of Medicine report, *Delivering High-Quality Cancer Care*, cancer quality measures are intended to "provide objective descriptors of the consequences of care and transform the nebulous concept of 'good medicine' into a measurable discipline."[1] Identifying and assessing quality require measures that assist and support health care systems, practices, and clinicians. Each of these instruments of evaluation is intended to evaluate quality from a unique perspective. For example, CPGs translate research results into evidence-based guidance for clinicians; performance improvement projects are operational at the local level as a means of making improvements, often at the site of care.[1] Quality metrics are intended to evaluate the quality of clinician and/or practice performance compared with recommended practice, with a focus on identifying areas for improvement.

In support of this quality movement, a number of professional and nonprofit organizations have developed or endorsed quality measures that are specific to or applicable to cancer for use in performance improvement and national reporting programs. Notably, the National Quality Forum (NQF), through funding from public and private sources beginning in 2009, has endorsed more than 62 cancer-specific measures that were developed by professional medical organizations through a consensus process.[2,3] The Agency for Healthcare Quality and Research (AHRQ) through its National Quality Measures Clearinghouse has set up a repository that includes hundreds of cancer-specific measures that have been developed by NQF and other national and international organizations.[4] The scope of these cancer-specific measures, however, are focused on screening, diagnosis and staging, initial treatment, and end-of-life issues, such as symptom management. Neither organization currently includes measures that specifically focus on the cancer survivorship period.

TABLE 1. Quality Metrics: Cancer Care

Type	Description	Benefits	Challenges
Structure	Measures settings in which clinicians practice: resources, organizational structure (such as models of care)	Identifies core infrastructure needed for high-quality care	Difficult to compare across settings; implications for patient outcomes not always clear
Process	Measures delivery in defined circumstances (screening, psychosocial evaluation, care planning)	Encourages evidence-based care; straight forward to measure	Need to consider patient choices and contraindications; implication for patient outcomes not always clear
Clinical Outcome	Measures personal health and functional status as a consequence of interaction with health care system	Allows assessment of multiple end points of care	Need to risk adjust for comorbidities; difficult to compare across settings with variable populations
Cost	Measures resources required to deliver care and the effect on patient, family, and payers	Allows parties to weigh relative values of treatment options when combined with outcome measures	Difficult to measure true cost of care; costs vary by perspective (patient, payer, society)
Patient-Reported Outcomes	Measures patient perceived physical, mental, and social well being on the basis of information that comes directly from the patient	Integrates patient voice into medical decisions	Some outcomes are outside the scope of clinical care

Yet, with this increased emphasis on measuring quality and improving cancer care, we also have growing attention to the needs of cancer survivors. This timely convergence of two important issues raises a number of important questions about how the focus on quality, already in place during cancer therapy, applies to survivorship care and services. We know that the number of cancer survivors is soon to be 19 million in 2024, and we have an active advocacy community for patients with cancer to voice their need for healthcare providers to pay attention to their post-treatment psychosocial and medical needs.[5] However, is it necessary to be concerned about measuring the quality of care in the post-treatment period? Is there a set of services that are known to be effective and/or important to the cancer survivor? In the absence of established evidence, can consensus guidance be developed to guide care and its evaluation? If so, how do we begin to focus on a parsimonious set of metrics that can be measured and will make a difference in the health of the cancer survivor? Where do we stand with respect to quality metrics for cancer survivors? Do we begin with process measures, or are we ready for the outcome measures described in Table 1? This is the challenge before us and the focus of this brief paper.

Survivorship is relatively young as a formal period along the cancer care continuum and, as such, has only recently been considered by national organizations that develop oncology guidelines and quality metrics. At the forefront in cancer survivorship guideline development are the American Cancer Society, the National Comprehensive Cancer Network (NCCN), and ASCO. Each of these leaders in oncology has taken a unique approach to developing guidelines, focusing on either a disease-specific approach or a symptom approach to survivorship care. In addition to a growing body of guidelines, two professional societies, ASCO, through its QOPI, and ACoS, with its Commission on Cancer (CoC) Cancer Program Standards, have developed cancer measures that include metrics specific to the survivorship period.[6,7] The next section of the paper will highlight the focused efforts of these two organizations.

KEY POINTS

- Increasingly, oncology is focused on the implementation of strategies to improve care, with an emphasis on evaluation.
- Survivorship-specific measures are essential to include in the suite of cancer guidelines and metrics to assure quality care during this period.
- Survivorship care plans need to be integrated into standard cancer care, and electronic health records can facilitate this implementation.
- The ASCO Quality Oncology Practice Initiative is an excellent mechanism to evaluate how well physician practices adhere to quality measures, including survivorship measures, over time.
- More effective ways to disseminate guideline recommendations and additional tools to measure quality are needed, especially in the area of cancer survivorship.

INTEGRATION OF SURVIVORSHIP CARE PLANS INTO ELECTRONIC HEALTH RECORDS

Survivorship care plans (SCPs), including the treatment summary and plan of follow-up care, were identified as tools to foster communication and coordination of care among the patient, oncology team, and primary care provider in the 2006 Institute of Medicine report, *From Cancer Patient to Cancer Survivor: Lost in Transition*.[8] However, adoption has been slow and inconsistent.[9] A number of barriers to adoption include the complexity of the SCP templates, unreimbursed time to complete the SCP, and a lack of a systematic approach to dissemination and implementation.[10] Many of these barriers can be addressed with the use of EHRs yet raise

TABLE 2. Minimum Data Elements to Be Included in a Survivorship Care Plan

Treatment Summary
Contact information of the treating institutions and providers
Specific diagnosis, including histologic subtype, when relevant
Stage of disease at diagnosis
Surgery (yes/no); if yes:
Surgical procedure with location on the body
Date(s) of surgery (year required, month optional, day not required)
Chemotherapy (yes/no); if yes:
Names of systemic therapy agents administered (listing individual names rather than regimens)
End date(s) of chemotherapy treatment (year required, month optional, day not required)
Radiation (yes/no); if yes:
Anatomic area treated by radiation
End date(s) of radiation treatment (year required, month optional, day not required)
Ongoing toxicity or side effects of all treatments received at the completion of treatment (Any information concerning the likely course of recovery from these toxicities should also be covered)
For selected cancers, genetic/hereditary risk factor(s) or predisposing conditions and genetic testing results, if performed
Follow-up Care Plan
Oncology team member contacts, with location of the treatment facility (repeat only if separate document)
Need for ongoing adjuvant therapy for cancer
Adjuvant therapy name
Planned duration
Expected side effects
Schedule of follow-up–related clinical visits (to include who will provide the follow-up visit and how often and where this will take place)
Cancer surveillance tests for recurrence (to include who is responsible for ordering/carrying out the test, the frequency of testing, and where this will take place)
Cancer screening for early detection of new cancers, to be included only if different from the general population (to include who is responsible for carrying out screening, the frequency of testing, and where this will take place)
Other periodic testing and examinations (Rather than outlining specific testing, the group suggested an inclusion of a general statement to "continue all standard non–cancer-related health care with your primary care provider, with the following exceptions: [if there are any]")
Possible symptoms of cancer recurrence (Rather than including a list of possible symptoms, the group suggested inclusion of a general statement, "Any new, unusual, and/or persistent symptoms should be brought to the attention of your provider")
A list of likely or rare but clinically significant late effects and/or long-term effects, if known, that a survivor may experience based on his or her individual diagnosis and treatment (including symptoms that may indicate the presence of such conditions)
A list of items (eg, emotional or mental health, parenting, work/employment, financial issues, and insurance) should be covered with standard language stating that survivors have experienced issues in these areas and that the patient should speak with his or her oncologist and/or primary care provider for related concerns. Include a list of local and national resources to assist the patient in obtaining the proper services
A general statement emphasizing the importance of healthy diet, exercise, smoking cessation, and alcohol use reduction may be included. Statements may be tailored if particularly pertinent to the individual

This information is available at www.facs.org/publications/newsletters/coc-source/special-source/standard33.[43] For the ASCO SCP templates and other survivorship resources, visit www.asco.org.

new issues that must be dealt with for successful implementation.

Since the 2006 IOM report, the rapid development of health information technology has increasingly fostered the ability to deliver value-based cancer care.[11] To that end, the Health Information Technology for Economic and Clinical Health (HITECH) Act of 2009 promotes the adoption and meaningful use of EHRs. Based on data from the American Hospital Association, 85% of acute care hospitals had certified EHRs that met Federal requirements for meaningful use by 2012, with variation by state.[12] This current adoption of EHRs is a dramatic increase from 9.4% in 2008.[12] An important aspect of use will be the interoperability among EHRs to allow data exchange in a meaningful way. Here is where the SCP will be critical as an important tool for care coordination and in sharing a concise history of patient diagnosis, summary of treatments received, surveillance plan, and management of the consequences of cancer and its treatment.

One component of valuable EHRs is the ability to have oncology-specific clinical decision support systems [CDSS] that draw on created knowledge bases and patient data, which have the potential to tailor decisions across of the cancer continuum.[11,13] CDSS have rules, alerts, and workflow tools that can be used for the development of SCPs. This includes the integration of CPGs, such as surveillance recommendations with patient data to create the SCP. Other ways

to enhance the quality of cancer care using the SCP could include the addition of patient-reported outcomes (e.g., if a symptom is reported, information about that symptom and ways to manage it could be incorporated into the SCP). Other opportunities to improve care would include data mining and research.[13] However, we are still in the nascent period of using EHRs to develop and deliver SCPs and have yet to realize the full possibilities for improving the quality of survivorship care. Many practices are currently working with EHR vendors to implement SCPs, so we will be learning many lessons about what works and what does not along the way. One can use Donabedian's conceptual framework, as described in Table 1, using structure, process, and outcomes to consider issues of EHRs implementation of the SCP.[14]

Structure

One must decide what elements to include in an SCP. There are a number of free-standing, independent templates (e.g., Journey Forward, LIVESTRONG) that have been used, but they have operability issues within EHRs. ASCO recently reviewed and revised the essential elements to include in an SCP.[15] These elements, endorsed and adopted by the CoC, can be identified or created within a template to be auto-completed or to provide standard options for completion within any EHRs (Table 2). Where these documents will be stored within EHRs, how they can be shared with intended users (survivor, primary care provider, and other relevant providers), and how they can be tracked and reported are other structural issues that need to be resolved.

Process

A number of process issues need to be addressed (see sidebar). These decisions need to be discussed, decided, tried, and revised based on experience with the stakeholders of this process. Furthermore, how these issues are addressed may vary by type and size of oncology practices.[16,17] Effective change management is needed and includes engaging key stakeholders, standardizing terminology, clinical practices, and processes.[16] Articulating and agreeing on key assumptions help guide the approach and assure that this process, and ultimately the document, is patient and primary care centered. This process should be standardized as much as possible but should allow for variations to reflect the complexity of cancer care. It is helpful to have at least one champion and to work with an interested and willing early-adopter group to pilot this process.[18]

Implementation of this process will take time and require flexibility until the system for developing and delivering SCPs becomes standardized and incorporated into practice. For example, in a large academic medical center, there may be a number of disease-specific groups with differing approaches about who sees the patient and how often. Decisions about who completes and delivers the SCP when all three treatment modalities are delivered versus when one is delivered could vary. For example, these decisions could fall on the last person who treats the patient or the first person

SIDEBAR. Questions to Consider When Implementing Survivorship Care Plans within an Electronic Health Record

1. How will eligible patients be identified and tracked?
2. How will a provider know when an eligible patient is due to receive a survivorship care plan (SCP)?
3. How will the SCP be created and by whom?
4. How will a provider know when to deliver the SCP?
5. How will the SCP be delivered to the patient and primary care provider and be documented?
6. How will you bill for this service?
7. Where will it be stored within the electronic health record for others to access?
8. How will you track the number of SCPs developed and delivered?
9. How will you monitor and evaluate your effectiveness in achieving the Commission on Cancer's goals for your cancer program?
10. How will this effort become a sustained standard of care?
11. Will you collect any patient/provider outcome measures related to the SCP?

who sees the patient during the first follow-up visit. To say that the devil is in the details is an understatement in trying to delineate and implement a new process such as this. The good news is that one is not trying to undo a previous way of implementing the SCP—this is a new endeavor.

Another important questions about the process is how is it delivered once it is completed. The SCP is a paper document and it does not serve the original intent by merely handing it to the patient and checking off that it was delivered. The SCP is meant to serve as a communication tool to facilitate review of the patient's diagnosis and treatment, guide discussion of planned surveillance and who will be responsible, and encourage identification and discussion of any current or future concerns or issues the patient may face post-treatment. In one study in patients with colon cancer, the delivery of the SCP did not lengthen the usual surveillance visit, but it did provide structure to what was discussed.[19] Nutritional concerns and bowel management problems quickly became identified as issues most of these patients raised, and these topics were then incorporated routinely into the SCP and visit.

There are many barriers to SCP implementation and these need to be addressed as they are identified. Working closely with the EHR vendor during the development and piloting phase is critical. Receiving input from anticipated users and having them try to use the SCP EHR system as intended will identify many issues with implementation. Answering the questions in the sidebar can be time consuming, and the approach may need to change over time with experience. One of the critical issues is reimbursement for SCP completion. As of January 1, 2015, SCP preparation can be billed as a new CPT code, 99490 (chronic care management services, at least 20 minutes of clinical staff time directed by a physician or

TABLE 3. Representative QOPI Survivorship Questions

Question	No. of Practices
Chemotherapy treatment summary completed within 3 months of chemotherapy end?	310
Smoking/tobacco use cessation administered appropriately in the past year?	313
Infertility risks discussed prior to chemotherapy?	181
Fertility preservation options discussed, or referral to specialist?	181
Imaging or tumor marker within 12 months after breast cancer diagnosis in patients treated with curative intent?	111
Complete family history documented for invasive breast cancer?	98
Genetic testing for invasive breast cancer?	95

Abbreviation: QOPI, Quality Oncology Practice Initiative.

other qualified health care professional per calendar month) to describe chronic care management.[20] This may help overcome the barrier of completing an unfunded mandate. Visits in which the SCP is delivered can be billed as appropriate for the visit.

Outcomes

A barrier to adoption has been the minimal amount of evidence demonstrating benefits for SCPs.[21] Receiving an SCP from an oncologist is associated with primary care providers reporting always or almost always discussing recommendations and delineation of provider responsibility with survivors (OR 9.22; 95% CI, 5.74 to 14.82; p < 0.001) compared to primary care providers reporting receiving SCP less than always or almost always from the oncologist.[22] Immediate outcomes may include increased knowledge about surveillance plans and satisfaction with care, while longer-term outcomes may include increased adherence to surveillance plans, with decreased undertesting and overtesting and identification and management of long-term effects. Other provider level

and system level outcomes might also be included. Ongoing studies eventually may demonstrate SCP effectiveness; regardless, the SCP is a requirement in the ACoS CoC Cancer Program Standards, and it is an ASCO QOPI measure and needs to be incorporated into cancer care. Based on stakeholders perspectives, SCPs have been positively viewed and, at a minimum, may enhance patient and primary care provider satisfaction of care with the oncology team.[8,23]

LESSONS FROM THE ASCO QOPI SURVIVORSHIP MEASURES

In addition to the dissemination of oncology CPGs by groups such as ASCO and the NCCN as a means of improving the quality of cancer care, it is essential to evaluate whether these recommendations influence physician practice. To this end, the ASCO QOPI project began in 2006 with the goal of measuring how well physician practices adhere to quality measures over time.[24] In 2013, data from 156 academic and community practice groups representing 2,100 physicians from different regions of the country was published.[25] Overall, adherence to standard of care and guideline recommendations improved over time in certain domains (e.g., testing for *KRAS* mutations in colorectal cancer when using targeted treatment), whereas end-of-life care and symptom/toxicity management remained static.[25] Thus, the QOPI is an effective tool to measure physician behavior and adherence to guidelines over time.

Several core QOPI survivorship measures that are based on guideline recommendations have been defined, including whether the patient received a summary of cancer treatment,[15] tobacco cessation referral,[26] counseling about infertility risks and fertility preservation options,[27] whether tumor markers/imaging tests were done within 12 months of completing treatment,[28,29] and the completion of a family history and genetic testing for invasive breast cancer.[30,31] Depending on the specific question asked (Table 3), between 95 and 313 medical practices contributed data in the form of medical re-

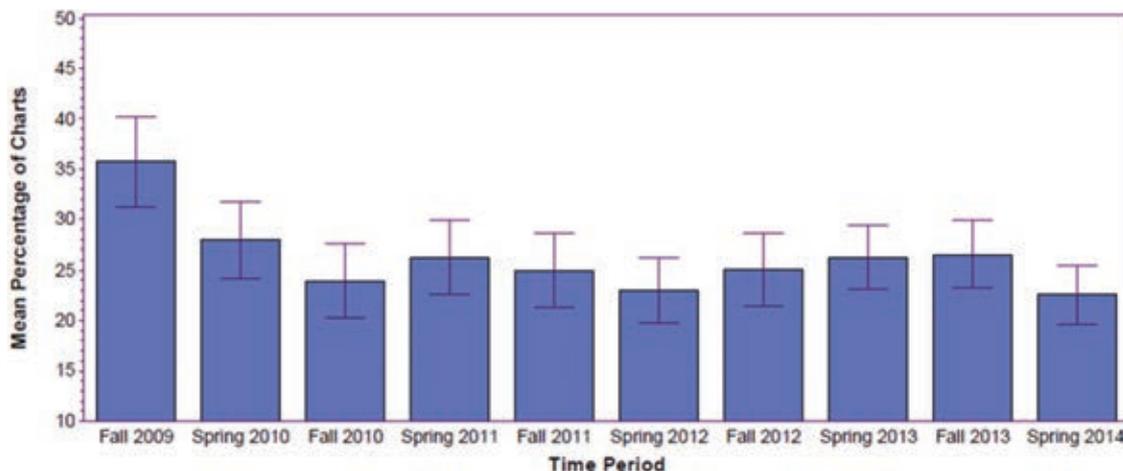
FIGURE 1. Chemotherapy Treatment Summary Completed within 3 Months of Chemotherapy End (310 Practices)


FIGURE 2. (A) Infertility Risks Discussed before Chemotherapy (181 Practices); (B) Fertility Preservation Options Discussed or Referral to Specialist (181 Practices)
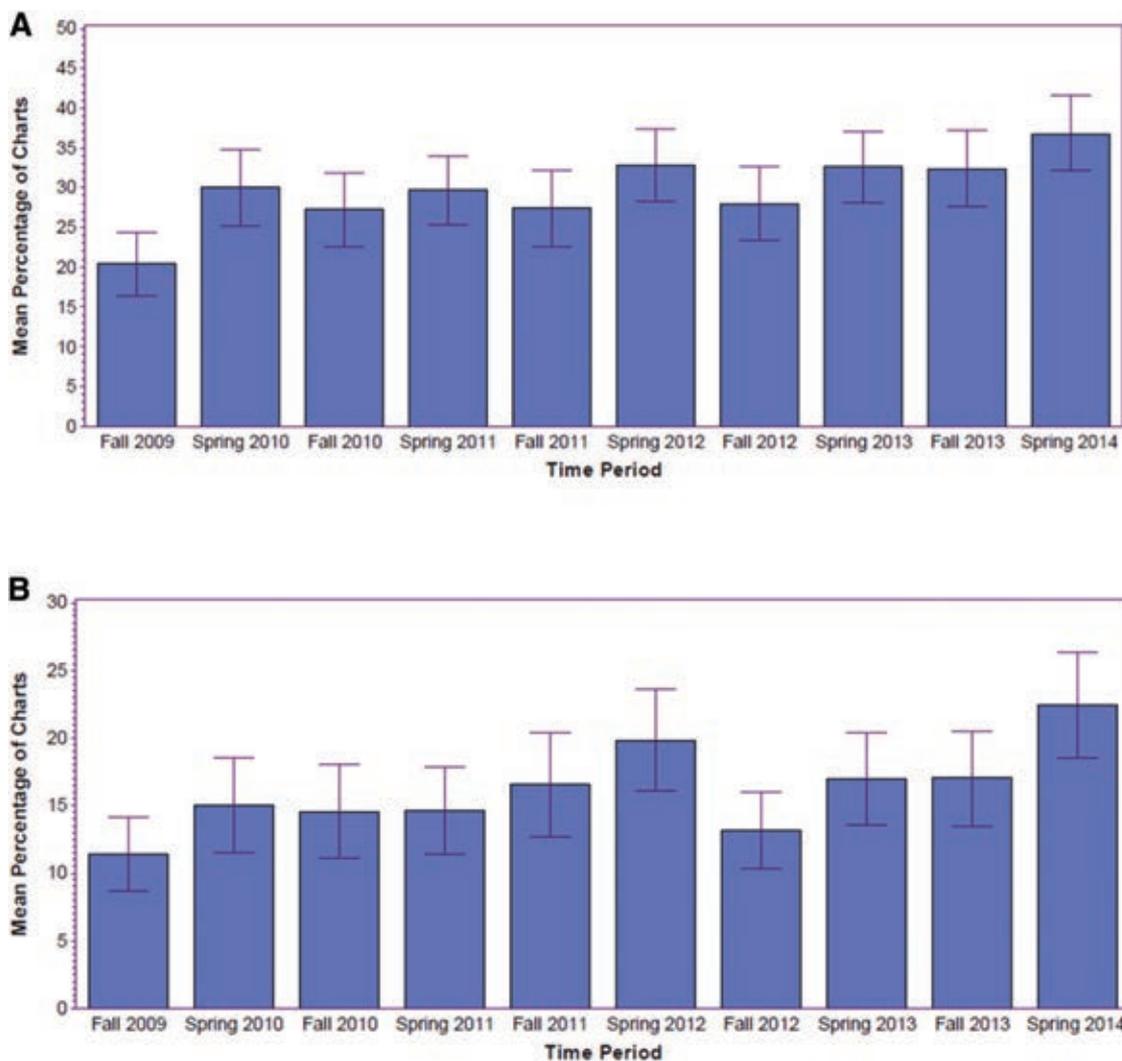


cords. The selected QOPI survivorship measures to assess physician adherence to these guideline recommendations are discussed below.

Treatment Summary

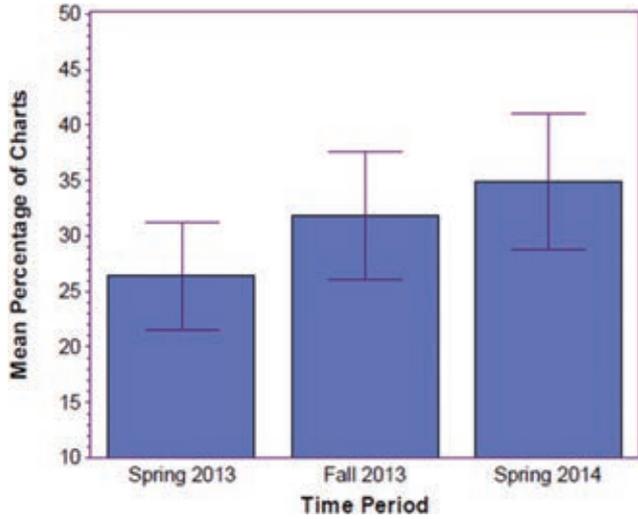
The development and implementation of the SCP has been described earlier in this article, and the QOPI effort to document uptake of this recommendation to provide a treatment summary within 3 months of completing treatment is documented in Fig. 1. The percentage of physician practices in which a treatment summary is documented decreased from 35% in 2009% to 20% in 2014. However, recent initiatives to simplify the ASCO SCP, along with extensive efforts to assure integration of the SCP with electronic medical records, and the requirement of the CoC that by January 2019 all individuals receive an SCP should begin to reverse this decreasing trend.[7] However, to be successful, the barriers previously described will need to be addressed.

Tobacco Cessation

In 2003, ASCO released a policy statement on tobacco cessation,[32] and an update was published in 2013.[26] A cornerstone of this policy is that every individual should be queried about smoking status, and appropriate interventions and referrals to smoking cessation programs should be undertaken. There were consistently 81% to 84% of medical records that documented a smoking/tobacco cessation discussion in the years 2009 to 2014. Although guideline adherence is consistently greater than 80%, one wonders whether that goal should be higher.

Risk of Infertility

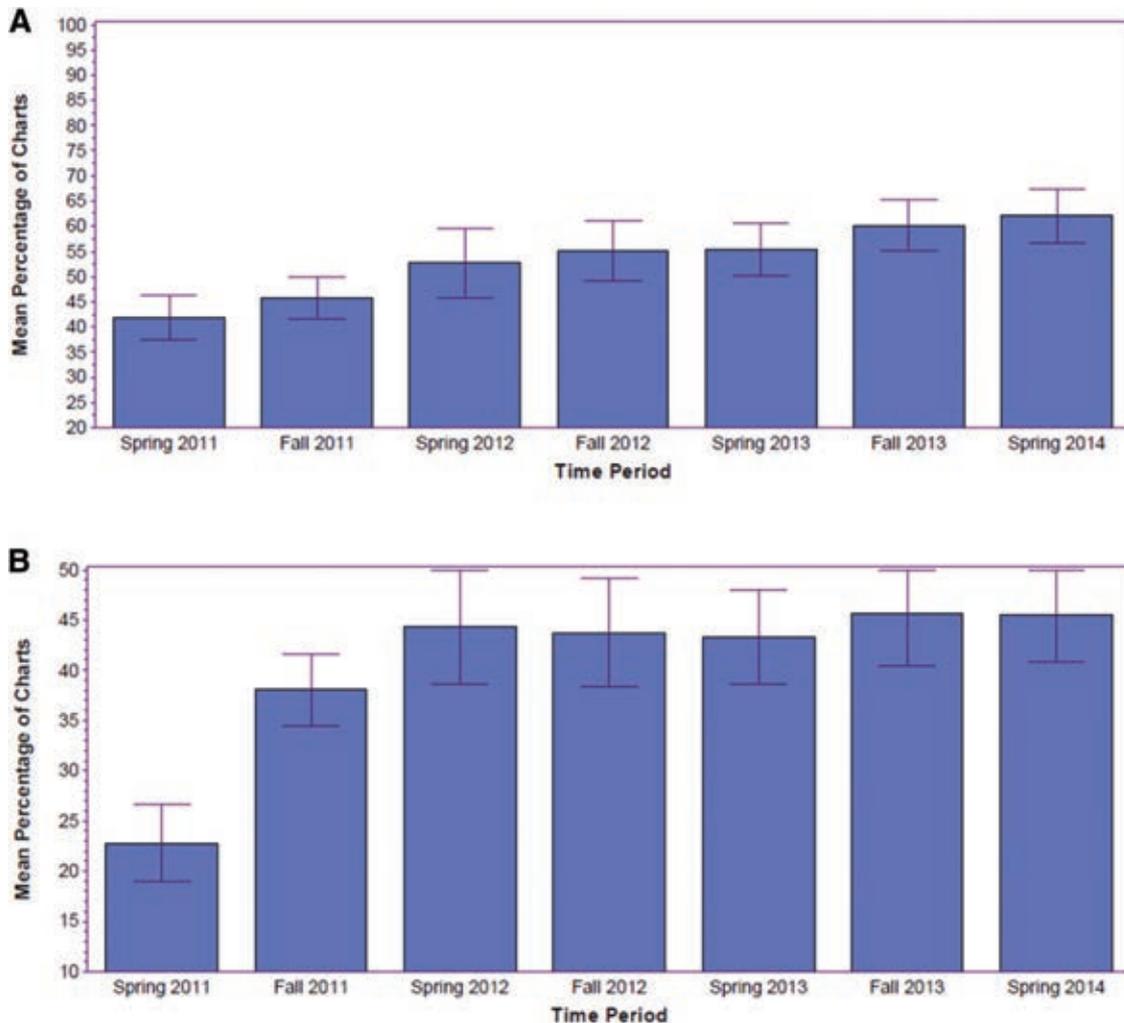
The ASCO clinical practice guideline on fertility preservation was published in 2006 and recently was updated in 2013.[27] Among the key recommendations were to discuss fertility preservation with all individuals of reproductive age and to refer those interested in fertility preservation to reproductive

FIGURE 3. Imaging or Tumor Marker within 12 Months of Completed Treatment with Curative Intent (111 Practices)


specialists. Figs. 2A and 2B show the improvement over time during the period 2009 to 2014. A discussion about the infertility risk before chemotherapy increased from 20% to 35%. Likewise, fertility options discussed or referred to a specialist increased from 11% to 24%. These increases over time may represent a validation of the QOPI process. However, these rates are overall low and highlight the need for improvement.

Imaging or Tumor Markers within 12 Months of Completing Treatment

First in 2006[28] and updated in 2013,[28] the ASCO guideline on breast cancer follow-up care states that imaging studies or tumor markers are not recommended in asymptomatic women with breast cancer who have completed treatment with curative intent. The percent of medical records that document imaging or tumor markers within 12 months of completing treatment with curative intent actually increased from 25% to 35% over 1 year (Fig. 3). Although there a too few data points to establish a convincing trend, the fact that even 25% of medical records document tests that are not ben-

FIGURE 4. (A) Genetic Testing for Invasive Breast Cancer (95 Patients) (B) Complete Family History Documented for Invasive Breast Cancer (98 Patients)


eficial suggests that current guidelines are not effectively reaching and/or influencing physicians who care for these women.

Genetic Testing and Family History

In 1996, 2003, and 2010,[31,33,34] ASCO provided a policy statement with recommendations for genetic testing. In 2014, ASCO issued an expert statement recommending the minimal family history for individuals with cancer.[30] Penetration into practice is evidenced by a steady increase in genetic testing of women with breast cancer (Fig. 4A), as evidenced by the QOPI data. In contrast, only 45% of medical records documented complete family histories in women with breast cancer (Fig. 4B).

QOPI was developed as a tool to measure quality of cancer care over time by providing a mechanism to assess physician adherence to guidelines.[24,35] It has several strengths, including that it draws from a mix of academic and community practices throughout the country. However, there are also several limitations, including reporting data from only those practices that participate in QOPI and reliance on what is and what is not documented in the medical record.[25] In addition, QOPI does not capture the complexity of patient care when

the clinical and psychosocial situation requires an exception to following practice guidelines. Nonetheless, QOPI is one of the very few ways in which the quality of survivorship care is being measured.

QOPI data highlight another important area that deserves mention. Tremendous time and effort has produced 50 ASCO guidelines and expert statements[36] and 20 years of NCCN practice guidelines.[37] Much less time has been devoted to evaluate the best methods of disseminating guidelines and increasing adherence to guideline recommendations. There are conceptual frameworks,[38-40] randomized trials,[41] and systemic reviews evaluating various interventions; the vast majority have non–cancer-related guidelines.[42] Efforts should be directed toward developing more effective ways to disseminate guideline recommendations and toward developing additional tools to measure quality.

In summary, as the scientific evidence base to guide cancer survivorship care grows, the role of guidelines to translate evidence into practice and metrics to assure that quality, or the lack thereof, is measured will become increasingly important. This will need to occur at both the individual practice level and the system level. Much is to be done, and we've only just begun.

Disclosures of Potential Conflicts of Interest

Cancer Pain Management: Safe and Effective Use of Opioids

Eduardo Bruera, MD, and Judith A. Paice, PhD, RN

OVERVIEW

Pain remains a serious consequence of cancer and its treatment. Although significant advances have been made in providing effective cancer pain control, barriers persist. Lack of knowledge, limited time, financial restrictions, and diminished availability of necessary medications serve as significant obstacles. Safe and effective opioid use in a patient with cancer requires skill to overcome these challenges. Understanding the mechanism of action, along with the pharmacokinetics and pharmacodynamics, of opioids will lead to appropriate selection, dosing, and titration of these agents. Rotation from one opioid or route to another is an essential proficiency for oncologists. As opioid-related adverse effects often occur, the oncology team must be expert in preventing and managing constipation, nausea, sedation, and neurotoxicities. An emerging concern is overtreatment—the excessive and prolonged use of opioids in patients when these agents may produce more harm than benefit. This can occur when opioids are used inappropriately to treat comorbid psychologic issues such as anxiety and depression. Recognizing risk factors for overuse along with key components of universal precautions will promote safe use of these medications, supporting adherence and preventing diversion, thereby protecting the patient, the prescriber, and the community. Because substance use disorders are not rare in the oncology setting, attention must be given to the balance of providing analgesia while limiting harm. Caring for patients with substance misuse requires compassionate, multidisciplinary care, with input from supportive oncology/palliative care as well as addiction specialists.

Pain is a serious consequence of cancer and its treatment. Although great strides have been made in increasing awareness of the need for effective cancer pain control, barriers persist that lead to undertreatment.[1-3] Health care professionals' lack of knowledge (despite extensive efforts to improve education), limited access to specialists, and diminished availability of necessary medications are significant obstacles. Insufficient time, resulting from increased demands to provide care for more patients during shorter visits, along with expanding requests for documentation, insurance authorizations, and other regulatory requirements, complicates delivery of comprehensive pain control.[4,5] Balancing these demands has proven challenging, and excellent pain control can suffer as a result.

Awareness of the safe and effective use of opioids in the oncology setting is essential to the provision of adequate pain relief. Understanding the mechanism of action, along with the pharmacokinetics and pharmacodynamics of opioids will lead to appropriate selection, dosing, and titration of these agents. As adverse effects often occur, the oncology team must be skilled in preventing and managing constipation, nausea, sedation, and neurotoxicities. An emerging concern is overtreatment with opioids—the excessive and prolonged use of opioids in patients when these agents may produce more harm than benefit. This can occur when opioids are used inappropriately to treat comorbid psychologic issues such as anxiety and depression. Recognizing risk factors for overuse along with key components of universal precautions will promote safe use of these medications, protecting the patient, the prescriber, and the community.

PRINCIPLES OF OPIOID USE

Opioid analgesics have been the most useful group of drugs for the management of severe pain for more than 200 years.[6] All opioid analgesics work mainly by binding the Mu opioid receptors located along the nociceptive pathway. These Mu receptors are found in multiple locations presynaptically and postsynaptically. The direct result of the opioid binding to the receptor is decreased afferent nociceptive neuronal depolarization. In recent years it has become clear that new receptors have multiple subtypes.[7] Different opioid Mu agonists will bind to slightly different subtypes of Mu receptors. This variability and the differences in pharmacokinetic and pharmacodynamic profile explain the frequently observed difference in both analgesic response and side effect to different opioid analgesics. An important pearl for clinicians is that there is considerable interpersonal variation in analgesic response to opioid agonists.

Choice of Opioid and Initial Opioid Titration

In patients who have never been exposed to opioids before, titration is quite simple. The starting dose is well established for all major opioid analgesics and it is the equivalent to 30 mg of morphine per day orally (20 mg oxycodone, 10 mg of oxymorphone, etc.). The starting dose of an opioid is not driven by the intensity of the patient's pain expression but rather by safety considerations, and therefore, the initiation of opioids is simple and generally very safe. In patients with good renal function and good liver function and who are not receiving other drugs that might interact at the pharmacokinetic or pharmacodynamic level, all opioids are similarly safe and effective.

Opioid metabolism. Opioids undergo phase I oxidation or hydrolysis mainly by the cytochrome 3A4 and 2D6 enzymes, followed by phase II glucuronization that increases their hydro-solubility for renal elimination. Table 1 summarizes some of the metabolic sub-products of the main opioid agonists. It is important to note that the 3A4 cytochrome produces largely inactive metabolites. Therefore, drugs that block 3A4 will increase either the parent compound or the alternative pathway toward active metabolites. Patients undergoing this interaction will develop opioid toxicity—mainly sedation. Agents frequently involved in these interactions for patients with cancer include macrolide and fluroquinolone antibiotics, azoles, HIV antiretrovirals, irinotecan, and many of the new targeted agents. On the other hand, the 2D6 cytochrome pathway produces largely active metabolites, and the blockage of this pathway by drug interactions will result in decreased analgesic effects. This is particularly important in the case of codeine since it does not largely bind to the opioid Mu receptor but requires activation by 2D6 to morphine. The main 2D6 drugs for patients with

Table 1. Phase I Metabolism of Opioids

Drug	Cytochrome	Results

	2D6	Hydromorphone*
Codeine	2D6	Morphine*
Methadone	3A4	M1-M2
Tramadol	2D6	Desmethyltramadol*

*Active metabolite.

cancer include some selective serotonin reuptake inhibitor antidepressants and neuroleptics such as haloperidol or chlorpromazine. It is important to remember that 8% to 20% of the population are genetically poor metabolizers at the 2D6 level.[8]

Some opioids have minimal or no phase I metabolism. These include morphine, hydromorphone, and oxymorphone. The likelihood of interactions at the cytochrome level from these opioids is minimal, making these three opioids ideal for patients with liver failure or potential drug interactions. Opioids with no major phase I (morphine, hydromorphone, oxymorphone) and the active metabolites of the other opioids (Table 1) undergo glucuronidation and renal elimination. Some of these glucuronides are active (e.g., morphine-6-glucuronide, glucuronide), and others are not active on the opioid receptor but neurotoxic (e.g., morphine-3-glucuronide and hydromorphine-3-glucuronide). For patients with renal failure, all these opioids should be used with frequent monitoring for neurotoxicity. Methadone is a very good alternative in renal failure since its metabolites are largely inactive and are not eliminated into the urine.

If a patient who has been on a stable dose of an opioid analgesic develops sedation it is important to ask if any new drugs have been added that might affect the pharmacokinetic profile. Also determine if the patient is now in liver or renal failure and if new drugs have been added that might increase the level of sedation of the patient from the pharmacodynamic perspective. These drugs include hypnotics, antihistamines, sedating antidepressants, and anticonvulsants frequently used for neuropathic pain.

Many extended release opioid preparations are available (Table 2). All the opioids in the table have been modified so as to delay absorption from the gut or the skin. Although methadone is not an extended release drug, it can be administered every 12 hours because of its very slow elimination after rapid oral, rectal, or subcutaneous absorption. Extended release opioids are generally not more effective or less toxic than immediate release opioids. Their main advantage is much more comfortable administration that might improve adherence

---

KEY POINTS

· Safe and effective control of cancer pain demands thorough knowledge of the pharmacokinetics and pharmacodynamics of opioids that guide dosing, titration, and rotation.
· Prevention and management of adverse effects of opioids requires careful assessment and knowledge regarding agents used to treat these complications.
· Overtreatment of cancer pain can occur when opioids are used to treat symptoms other than pain or dyspnea, including anxiety, depression, or sleep disorders.
· Evaluation of risk factors for opioid misuse, including current or past use of illicit substances, family history of substance use disorder, environmental exposure, along with a history of sexual or physical abuse, guides safe and effective care.
· Universal precautions, including measures to advance adherence and safe storage, will promote safe use of these medications while protecting the patient, the prescriber, and the community.

Table 2. Extended Release Opioids

Drug	Route	Frequency
Morphine	Oral	Every 12 hours
Hydromorphone	Oral	Every 24 hours
Oxycodone	Oral	Every 12 hours
Fentanyl	Transdermal	Every 72 hours
Oxymorphone	Oral	Every 12 hours
Hydrocodone	Oral	Every 12 hours

to chronic treatment for patients as compared to taking immediate release opioids such as morphine, hydrocodone, hydromorphone, or codeine every 4 hours day and night. However, extended release opioids are generally five times more expensive than immediate release opioids, and insurance payers frequently deny payment for these agents.[9] Therefore, the insurance company occasionally may request that patients change opioid analgesic or pay large amounts of money out of pocket. In these cases, chronic management with immediate release opioid is an appropriate alternative.

All patients with chronic cancer pain should be started on regular opioids, ideally using an extended release formulation (Sidebar 1). In addition, patients with cancer pain require access to immediate release opioids for episodes of break-through pain. Each dose should be approximately 10% (ranging between 5% and 20%) of the daily regular opioid dose. Close to 100% of the patients need to be prescribed a regular laxative every day since constipation is a universal and frequently under diagnosed problem. In addition, patients should be prescribed antiemetics since approximately half of the patients started on an opioid agonist will develop nausea for the first 3 days. Metoclopramide is an excellent option because of its combination of central and pro-kinetic effects. After the first 3 to 4 days, nausea is either minimal or absent.

Opioid titration. Even after ideal management, only approximately 50% of the patients will reach their personalized pain goal (3/10) after one visit.[10] Therefore, it is important to either follow up or phone the patient less than 1 week after the initial management to further titrate the opioid dose and to consider adjuvant drugs or drugs for the management of side effects. The minimal clinically important increase or decrease in dose will be approximately 30% of the daily dose. Opioid titration is always conducted as a percentage rather than an absolute number because of the large dose range. For example, a patient coming for follow-up in poor pain control receiving 100 mg of equivalent morphine daily dose will require an increase of at least 30 mg per day. A patient coming with a similar degree of poor pain control but receiving a dose of 300 mg of equivalent morphine per day will require an increase of approximately 100 mg per day.

When calculating the daily morphine equivalent dose, ask the patient how many extra opioid doses they received per day. For example, a patient started on 15 mg of extended release morphine every 12 hours and 7.5 mg of immediate release morphine orally every 4 hours as needed. One week later the patient complains of pain 8/10. The patient is receiving four immediate release doses per day. Total morphine equivalent dose for this patient is regular daily dose 30 plus breakthrough pain 30, making a total daily dose of 60 mg. An appropriate increase for this patient would be approximately 30% to 50% of the daily dose (20–30 mg). Therefore, the new regular opioid dose should be approximately 90 mg/day (either 30 mg every 8 hours or 45 mg every 12 hours). The new extra dose will need to be approximately 9 to 10 mg every 4 hours as needed since the ideal extra dose is approximately 10% of the daily dose.

Opioid rotation. Approximately 80% of patients with cancer will need at least one change in the type of opioid. The main reasons for opioid rotation are the development of opioid induced neurotoxicity or lack of appropriate pain control after appropriate dose titration. Sidebar 2 summarizes the main clinical features of patients who develop opioid-induced neurotoxicity. Whenever patients develop clinical findings—including a combination of sedation, myoclonus, hyperalgesia either localized at the area of the existing pain or generalized cutaneous hyperalgesia, or elements of delirium (confusion, inattention, disorientation, hallucinations, psychomotor agitation)—an opioid rotation should be conducted. Opioid rotation works by eliminating the offending drug, and it is more important to make the diagnosis of opioid-induced neuro-

---

Sidebar 1. Ideal Initial Management of Chronic Pain Due to Cancer

· Extended opioid regularly (oral or transdermal)
· Immediate release opioid for breakthrough pain, orally (10% of the daily dose)
· Laxative regularly and titrate to normal frequency before cancer (e.g., senna, polyethylene glycol)
· Antiemetic available for all patients upon initiation or dose increase (metoclopramide)
· Consider adjuvant drugs
· Follow up by telephone or in person in approximately 1 week

toxicity and proceed to change the type of opioid than which new opioid the patient is rotated to.

The total morphine equivalent daily dose of the current opioid is determined by adding the regular and all breakthrough pain doses for the past 24 hours. This dose can then be translated into the dose of the new opioid using dose ratio tables. For example, for a patient receiving a total daily dose of morphine of 300 mg per day, the equivalent daily dose of oxymorphone could be approximately 100 mg per day, for oxycodone 200 mg per day, etc.

There is considerable interpersonal variation in the opioid dose ratio, and therefore, frequent follow-up after conducting an opioid rotation is important. Opioid rotation is safe for most opioid agonists since most patients develop a significant level of cross-tolerance. Since cross-tolerance to sedation and respiratory depression is not complete, in most cases, the opioid rotation is conducted by reducing the dose of the new opioid by 30% to 50%.

One of the most remarkable exceptions to this rule of cross-tolerance is methadone.[11] Methadone is one of the most exciting opioid analgesics because of its ability to control pain that has been refractory to multiple other opioids, its lack of active toxic metabolites, its long half-life that allows for administration once or twice a day, and its very low cost that makes it affordable for low-income patients or those who are uninsured. However, methadone also has significant 3A4 cytochrome interactions and can be dangerous for opioid rotation because of its lack of cross-tolerance with all other Mu opioid agonists. For this reason, only experienced clinicians should conduct opioid rotations to methadone.

Opioid Side Effects

Adverse effects to opioids are common and should be assessed regularly (Table 3). The vast majority of patients will need regular laxatives. The most commonly used include senna and polyethylene glycol. These laxatives should be given daily, and patients should be instructed to self-titrate

Table 3. Opioid Side Effects

the dose of laxative until they have bowel movements of the same frequency and volume as they had before the diagnosis of cancer. Patients will quite commonly underestimate their level of constipation since their intake is less, they are less physically active, and they may assume constipation as "normal." The addition of an opioid can lead these patients to severe cases of obstipation, emesis, abdominal pain, anorexia, and even bowel perforation. Universal precautions regarding education and management of constipation are required whenever an opioid analgesic is prescribed.

Nausea is a frequent side effect during the initiation of opioids but is much less frequent during titration or opioid rotation. Preventative antiemetics including metoclopramide can be very useful.

Sedation is also a frequent side effect of opioid initial titration or opioid rotation. In patients who develop persistent opioid sedation, methylphenidate has been shown to reduce this side effect and allow patients to function better.[12] Methylphenidate can be used intermittently for the first few days after each dose change, and it can also be used as needed so patients can self-titrate during daytime.

Respiratory depression is rare but life threatening. It may result from excessive dose, patient chemical coping, drug or active metabolite accumulation from renal or liver failure, pharmacokinetic changes from drug interaction, or pharmacodynamic effects when combined with alcohol, benzodiazepines, and other sedatives.

As previously noted, neurotoxicity is the most dramatic side effect of opioid analgesics. Delirium occurs in more than 85% of patients with cancer at some point before death, and opioids might be a contributor in these patients, so it is important to conduct early opioid rotation. There are also multiple other causes for delirium in patients with advanced cancer, and delirium will ultimately occur in the vast majority of patients with cancer before death, even when they are not receiving any opioid analgesics.

SCREENING AND MANAGING OPIOID OVERTREATMENT, MISUSE, AND ABUSE

An emerging challenge to safe and effective cancer pain control is overtreatment with excessive and prolonged use of opioids in patients when these agents may produce more harm than benefit. Many of the same barriers that have contributed to undertreatment, such as lack of knowledge, time, and reimbursement, have advanced opioid overuse. As a result of these obstacles, comprehensive pain assessments are not conducted, and referrals for mental health counseling or physical therapy are not provided because these treatments are frequently not compensated by third-party payers. Seemingly, the provider may believe the only option is to prescribe an opioid.

Although limited data exist in the oncology setting, strong support for opioid overutilization comes from the treatment of pain in chronic nonmalignant pain settings. Higher doses of opioids in this population are often associated with mental

Encephalopathy or cognitive disorders
Inability to Follow Treatment Plan
Low literacy
Misunderstanding regarding "prn"
Substance Use Disorder
Criminal Intent

health conditions such as anxiety or depression, along with substance use disorders.[13] Emerging data suggest that prolonged use of opioids leads to hypogonadism, fractures, and cognitive blunting.[14] Provocative data from the laboratory suggest opioids may accelerate tumor growth.[15] Finally, in some patients, opioid use is not leading to improved function or quality of life— essential goals for those with chronic non-malignant pain and long-term cancer survivors.

Risk Factors for Overtreatment

Providing effective pain control should include consideration of factors associated with risk for overtreatment (Table 4). The cancer and/or its treatment may have resulted in persistent pain, the uncertainty of recurrence can be associated with significant anxiety or depression, and limited coping strategies along with reduced financial resources (sometimes a consequence of cancer treatment and/or losing one's job) all contribute to a state of great distress.[16] Coupled with a history of substance use disorder, the patient may conclude that opioids may be the most appropriate, or only, solution.

To avoid labeling, when apparent aberrant behavior occurs, the oncology team must carefully reflect on alternate explanations (Table 5). Is the patient calling frequently for refills because he or she is not getting an adequate supply of medications, because either our orders are insufficient or the insurance company has a ceiling on the dispensed amount of tablets at a number too low to meet the need? Or is the patient overwhelmed with trying to understand when to take a drug "prn" or "as needed," and they default to every 3 hours, regardless of their pain intensity? Or is the patient selling the medication to purchase other powerful illicit agents or to feed their children?

Universal Precautions

To provide safe and effective pain care, experts suggest implementing universal precautions. These measures are considered universal because we cannot predict who has a substance use disorder. These precautions employ screening, agreements, and adherence monitoring strategies.[17] Comprehensive assessment of the current and past use of legal (e.g., tobacco, alcohol) and illicit substances (e.g., prescription drugs obtained from family or purchased illegally) is

warranted. Cannabis use should be specifically evaluated, as many do not consider it to be illicit, particularly as more states are legalizing its recreational or medical use. Screening tools, such as the CAGE questionnaire, can be used to complement this assessment by determining the extent of harmful behaviors. Substance use disorders are not rare in the oncology setting.[18,19]

Agreements, formerly called contracts, detail both the patient's and provider's responsibilities in managing pain.[20] Key components generally include the requirement to use one prescriber and one pharmacy along with the condition that any changes in the plan must first be discussed. These agreements also clarify how the patient can contact the provider or their team and the expected frequency of clinic visits. Safe storage and handling of medications may be included to prevent diversion and community exposure to controlled substances. There are limited data regarding the efficacy of these agreements in the oncology setting.

Adherence monitoring strategies include the use of pill counts, prescription monitoring programs, and urine toxicology screening. Pill counts can be performed in the clinic to determine appropriate use of an opioid or other medication by comparing the number of pills remaining with what might be expected. Complementing this information is the regular use of prescription monitoring program records. Forty-nine states currently provide databases that inform prescribers about the dispensing of controlled substances. Although the information provided among states varies, using a patient's name and date of birth, the prescriber can determine the drug, date it was dispensed, dose, number of tablets, name of prescriber and pharmacy, and payment method (i.e., self-pay versus third-party payer). This informs safe prescribing but also assists when seeing new patients with low health literacy who do not know the name or dose of their medication.

Random toxicology screening can tell the prescriber whether the drug ordered is present and if nonprescribed substances have been ingested.[21] Most screening is conducted using urine, as it is less invasive and more cost-

effective. Basic screens use immunoassay to ascertain the presence of certain classes of substances (or their metabolites), with most including opioids, amphetamines, benzodiazepines, barbiturates, cocaine, phencyclidine, and tetrahydrocannabinol. If findings are abnormal, more elaborate and expensive testing can be performed to determine the presence of specific agents (e.g., oxycodone or morphine) using gas chromatography-mass spectroscopy. Caution is warranted when interpreting findings as false negatives and positives can occur. For example, screens may be negative for opioids when patients are appropriately using fentanyl patches, as fentanyl is often missed by immunoassays. Additionally, patients who are supposed to be taking hydrocodone might have a urinary drug screen positive for hydrocodone, hydromorphone, and morphine since the liver metabolizes hydrocodone into these substances.

An essential component of universal precautions is education about safe storage and disposal of controlled substances.[22] Unfortunately, the majority of patients are unaware of the importance of these measures.[23] One of the most common sources of prescription opioids for abuse is family members and acquaintances. Unfortunately, in the case of patients receiving high doses or opioids, one single tablet taken by an opioid-naive relative or acquaintance can result in death. Since these drugs are frequently called "painkillers," relatives or acquaintances with a minor pain who are opioid naive may ask the patient to share a tablet, and patients should be warned about the danger of this practice.

Substance Use Disorder: Addiction and Chemical Coping

Addiction and chemical coping can occur in patients receiving opioids for cancer pain. By binding to the receptors in the limbic system, opioids not only have an analgesic effect but also produce reward. Patients at risk for opioid misuse will become dysphoric if they do not receive escalating doses. Patients' use of opioid in an effort to manage emotional distress rather than purely physical pain has been defined as chemical coping. This syndrome is more common among young, male patients with a history of alcoholism, drug abuse, and smoking.[24] Patients who rapidly escalate the opioid dose, frequently complain of pain with intensity of 10/10, or are at risk for chemical coping should be referred to a supportive care/palliative care team for interdisciplinary management of this complex problem. Collaboration with addiction specialists may be useful.

One might consider the phenomenon of opioid misuse as a continuum with chemical coping being an early stage of substance use disorders. In our clinical experience, when patients use opioids to treat anxiety, depression, or sleep disorders, these actions can often be countered with compassionate use of motivational interviewing to assist them in gaining insight into their behaviors and to appropriately treat their emotional distress. Early identification is necessary.

Patients with ongoing, untreated substance use disorders, such as regular use of heroin or other illicit substances, re-quire more complex care than can usually be provided in an oncology setting without significant interdisciplinary support.[25] The goal may be the provision of pain control while employing "harm reduction"—preventing diversion of substances to the community while providing safe and effective care. A week's supply of opioid may be prescribed, rather than 1 month, and frequent urine screening may be employed. Interdisciplinary care is warranted.

People with a past history of substance use disorder and those who are in recovery may present a unique challenge. Fears of relapse when presented with an opioid for the treatment of cancer pain may lead the patient to refuse these medications. Thoughtful discussions about using these opioids, trying nonopioid analgesics, employing interventional therapies, and incorporating the patient's sponsor or case manager can be helpful to provide effective relief while limiting the risk of relapse.

A number of new opioid preparations are currently aimed at reducing the risk of illegal use.[26] The idea behind their formulation is that many abusers tamper with tablets to facilitate intranasal or intravenous administration since these routes result in a more rapid peak serum level and a feeling of euphoria. All these preparations consist of an extended release opioid agonist (morphine, oxymorphone, oxycodone, or buprenorphine) modified in one of three different ways: (1) introducing barriers to crushing, chewing, or dissolving; (2) adding an aversive substance that will cause irritation if inhaled, injected, or chewed; and (3) adding an opioid agonist, such as naloxone or naltrexone, that will not be absorbed if the tablet is taken orally as prescribed but will reduce the opioid effect or result in withdrawal if inhaled, injected, or chewed.

These preparations are now in different levels of approval in the United States and other countries. Although they may help reduce the intravenous injection of extended release opioids and perhaps reduce overdose mortality, these preparations will not be able to avoid the two most common sources of chemical coping: taking more than the prescribed dose of intact tablets, and using the immediate release rescue opioid aberrantly. These preparations are also likely to dramatically increase financial toxicity for patients who already face difficulties paying for opioids.

SUMMARY

Safe and effective opioid use in patients with cancer requires balance and skill. These skills include comprehensive assessment, understanding the pharmacokinetics and dynamics of these agents, and knowledge of dosing, titration, and rotation. Balance speaks to the awareness that opioids might be misused, either inadvertently by patients who note they fall asleep or feel less anxious when using these drugs, or purposefully by those with substance use disorders or criminal intent. Universal precautions can support adherence and prevent diversion. Caring for patients with misuse requires interdiscplinary care, with input from supportive oncology/palliative care and addiction specialists.

OVERVIEW

It is an exciting era in pediatric oncology with the advent of new technologies to comprehensively characterize cancer genomes in childhood tumors. Defining the genetic landscape of pediatric tumors has not only provided critical insight into tumor evolution, but it has also offered promise for more effective treatment in some cases, such as Philadelphia chromosome-positive acute lymphoblastic leukemia (ALL) and anaplastic lymphoma kinase (ALK)-mutated tumors. However, several challenges remain as the field of genomic tumor profiling emerges. This new technology is costly, and the overall impact on survival has yet to be determined. Tumor heterogeneity and clonal evolution have also presented challenges in the development of targeted therapy. In this article, we review breakthroughs in gene sequencing methodology and discuss examples where genomic discoveries have resulted in the recognition of tumor susceptibility as well as incorporation of targeted therapy. We also discuss how broad scale comprehensive tumor analyses have demonstrated the convergence of individual genetic alterations on common relevant pathways. Although the impact of tumor profiling is best studied within the context of rigorously designed clinical trials, there is promise that there will be growing opportunities for the adaption of precision medicine in pediatric oncology in the future.

The Human Genome Project and technical breakthroughs in gene sequencing methodologies have ushered in unprecedented discoveries into the origins of human cancer. More than 10,000 human tumors have been profiled at the genetic and epigenetic level, and this information has been translated into remarkable improvements in therapy for a minority of cancers where the underlying genetic lesion/pathway can be targeted with specific agents. Most of these examples come from adult cancers, most notably in *BRAF*-mutated melanoma that can be treated with inhibitors like vemurafenib and, more recently, for the small percentage of adults with non-small cell lung cancer that contain *ALK* rearrangements that can be targeted with crizotinib (originally designed as a C-MET inhibitor). However, even before application of high-throughput sequencing, the promise of personalized or precision medicine was realized in the treatment of pediatric Philadelphia chromosome-positive (Ph+) acute lymphoblastic leukemia (ALL) with the tyrosine kinase inhibitor imatinib.[1]

Currently, precision medicine has the potential to improve outcome and decrease side effects for already curable pediatric cancers, either in conjunction with chemotherapy or by replacing some conventional agents (e.g., most ALLs, lymphomas, and low-/intermediate-risk solid tumors) and may finally lead to better outcomes for children with high-risk tumors where progress has been either slow or stalled (e.g.,

metastatic solid tumors, advanced neuroblastoma, many brain tumors, acute myeloid leukemia and relapsed disease).

Although there is no doubt that there has been a great success in terms of basic science discovery, there are many practical biologic, technical, and financial hurdles that are likely to interfere with successful full-scale deployment of this strategy for routine treatment of pediatric patients with cancer.[2,3] This review will highlight biologic discoveries in pediatric cancers in the context of changing treatment. The focus will be on current opportunities as well as those on the horizon. This review will specifically focus on targeted therapy in the context of pharmacologic inhibition of a somatically altered gene product or downstream pathway.

NEXT-GENERATION PLATFORMS AND THE COST OF SEQUENCING INDIVIDUAL CANCER GENOMES

Current platforms are capable of performing a variety of sequencing approaches including whole genome (single nucleotide variations and copy number differences in all DNA base pairs), whole exome (mutations and copy number differences in transcribed exons—protein coding, miRNAs, and other RNA species), RNA sequencing (gene expression, splicing changes, fusion transcripts), as well as epigenetic differences using Methyl sequencing (methylation differences in DNA, likely to affect expression) and Chromatin Immu-

noprecipitation (ChIP) sequencing, which determines chemical changes to the surrounding chromatin that are also likely to affect gene expression. In some cases, data can be produced on an individual in less than a day. Ideally, all platforms would be used to create a full portrait of the genetic and epigenetic landscape of an individual, and there are many examples where combining data (e.g., copy number, gene expression, methylation, and DNA sequencing) shows convergence on alterations in pathways shared among patients of an individual tumor type and/or pathways used by tumor cells to evade therapy. However, the prohibitive cost of sequencing and data analysis now prevents simultaneous deployment of multiple strategies.

The details of these approaches vary but, in general, involve the generation of single-stranded DNA (from genomic DNA, hybridization captured [exome], cDNA [RNA sequencing], bisulfite treated DNA [methyl sequencing] or immunoprecipitated DNA [ChIP sequencing]) with ligation of DNA adapters. Rounds of amplification on beads or glass slides allow adequate coverage of the DNA, and strands can then be sequenced by the sequential addition of fluorescently labeled nucleotides. Varieties of bioinformatic approaches are used to determine quality, align sequences to the genome, and determine variations in sequence. Each approach has advantages and disadvantages. For example, whole-exome sequencing (WES) is less expensive than whole-genome sequencing and focuses on somatic variants in protein coding domains that are likely to contain critical lesions. However, it can miss fusion transcripts and does not provide gene expression information that may highlight activation of biologic pathways.

The sequencing of an individual cancer genome in a short period of time to allow integration into clinical practice is now a reality. However, the cost of a single sequencing run, including analysis and validation, is significant, especially since reimbursement of such assays is still uncertain in many cases. The $1,000 genome has been often quoted as a holy grail for clinical sequencing, and the recent development of the HiSeq X Ten system (Illumina) has finally laid claim to this title. However, achieving this goal requires the purchase of 10 systems costing approximately $10 million and opera-

tion more than 4 years yielding about 72,000 genomes for a total outlay of $82 million in capital and operational costs.[4]

PEDIATRIC CANCER GENOMES AND THERAPEUTIC TARGETS

The practical implementation of precision medicine is facilitated by the identification of somatic changes unique to the tumor that fuel cancer initiation and progression. Moreover, such drivers that are shared among and across tumor types would increase the effect of agents that selectively target the gene product and/or downstream pathway. Although there are a few exceptions, in general, childhood tumors contain far fewer mutations than adult tumors and within tumors types, most mutations are not shared by the majority of cases.[5,6] Overall, the number of nonsynonymous coding mutations varies from one to 12 per pediatric tumor sample. Outliers exist with higher mutation frequency in a small percent of pediatric tumors that may harbor alterations in DNA repair pathway genes. Despite the relatively low mutation burden, there are many examples where actionable mutations are likely to lead to novel therapeutic interventions in the near future.

There are a handful of pediatric tumors where high-frequency shared genomic alterations are characteristic. Examples include malignant rhabdoid tumors in which *SMARCB1* mutations occur in 100% of cases and may be the sole abnormality, as well as diffuse pontine gliomas where *H3* histone mutations are observed in 78% of cases.[7,8] Such mutations converge on epigenetic pathways, and although these targets are not actionable at the present time, downstream targets in which expression is affected have been identified.

More commonly, recurrent mutations are seen in smaller subsets of samples within a given class of tumors. There was great anticipation that deciphering the genetic landscape of high-risk pediatric tumors, where clinical progress has been stalled, would lead to catalytic advances in treatment. Improving therapy for the most common extracranial solid tumor, neuroblastoma, is a top priority in pediatric oncology. Although the prognosis is favorable for low-stage disease, most patients present with widely metastatic disease. Therapy for stage IV neuroblastoma has improved somewhat, but further progress is urgently needed.[9] In one of the largest sequencing efforts directed at neuroblastoma, 240 cases were examined. Individual samples had on average 14 nonsilent or nonsynonymous mutations.[10] The most commonly seen alterations were *ALK* mutations (9.2%, gain of function), *ATRX* alterations (9.6%, deletions and loss of function mutations), and *PTPN11* mutations (2.9%). Thus, it is somewhat disappointing that neuroblastomas do not contain high-frequency variants suitable for targeted therapy; however, the use of ALK inhibitors for the 10% of patients who carry *ALK*-activating mutations is an important avenue to pursue. This disappointment is tempered by new approaches to inhibit MYCN and its downstream targets. Amplification of the *MYCN* oncogene is observed in 25% of cases but, to date, numerous approaches to target transcription factors like MYC

KEY POINTS

- The genetic landscape of childhood cancer is far less complex than that of tumors that occur in adulthood.
- Tumor profiling has revealed genetic alterations unique to traditional histological tumor subtypes as well as changes that are shared across seemingly disparate tumors.
- With few exceptions, high-frequency shared genetic alterations are not observed, but low frequency individual genetic alterations may coalesce into biological pathways that offer the possibility of novel treatment approaches.
- The impact of precision medicine is best evaluated in the context of carefully controlled clinical trials.

have failed. However, the development of BET bromodomain inhibitors is emerging as a powerful approach to target MYC-overexpressing tumors. These agents effectively displace BRD4, a protein targeted to acetylated lysines, from the *MYCN* promoter, thereby downregulating MYCN expression as well as downstream targets. The clinical efficacy has been documented in preclinical models and clinical trials are underway.[11] Likewise CDK7 inhibitors selectively suppress MYC-driven cancers.[12]

Interestingly, even in tumors that harbor sentinel genetic translocations, there may be surprising heterogeneity of additional genetic alterations. Ewing sarcoma is characterized by translocations between *EWSR1* on chromosome 22 (q11.2) and members of the *ETS* family; usually *FLI1* (11q12). More than 90% of Ewing sarcomas contain *EWSR1* fusions. Recent sequencing efforts have noted that samples had an average of 10 coding variants per tumor, consistent with what has been observed for other childhood cancers.[13,14] However, despite this relatively uniform genetic class, only a minority of sequence variants were shared. The most consistent lesions were *STAG2* mutations, which were observed in only 17% of cases, followed by *CDKN2A* deletions (12%) and *TP53* mutations (7%). *EZH2, BCOR,* and *ZMYM3* mutations were each seen in 2.7% of samples. *STAG2* and *TP53* mutations often coexisted and were associated with an inferior outcome. Thus, the majority of single nucleotide variants were unique. Likewise the poor prognosis alveolar subtype of rhabdomyosarcoma is characterized by genetic fusions between the *PAX3* or *PAX7* genes and *FOXO1*. Interestingly, these tumors have far fewer nonsynonymous mutations compared with fusion-negative embryonal tumors that have a better prognosis (average 6.4 vs. 17.8).[15] Moreover, there was no significant sharing of mutations across *PAX-FOXO1* samples and individual mutations did not converge on biologic pathways (see below).

INDIVIDUAL GENETIC ALTERATIONS MAY CONVERGE ON BIOLOGIC PATHWAYS

Results to date indicate that many samples from patients with a wide variety of histologic subtypes lack high frequency shared genetic alterations. To interpret these results it must be recognized that approximately 50% of the somatic variants detected are likely to be passenger mutations, possibly acquired from the initial nontransformed stem cell of origin.[5] Second, it is likely that although the mutational landscape may vary markedly between tumors of the same histologic or genetic subtype, the lesions may converge on common pathways.

Remarkably, about 50% of embryonal rhabdomyosarcomas contain activating mutations in the RAS pathway (*RAS* [22.4%: *NRAS,* 11.7%; *KRAS,* 6.4%; *HRAS,* 4.3%], *FGFR4* [11.7%], *PI3CA* [7.4%] and *NF1* [5.3%]).[15] Although RAS remains an elusive target there are many downstream inhibitors currently under investigations as well as the U.S. Food and Drug Administration (FDA)-approved MEK1/2 inhibitor trametinib.

Overall survival for the most common pediatric bone tumor osteosarcoma has remained at a plateau for three decades. Osteosarcoma stands out among all pediatric tumors for its relatively high mutation rate and number of structural variations per sample. A recently published analysis showed that on average osteosarcoma samples have 37 nonsynonymous mutations, which is at least three-fold greater than that observed for other pediatric cancers.[16] In addition, osteosarcomas contain frequent copy number alterations including deletions in *RB1, TP53,* and *CDKN2A/B,* and amplifications in *COPS3, CCNE1, CDK4,* and *MYC.* Inactivation of *TP53* either by mutation and/or deletion is seen in three-fourths of cases (some cases have germ line *TP53* mutations), whereas, *RB1* deletion is seen in approximately 60% of samples. Combined *RB1/TP53* inactivation occurs in half of all cases. In examining the mutation spectrum, little to no shared mutations were seen beyond the 22% of samples containing *TP53* mutations. However, gene set enrichment analysis indicates that 24% of patients have tumors with alterations in the PI3K/mTOR pathway. This observation was validated in a genome-wide pooled shRNA screen and murine xenograft experiments confirmed therapeutic efficacy for dual PI3K/mTOR inhibitors (GSK2126458, BEZ235) and the PIK3CA inhibitor (PIK75).

Although the outcome for all subtypes of childhood ALL has improved considerably, patients who relapse have a dismal prognosis even with high-dose chemotherapy and stem cell rescue. In an effort to identify the underlying biologic pathways that drive drug resistance and relapse, many investigators have performed gene expression, copy number, methylation, and sequencing analyses on diagnosis relapse pairs. These efforts have identified alterations enriched at relapse and in some cases these alterations have been shown to alter drug sensitivity to individual agents (e.g., *BTG1* and *TBLXR1* deletions and decreased sensitivity to glucocorticoids and *NT5C2* mutations and resistance to purine analogs).[17,18] However, these alterations occur in a small but significant subpopulation of patients. When changes across three platforms were integrated (copy number alterations, changes in methylation, and gene expression) there was significant convergence on activation of the WNT and MAPK pathways. Activation has been subsequently validated by phosphoflow protein levels and inhibitors of both pathways have been shown to synergize with chemotherapy in cell lines and patient samples.[19-21]

These examples illustrate the value of sequencing a large collection of samples and emphasize the importance of pathway analysis and validation.

PRIMETIME EXAMPLES OF GENETIC PROFILING AND TARGETED THERAPY

The ALK oncogene is perhaps the best example of an emerging new target in pediatric oncology. Almost all (> 90%) pediatric anaplastic large cell lymphomas (ALCL) contain activating ALK fusion transcripts, usually *NPM-ALK.* Inflammatory myofibroblastic tumors (IMT) are quite rare and

most are treated with surgical excision, but 50% of cases also show an *ALK* rearrangement, most commonly with *TPM3* and *TPM4*. Finally, the majority of familial neuroblastomas and, as described above, 8% to 10% of sporadic cases have *ALK* activating point mutations. Another 2% to 3% of sporadic cases have *ALK* amplification. Early phase clinical trial experience with the ALK inhibitor crizotinib (originally designed as an MEK inhibitor) shows a remarkable response in patients with refractory ALCL (eight of nine patients) and IMT (three of seven patients), but less activity in ALK-activated neuroblastoma (one of 11 patients).[22] These encouraging results, in part, led to the development of the currently open Children's Oncology Group (COG) ANHL12P1 randomized phase II trial for newly diagnosed ALCL using brentuximab vedotin or crizotinib in combination with chemotherapy.

Successful introduction of imatinib into conventional chemotherapy for Ph+ ALL has had a profound effect on survival, and this success has been followed by the investigation of the second-generation tyrosine kinase inhibitor, dasatinib in combination with chemotherapy.[1,23-25] Most children can now be successfully cured without the use of stem cell transplantation. Perhaps even more importantly from a population base effect standpoint, approximately 10% of children with standard-risk ALL and 27% of young adults with ALL have "Philadelphia-like" (Ph-like) ALL that share a gene expression profile like Ph+ ALL but lack the BCR-ABL1 fusion protein. These cases often share *IKZF1* deletions, CRLF overexpression, and have a poor prognosis. Recent large-scale sequencing efforts have documented that the overwhelming majority (91%) of samples from patients with Ph-like disease carry kinase-activating alterations.[26] In particular, 12.6% of a recent series of such patients had fusions that would respond to ABL1 inhibitors such as imatinib (e.g., *ABL1*, *ABL2*, *CSF1R,* and *PDGFRB* fusions) and more than one-half had JAK-STAT pathway lesions such as *CRLF2* rearrangements with and without *JAK2* mutations and other JAK-STAT alterations. In vivo and in vitro models have confirmed response to ABL1 inhibitors and JAK1/2 inhibitors, respectively.[26-28] There have now been numerous anecdotal reports of patients with *ABL1* class fusions showing dramatic responses to tyrosine kinase inhibitors.[29,30] As a result, COG plans to open a prospective trial comparing the outcome of patients with ABL1 fusion treated with a combination of dasatinib and chemotherapy with a historic control of recently treated patients (chemotherapy alone).

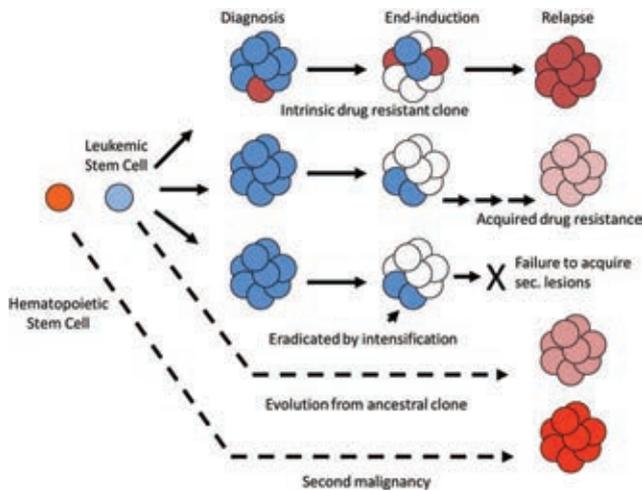
These two trials for ALK-positive ALCL and Ph-like ALL (as well as the previous two COG studies for Ph+ ALL) illustrate the rapid integration of new agents for newly diagnosed patients in a nonrandomized fashion. Preclinical data indicate that the targets are essential for tumorigenesis and early experience (some anecdotal for Ph-like ALL) shows spectacular clinical efficacy. Given the strong biologic rationale and preclinical data for certain targeted agents a randomized trial may not always be feasible, and in this case the two trials differ remarkably in technical approaches. Simple ALK staining indicates ALK activity, whereas, expression profiling is being used to detect Ph-like ALL followed by a stepwise targeted approach to identify cases appropriate for treatment with tyrosine kinase inhibitors.

TUMOR HETEROGENEITY AND EVOLUTION

In addition to the relative dearth of effective targeted agents, one of the biggest barriers to effective implementation of clinical sequencing in oncology is tumor heterogeneity.[31] Indeed many home grown sequencing efforts have not accounted for this property of cancer populations. In contrast to most adult cancers, pediatric tumors appear to have less genomic instability with the possible exception of osteosarcoma. Thus, endogenous sources of ongoing mutational frequency throughout tumor evolution may be less of an issue in childhood cancer; although, exogenous sources of genome instability through cytotoxic therapy remains a possibility. There is no doubt, however, that multiple subclones exist within a given tumor and subclones may be geographically distinct so that a single biopsy may not capture the full mutational spectrum of a given tumor. In addition, human tumors have been shown to follow a branched chain model in which certain mutations, which are typically acquired early, are truncal drivers, whereas, as others appear to drive subclones (branch drivers). Targeting truncal drivers may provide more clinical benefit. Last, there is evidence to suggest that clones may compete with one another so that targeting one may lead to emergence of the competitor. Conversely, clones may exist in a symbiotic relationship so that targeting one may have a collateral effect on regression of another. All these potential confounding evolutionary features of cancer progression require consideration when designing sequence-based therapeutic interventions.

Acute leukemia provides a convenient model to study tumor evolution considering the feasibility of serial tumor sampling. However, the use of cell-free DNA in the circulation is proving to be a potential option of monitoring solid tumors where access is challenging. As mentioned above, studies have generally showed a complex, nonlinear evolutionary history during which mutations may be acquired independently.[32] Examination of diagnosis and relapse pairs frequently reveals outgrowth of a minor subclone that can be backtracked to diagnosis (Fig. 1). These small subclones may not be detected by conventional NGS approaches. These studies have shown enrichment of genetic alterations (e.g., deletions of *IKZF1*, *MSH6*, *EBF1*, *BTG1,* and *TBL1XR1*, and mutations of *NT5C2* and *RAS* pathway mutations) that account for resistance to conventional chemotherapy.[17-19,33,34] Thus, the outgrowth of these clones is profoundly shaped by the selective forces of the chemotherapy applied. Earlier detection and/or monitoring for emergence of subclones may allow preemptive alteration of conventional agents and/or targeted therapy to prevent overt relapse.

Although targeted therapy has had a profound effect on disease regression for adult tumors like advanced *BRAF*-mutant melanoma and *ALK* fusion non-small cell lung cancer, the beneficial response is short lived with emergence of

FIGURE 1. Clonal Evolution of Relapsed Disease in ALL


A pre-leukemic stem cell (LSC; light blue) gives rise to frank ALL (dark blue cells). Intrinsically, drug-resistant clones (red) may be present and detected at diagnosis at low levels in approximately 34% of cases. However, relapse might emerge from an ancestral clone or LSC (52% of cases). LSCs and other subclones may survive initial treatment and may acquire additional lesions that result in acquired drug resistance and relapsed disease (52% of cases). Rarely, relapse clones are genetically distinct from that at diagnosis (second malignancy; 6% of cases).[33,45]

resistant subclones either through gatekeeper mutations that interfere with drug-target interaction or off-target resistance through activation of biologic pathways that bypass the mechanism of therapeutic targeting. Based on analysis of samples at relapse, the development of next-generation agents that accommodate gatekeeper mutations and dual pathway inhibitors have shown greater efficacy, yet the enormous repertoire of tumor subclones is likely to be an ongoing issue. In this regard, the nonspecificity of conventional agents may prove to be an advantage when given with targeted agents.

CURRENT CLINICAL EXPERIENCE WITH PEDIATRIC TUMOR SEQUENCING

NGS is now being rapidly incorporated into clinical laboratory settings,[35] which have resulted in the fast growing field of genomic medicine. More often WES is being performed as approximately 85% of disease-causing mutations reside in coding regions of the human genome.[36] This has led to multiple recent studies that reported on the implementation of these tests as well as the evaluation of the clinical utility that exome data can provide in pediatric oncology populations. In a study that examined obtaining informed consent for clinical WES in newly diagnosed solid tumors, 83% of eligible families choose to participate, allowing analysis of both tumor and germ line DNA.[37] No significant differences in enrollment were seen based on race, ethnicity, use of interpreters, or language of consent forms. Additionally, no difference in enrollment was seen based on tumor type or availability of specimens. Of those families that chose to decline, the most commonly stated reason was being overwhelmed by the new diagnosis. Furthermore, of the 83% of

patients that consented to the study, clinically relevant mutations were identified in 28% of tumor cases (22 of 80 cases).[38] Similar data were obtained by another group profiling high-risk and refractory pediatric solid tumors.[39] Using targeted NGS, Sequenom assay or array comparative genomic hybridization individualized cancer therapy recommendations were made in 30% of cases based on profiling results.

In addition to WES, targeted NGS panels are currently being developed that are specifically tailored to capture cancer-related genes and introns of genes commonly rearranged in pediatric tumors. The hybridization capture assay currently offered by Foundation Medicine, which can be completed in 14 to 17 days, surveys 236 genes and 47 introns of genes commonly involved in chromosome translocations. Recent analysis of 400 cases profiled by this method, consisting of both solid and hematopoietic tumors, showed 60% of samples obtained at least one alteration associated with a FDA-approved or experimental therapy in an open clinical trial.[40] Although these studies show that sequencing can lead to therapeutic decisions, additional research is still needed to determine the effect NGS has on overall survival and outcome.

Although most WES studies have focused on somatic variants, germ line data is also routinely profiled in pediatric tumors in tandem to provide an analysis of pathogenic mutations in cancer susceptibility genes as well as mutations present in nononcogenic-related diseases. In a large study surveying 565 genes in 1,120 pediatric cancers, 8.6% of patients were found to have a pathologic or likely pathologic germ line variant.[41] Likewise, 14% of cases harbored a predisposing pathogenic mutation in the germ line DNA in 80 solid tumor cases mentioned previously.[38] This demonstrates that the number of pediatric cancers caused in part by inherited variation may be much higher than anticipated previously, and in many of these cases a family history was not suggestive of a predisposition. Additionally, the discovery of unanticipated incidental germline findings raises a considerable debate about the return of such information to patients.[38] Early recommendations included mandatory return of germ line results on 56 genes associated with 24 inherited conditions, but an early revision of this policy is that patients may opt out from receiving such information.[42]

CLINICAL TRIALS OF PRECISION MEDICINE: PEDIATRIC IMPACT

Given all the challenges discussed, the true effect of precision medicine on patient outcome remains uncertain. It is noteworthy that from 2002 to 2014, 71 agents were approved for use in adult solid tumors, with many qualifying as targeted agents. Although there were striking exceptions, the median improvement in progression-free survival and overall survival was 2.5 months and 2.1 months, respectively.[43] In this context, careful clinical trials that rigorously incorporate NGS would seem to be essential before routine adaptation of this approach at individual centers that treat pediatric oncology patients. Although N-of-1 protocols and molecular tumor boards may add value, the true effect of precision medicine is best measured when bio-

markers and interventions are defined at the outset. The National Cancer Institute (NCI) MATCH prospective clinical trial will open for patients age 18 or older in which standard therapy has failed and who are willing to undergo a rebiopsy.[44] Analysis of approximately 200 genes that have been selected for alignment with a targeted agent will be performed in one of four Clinical Laboratory Improvement Amendment-certified laboratories. The trial will use FDA-approved drugs outside of their indication as well as agents not yet approved but that have shown activity in a given tumor type. The NCI MATCH study will be open to all four adult cooperative groups. NCI is now planning a Pediatric MATCH study with COG, thus, paving the way for precision medicine for all COG members.

SUMMARY AND CONCLUSIONS

Next-generation genomic analysis of pediatric tumors has yielded profound insights into the origins of childhood cancers and has shed light on biologic pathways that drive tumorigenesis and drug resistance. Integration of new agents on a backbone of traditional therapy is being pursued in many tumor types, and there is great anticipation that such approaches will lead to improved outcomes. The integration of NGS into therapeutic decision making for individual patients poses many technical, financial, and biologic challenges. It may be anticipated that such hurdles will be overcome through careful application of precision medicine in the context of rigorous clinical trials.

Approaches to Reduce the Long-Term Burden of Treatment-Related Complications in Survivors of Childhood Cancer

Saro H. Armenian, DO, MPH, Leontien C. Kremer, MD, PhD, and Charles Sklar, MD

OVERVIEW

Advances in diagnostics, treatment strategies, and supportive care have contributed to a marked improvement in outcomes for children with cancer. This has resulted in a growing number of long-term childhood cancer survivors. Currently there are over 360,000 individuals who are survivors of childhood cancer in the United States. However, treatment for patients with childhood cancer with chemotherapy, radiation, and/or hematopoietic stem cell transplantation can result in health-related complications that may not become evident until years after completion of treatment. As a result, several initiatives have been established to help standardize the surveillance for treatment-related late effects in childhood cancer survivors. This review highlights emerging concepts related to commonly reported late effects, such as subsequent malignant neoplasms, cardiovascular disease, and endocrinopathies. It also discusses relevant population-based screening strategies to mitigate the long-term health-related burden in vulnerable populations of survivors.

Advances in diagnostic precision, treatment strategies, and supportive care have resulted in marked improvements in outcomes for children diagnosed with cancer. Overall 5-year survival rates for these children now exceed 80%, resulting in over 360,000 individuals who are survivors of childhood cancer in the United States.[1] Of these, 24% are estimated to have survived more than 30 years since their diagnosis, contributing to the growing number of long-term survivors of childhood cancer in the United States.[1] These survivors are at high risk for developing complications, such as subsequent malignant neoplasms, cardiovascular disease, and endocrinopathies, years after completion of cancer treatment.[2-4] For many of these complications, there are well-established associations between therapeutic exposures and adverse health-related outcomes,[4] which sets the stage for primary prevention (avoidance of certain treatments, when possible) and secondary prevention (screening for and treatment of asymptomatic disease) strategies in these survivors.

Recognizing the need for a systematic plan for surveillance of health-related complications, a number of groups[5-8] have developed risk-based, exposure-related guidelines to facilitate the long-term follow-up care of childhood cancer survivors. These efforts have been further enhanced by an ongoing international effort (International Guideline Harmonization Group [IGHG])[9] to develop uniform recommendations for population-based surveillance. Recommendations for breast cancer[10] and cardiomyopathy[11] screening have been established, and there are a number of ongoing initiatives that will address topics related to reproductive health, other subsequent malignancies, and cardiovascular complications. We present an overview of some of the more commonly reported health-related complications in survivors of childhood cancer and outline current recommendations for early screening and disease prevention.

SUBSEQUENT MALIGNANT NEOPLASMS

Subsequent malignant neoplasms (SMNs), defined as histologically distinct malignancies that develop in children with a primary malignancy, are the leading cause of nonrelapse late mortality.[12-14] The incidence of SMNs in childhood cancer survivors increases with sustained age, with the cumulative incidence exceeding 20% at 30 years after diagnosis of the primary cancer.[13-15] These survivors have an up to sixfold risk of SMNs when compared with age- and sex-matched general population, and the excess risk of SMNs is highest for Hodgkin lymphoma (HL) and Ewing sarcoma survivors (8.7-fold and 8.5-fold, respectively).[15] A recent report[16] found that survivors who develop a first SMN (SN1) are at an especially high risk of multiple occurrences of subsequent neoplasms. Within 20 years from diagnosis of the first SMN, nearly one-half (47%) will develop a subsequent neoplasm. Previous studies have demonstrated that childhood cancer survivors with either a family history of cancer, and even more so, presence of Li-Fraumeni syndrome or hereditary retinoblastoma, carry an increased risk of developing an SMN[17-19]; suggesting that germ line predisposition to cancer may play a role in SMNs.

Commonly reported solid SMNs include breast, thyroid, skin, and brain cancer. There is a well-defined association between radiation exposure that is characterized by a long latency that exceeds 10 years.[13,15] The incidence of many of these solid SMNs continues to increase with longer follow-up, with no plateau of risk over time.[13,15] Other SMNs, such as treatment-associated leukemia (myelodysplastic syndrome/acute myeloid leukemia [tMDS/AML]) are notable for their shorter latency (< 5 years from primary cancer diagnosis), and association with alkylating agent and/or topisomerase-II inhibitor chemotherapy.[20,21] The distinct differences in the onset and role played by specific therapeutic exposures often have resulted in the classification of SMNs into two distinct categories: (1) radiation-related solid SMNs, and (2) chemotherapy-related tMDS/AML.[21]

Radiation-Associated Solid Subsequent Malignant Neoplasms

Breast cancer. Female childhood cancer survivors treated previously with radiation involving the chest area (e.g., mantle, mediastinal, whole lung, and axillary fields) are at high risk of developing breast cancer later in life.[22-24] In this population, the cumulative incidence of breast cancer ranges from 12% to 20% by age 45,[22-24] an incidence equivalent to that seen in women who have a *BRCA* gene mutation (incidence 10% to 19% at age 40).[24] In childhood cancer survivors, the latency of breast cancer after chest radiation ranges from 8 to 10 years, and the risk increases in a linear fashion with radiation dose.[24,25] The relative risk is 6.4 at a dose of 20 Gy and it increases to 11.8 at a dose of 40 Gy.[24,25] Breast cancer risk is attenuated among women who also received radiation to the ovaries, which reflects the role of hormone stimulation on patients with radiation-induced breast cancer.[24,25]

Screening recommendations[10] for women exposed to 20 Gy or more of radiation to the chest area (Table 1) include monthly breast self-examination beginning at puberty, annual clinical breast examination beginning at puberty until

KEY POINTS

- There are a growing number of long-term survivors of childhood cancer at risk for treatment-related complications later in life.
- There are well-established associations between therapeutic exposures and adverse health-related outcomes such as subsequent malignant neoplasms, cardiovascular disease, and endocrinopathies.
- A number of risk-based exposure-related guidelines have been established to facilitate the long-term follow-up care of childhood cancer survivors.
- These surveillance guidelines are an integral component of the lifelong follow-up of childhood cancer survivors.
- Studies are needed to evaluate the efficacy of these recommendations in survivors who have the highest risk for treatment-related complications.

age 25, and clinical breast examination every 6 months with annual mammograms and MRIs beginning 8 years after radiation exposure or at 25 years (whichever occurs last).

Thyroid cancer. Survivors at risk include those treated with head, neck, chest, mantle, craniospinal, or total-body irradiation (TBI).[26,27] The association between radiation dose and thyroid cancer is curvilinear, with risk increasing at low to moderate doses and decreasing at doses more than 30 Gy because of cell-killing effect.[27-29] Additional risk factors for developing thyroid cancer include younger age at diagnosis, female sex, and longer duration of follow-up.[27,29,30]

Childhood cancer survivors treated with radiation affecting the thyroid should have lifelong annual screening exams for thyroid abnormalities (Table 1). Although some have advocated the use of thyroid ultrasonography to screen for thyroid cancer in previously irradiated patients,[31,32] the Children's Oncology Group (COG) currently recommends careful palpation annually.[5] The indolent course and excellent outcome of the vast majority of second primary thyroid cancers has prompted debate about the risks versus the benefits of ultrasound screening in at-risk survivors.[32,33]

Brain tumor. Childhood cancer survivors have an 8.1 to 52.3 times higher incidence of developing subsequent brain tumors compared to the general population.[34] High-grade gliomas and meningiomas are the two most common SMNs, and the vast majority of these tumors develop in children treated with cranial radiation.[34,35] Although the risk for subsequent brain tumors demonstrates a linear relation with radiation dose, the dose-response appears to be weaker for gliomas than for meningiomas.[15,34]

Survivors treated with cranial radiation should have an annual follow-up that includes a targeted history and a comprehensive neurologic examination.[5] The additional benefit of screening using neuroimaging (e.g., MRI) is not known, but it remains an active area of investigation.[35,36]

Skin cancer. Nonmelanoma skin cancer (NMSC; e.g., basal cell, squamous cell) is one of the most frequent SMNs in childhood cancer survivors.[15,37] Compared to the general population, childhood cancer survivors have a fivefold increased risk of NMSC, and 90% of tumors occur within the radiation field.[37] Although melanomas are less common than NMSCs, survivors of hereditary retinoblastoma are at an especially high risk.[38,39] This may be the result of common etiologic factors between the two tumor types.

Areas of the skin previously exposed to radiation should be monitored closely during annual physical examinations, with prompt referral to dermatology for evaluation of nevi that are concerning for skin cancer.[5]

Colorectal cancer. Recent reports[13,40,41] from aging cohorts of childhood cancer survivors have highlighted the markedly increased risk of digestive SMNs (absolute excess risk in survivors older than 40, 5.9 per 100,000), with the highest risk

TABLE 1. Risk-Based Screening for Subsequent Malignant Neoplasms

Potential Late Effect	Cancer Treatment	Screening Tests
Breast Cancer	Radiation to the chest area	Females: Clinical breast exam yearly beginning at puberty until age 25, then every 6 mo Mammogram and breast MRI yearly for patients who received ≥ 20 Gy beginning 8 yr after radiation or at age 25, whichever occurs last. For patients who received 10-19 Gy, clinicians should discuss benefits and risks/harms of screening with patients.
Thyroid Cancer	Radiation to the thyroid	Yearly physical examination
Brain Tumor	Cranial irradiation	Yearly targeted history and comprehensive neurologic examination
Skin Cancer	Radiation to the skin	Yearly physical examination
Colorectal Cancer	Abdominal/pelvic irradiation	Colonoscopy every 5 yr (minimum for patients who received ≥ 30 Gy, beginning 10 yr after radiation or at age 35, whichever occurs last)
	Spinal irradiation	
tMDS/AML	Alkylating agents, topoisomerase-II inhibitors	Yearly targeted history/physical examination

Abbreviations: mo, months; yr, years; tMDS, trilineage myelodysplasia; AML, acute myeloid leukemia.

seen in survivors exposed to abdominal radiation. In fact, by age 50, the incidence of colorectal cancer (CRC) for survivors treated with direct abdominopelvic radiation is comparable to the risk in individuals with at least two first-degree relatives affected by CRC.[13]

For survivors treated with 30 Gy or more of abdominopelvic radiation, the COG recommends a screening colonoscopy every 5 years, beginning 10 years after radiation or at age 35, whichever occurs last.[5]

Chemotherapy-Related TMDS/AML

Survivors treated with alkylating agents (e.g., cyclophosphamide, ifosfamide, mechlorethamine, melphalan, busulfan, nitrosureas, chlorambucil, dacarbizine, and platinum compounds) or topoisomerase-II inhibitors (e.g., epidophyllotoxins, anthracyclines) are at risk for developing tMDS/AML.[18,42] The risk of alkylating-agent–associated tMDS/AML is dose-dependent, with a latency of 3 to 5 years after exposure. Typically, it is associated with cytogenetic abnormalities involving chromosomes 5 (−5/del[5q]) and 7 (−7/del[7q]). Topoisomerase-II inhibitor-related tMDS/AML has a shorter latency (< 3 years), and is associated with balanced translocations involving chromosome bands 11q23 or 21q22.[18,42]

Since chemotherapy-related tMDS/AML usually develops by 10 years after exposure to these agents, current recommendations are to monitor at-risk survivors with a targeted history and physical examination for up to 10 years postexposure.[5] A complete blood count and bone marrow examination may be warranted for those with a history or physical examination findings suspicious for tMDS/AML (e.g., easy bruising, fatigue, pallor, and petechiae).[5]

CARDIOVASCULAR DISEASE

Cardiovascular disease is a major health problem in children and adults after treatment for childhood cancer.[43] In fact, childhood cancer survivors have a sevenfold increased risk of cardiac death when compared with the general population.

The risk is highest in survivors of HL, kidney tumors, and Ewing sarcoma.[12,14] Cardiovascular complications after treatment for childhood cancer include cardiomyopathy/heart failure, coronary artery disease, valvular disease, conduction abnormalities, and pericardial disease.[43] Outcome following onset of cardiovascular complications such as heart failure is especially poor, with 5-year survival less than 50%.[44]

In survivors of childhood cancer, there is a long latency between cancer treatment and onset of clinically overt cardiovascular disease.[43] As a result, there have been a number of initiatives to facilitate early detection and treatment of asymptomatic disease,[5,7,8,42] setting the stage to minimize the long-term burden as a result of these complications. Recently, an international collaborative effort was organized to develop evidence-based guidelines for cardiomyopathy surveillance in at-risk survivors of childhood cancer.[11] Additional surveillance guidelines pertaining to coronary artery disease, valvular disease, conduction abnormalities, and pericardial disease are pending. When completed, these recommendations may facilitate the implementation of uniform evidence-based guidelines to minimize the long-term burden as a result of cardiovascular disease in these survivors.

Cardiomyopathy

Childhood cancer survivors treated with cardiotoxic therapies (anthracycline chemotherapy and/or chest radiation) are at risk for developing asymptomatic cardiomyopathy that can progress to symptomatic heart failure over time.[43] The risk of heart failure is 15-fold greater in survivors of childhood cancer when compared to the general population,[3] and there is a dose-dependent association with anthracycline (doxorubicin, daunorubicin, epirubicin, idarubicin, and mitoxantrone) chemotherapy and risk of heart failure. This risk is further increased by exposure to chest radiation.[43] Among anthracycline-exposed survivors, asymptomatic cardiomyopathy is characterized by a decrease in left ventricular systolic function, which often presents with a clinical picture similar to dilated cardiomyopathy.[43] Patients treated with

chest radiation may have a combination of dilated and restrictive cardiomyopathy.[43]

Who Needs Surveillance?

It is well established that children and adolescents treated with anthracyclines and/or chest radiation are at increased risk of developing cardiomyopathy when compared to the general population. In fact, there appears to be an exponential increase in risk of cardiomyopathy with increased lifetime cumulative anthracycline dose. The highest risk is among survivors treated with 250 mg/m^2 or more.[46-48] Although it is generally believed that the risk for cardiomyopathy among those treated with less than 100 mg/m^2 is very low, there appears to be no clear cutoff for a safe anthracycline dose.[46-48] Patients treated with 35 Gy or more of chest radiation also are at high risk of developing cardiomyopathy, and there remains an elevated risk among those treated with lower doses (15 Gy to < 35 Gy) of radiation.[46,47] However, no data exist to suggest that children treated with lower doses (e.g., < 15 Gy in < 2 Gy daily fractions), such as TBI alone, are at increased risk of cardiomyopathy.

Survivors treated with anthracyclines and/or radiation therapy involving the heart region should be aware of the risk of cardiomyopathy.[11] Furthermore, the IGHG cardiomyopathy surveillance guidelines strongly recommend screening for survivors who have a fourfold or greater risk (anthracycline dose ≥ 250 mg/m^2, or chest radiation dose ≥ 35 Gy, or both anthracycline and radiation exposure) of heart failure when compared to those not treated with anthracyclines and/or chest radiation.[11] Screening may be considered for survivors who have a lower (1.5-fold) but increased risk of heart failure (anthracycline dose < 250 mg/m^2, or chest radiation dose 15 to < 35 Gy).[11]

What Is Optimal Surveillance Modality?

Echocardiographic measurements such as shortening fraction or ejection fraction are the most frequently used tests in childhood cancer survivors to assess the left ventricular function of the heart.[43] An increasing number of studies also are evaluating the role of other echocardiographic parameters, such as wall stress, diastolic function, and isovolumetric relaxation time in routine surveillance.[43,49,50] Currently, studies evaluating the predictive value of these parameters for the development of heart failure or mortality in survivors are lacking. Other, nonechocardiographic imaging approaches to screening that have been evaluated include radionuclide angiography and cardiac MRI (CMR).[43,51] However, radiation exposure from radionuclear tests and the high costs of CMR limit the applicability of these tests for population-based screening. Finally, cardiac biomarkers (NT-Pro-BNP, BNP ANP) play an important role in screening for heart failure in the nononcology population.[43] However, at this time, the diagnostic value of these markers to detect asymptomatic cardiomyopathy in childhood cancer survivors appears to be suboptimal.[11]

No randomized clinical trials have studied the effect of screening of childhood cancer survivors by echocardiography on later outcomes, such as heart failure or cardiac mortality. However, decision-modeling studies[52,53] have found that echocardiographic screening in survivors of childhood cancer can be cost-effective when compared to no screening, which supports the screening recommendations outlined below.

Echocardiography should be used as the primary cardiomyopathy surveillance modality for assessment of left ventricular systolic function in survivors treated with anthracyclines or chest radiation.[11] Screening with radionuclide angiography or CMR may be considered in patients for whom echocardiography is not technically feasible or optimal. Additional diagnostic studies, such as cardiac blood biomarkers, should be considered in conjunction with imaging, based on availability of resources and clinical suspicion for cardiac dysfunction.[11]

At What Frequency and for How Long Should Surveillance Be Performed?

No data are available on the rate of cardiac function deterioration in childhood cancer survivors. Moreover, a paucity of studies describes the incidence of heart failure more than 30 years after cancer diagnosis. Recognizing these limitations, current recommendations on initiation, frequency, and duration of screening are largely based on consensus.

Routine surveillance is recommended for survivors at high risk (anthracycline dose ≥ 250 mg/m^2, or chest radiation dose ≥ 35 Gy, or both anthracycline and radiation exposure) for cardiomyopathy, to begin no later than 2 years after completion of cardiotoxic treatments and repeated at 5 years after diagnosis and continued every 5 years thereafter. More frequent screening may be reasonable in these survivors.[11] Specific screening recommendations for low- to moderate-risk patients should take into consideration the relative risk of heart failure in these populations, along with cost and benefits associated with lifelong screening.[11]

What Should Be Done When Abnormalities Are Identified?

Primary care providers or oncologists who treat childhood cancer survivors should work closely with their cardiology colleagues to ensure that timely and age-appropriate follow-up is provided to all at-risk survivors. To date, no randomized studies have evaluated the efficacy of interventions in survivors of childhood cancer with asymptomatic cardiomyopathy on heart failure risk reduction. However, well-established general pediatric[54] and adult-onset[55] heart failure treatment guidelines may facilitate the implementation of early interventions to minimize long-term morbidity in these survivors.

Cardiology consultation is recommended for patients who have abnormal cardiac function that is detected during surveillance. When possible, pharmacologic intervention following diagnosis of cardiomyopathy should be personalized and should take into consideration existing age-appropriate treatment guidelines.[11]

Additional Considerations

Studies conducted of nononcology populations support the benefits of interventions to reduce modifiable risk factors, such as obesity, smoking, hypertension, diabetes, and dyslipidemia.[56,57] Childhood cancer survivors are at a higher risk of developing many of these conditions when compared to the general population, which places them at increased risk of developing cardiovascular disease.[58,59] In fact, survivors with hypertension or diabetes in addition to past exposure to anthracyclines and/or radiation are at an especially high risk of developing cardiomyopathy and heart failure.[60] Findings from studies of nononcology populations strongly suggest that routine screening for these risk factors can be beneficial and set the stage for interventions (e.g., lifestyle modification and pharmacologic therapy) to mitigate adverse cardiovascular outcomes. Lastly, cardioprotectants such as dexrazoxane have been shown to minimize cardiac injury shortly after anthracycline administration without compromising its anti-tumor efficacy.[61,62] However, long-term data on efficacy of dexrazoxane is lacking. Studies are needed to address this gap in knowledge, setting the stage for the implementation of primary prevention strategies in survivors at highest risk for developing cardiovascular disease.

ENDOCRINE COMPLICATIONS
Thyroid Disorders

Primary hypothyroidism. Primary hypothyroidism frequently occurs after treatment for patients with childhood cancer. Survivors at risk include those treated with radiation to the thyroid gland, including nasopharyngeal, cervical, mantle/supraclavicular, and craniospinal fields, as well as those exposed to TBI.[63-67] The risk of primary hypothyroidism is observed beginning at about 10 Gy of thyroidal irradiation and it increases as the dose of radiation increases above this dose.[63] The risk is greatest within the first 5 years after radiation, but it continues to increase over time. Other risk factors include female sex, white race, and older age at diagnosis.[63]

Patients treated with radiolabeled agents, such as 131-I-metaiodobenzylguanidine[68,69] or 131-I-labeled monoclonal antibody,[70,71] and those treated with tyrosine kinase inhibitors,[73] also are at risk. Although standard-dose chemotherapy alone does not appear to be a risk factor for hypothyroidism,[63] patients who have received stem cell transplants following treatment with myeloablative doses of alkylating agents (e.g., busulfan and cyclophosphamide) are at increased risk for developing primary hypothyroidism.[73]

At-risk childhood cancer survivors should have their thyroid function serially monitored, generally at least annually. Measurement of plasma levels of thyroid-stimulating hormone (TSH) is the most sensitive means of diagnosing primary hypothyroidism (Table 2). Since hypothyroidism can develop more than 25 years after cancer treatment, the need for lifelong screening is essential.[74]

Hyperthyroidism. Treatment-related hyperthyroidism occurs less often than primary hypothyroidism in childhood cancer survivors. It most often results after exposure of the thyroid gland to radiation. In survivors of HL, a radiation dose of more than 35 Gy to the thyroid has been identified as a risk factor for developing hyperthyroidism.[63] Survivors of acute lymphoblastic leukemia treated with a radiation dose of more than 15 Gy to the thyroid also appear to have an increased risk of hyperthyroidism.[64] Immune-mediated hyperthyroidism, as a result of adoptive transfer of abnormal clones of T or B cells from donor to recipient, also has been reported after stem cell transplantation.[73]

Given the low incidence of hyperthyroidism, routine screening is not currently recommended. However, at-risk survivors who present with clinical signs or symptoms (e.g., unexplained weight loss, tachycardia, bilateral exophthalmos, or goiter) suggestive of hyperthyroidism should have, at minimum, a blood level of TSH. A TSH level below the lower limit of normal is highly suggestive of a diagnosis of hyperthyroidism and warrants referral to an endocrinologist for further work up.

Gonadal Dysfunction: Men

The human testis has two primary functions: sperm production and testosterone production. One or both of these functions may be negatively affected by cancer treatment. Germ cells and Sertoli cells form the seminiferous tubules in which spermatogenesis occurs; Leydig cells are responsible for the production of testosterone.

Germ cell dysfunction. Exposure of the sperm-producing cells to radiation and/or certain types of chemotherapy may result in oligo/azoospermia.[75] Chemotherapeutic agents commonly associated with impaired spermatogenesis include mechlorethamine, cyclophosphamide, ifosfamide, procarbazine, busulfan, and melphalan, which are all alkylating agents.[76,77] Risk is dose-dependent, but individual responses vary greatly.[77] Although earlier studies suggested that younger age at treatment was associated with a lower risk of germ cell dysfunction, the data are inconclusive.[76,77]

The testicular germinal epithelium is exquisitely sensitive to radiation. Sperm production may be impaired at radiation doses as low as 0.15 Gy with permanent sterility common following testicular doses of more than 6 Gy.[76] Impaired sperm production may result from direct testicular radiation or scatter from adjacent treatment fields, such as the pelvis, bladder, or inguinal/femoral area. Germ cell dysfunction is present in virtually all men treated with TBI.[73]

Although a variety of clinical (e.g., decreased testicular volume) and biochemic markers (e.g., raised plasma concentrations of follicle-stimulating hormone (FSH) and reduced plasma concentrations of inhibin-B) have been associated with impaired sperm production in population studies. None, however, is suitable as a surrogate test for a given patient's ability to produce sperm because of poor sensitivity and/or specificity.[78] Thus, currently, a sperm analysis in a sexually mature patient is the only definitive test available to determine a survivor's ability to produce sperm.

TABLE 2. Risk-Based Screening for Potential Endocrinopathies Following Cancer Treatment

Potential Late Effect	Cancer Treatment	Screening Tests
Thyroid Dysfunction	· Radiation impacting the thyroid · Agents labelled with 131-I · Tyrosine kinase inhibitors	· TSH, Free T4
Gonadal Dysfunction (Female)	· Alkylating agents · Nitrosoureas · Cisplatin · Radiation to the gonads	· Physical exam with Tanner staging · LH · FSH
Gonadal Dysfunction (Male)	· Alkylating agents · Nitrosoureas · Cisplatin · Radiation to the gonads	· Physical exam with Tanner staging · LH · FSH · Testosterone

Abbreviations: LH, luteinizing hormone; FSH, follicle stimulating hormone; TSH, thyroid stimulating hormone.

Leydig cell dysfunction. Leydig cells are susceptible to radiation-induced damage at higher doses than those associated with germ cell dysfunction. Risk is directly related to testicular radiation dose and inversely related to age at treatment.[79] Although the majority of men who receive less than 20 Gy fractionated radiation to the testes will produce normal amounts of testosterone, most prepubertal males who receive radiation doses of 24 Gy or greater to the testis will develop Leydig cell failure.[80] Chemotherapy alone rarely results in Leydig cell failure, although subclinical Leydig cell dysfunction has been reported following treatment with alkylating agents.[79]

Leydig cell failure will result in pubertal delay or arrest, if it occurs before or during puberty, and in reduced libido, erectile dysfunction, decreased bone mineral density, and decreased muscle mass if it occurs after completion of normal puberty. Patients who are noted to have developed any of the above symptoms after gonadotoxic therapy should be assessed for Leydig cell failure.

Men treated with 20 Gy or more radiation to areas that may affect the testes (flank/hemiabdomen, whole abdomen, inverted Y, pelvic, prostate, bladder, iliac, inguinal, femoral, testicular, total lymphoid, or TBI) should have periodic screening with LH and an early-morning testosterone level beginning at the time of puberty (e.g., by age 14; Table 2).[5] Elevated serum levels of LH with low levels of testosterone are consistent with a diagnosis of Leydig cell failure.

Gonadal Dysfunction: Women

Because of the interdependence of sex steroid-producing cells and oocytes within the ovarian follicle, ovarian failure results in impairment of both sex hormone production and fertility.

Ovarian dysfunction may result from treatment with gonadotoxic chemotherapy, radiation affecting the ovaries, or surgical removal of the ovaries.[81] Chemotherapy-induced ovarian failure typically results from treatment with high-dose alkylators,[82,83] particularly when administered in prep-

aration for stem cell transplantation.[84] Risk is directly correlated with cumulative dose and older age at exposure.

Women treated with radiation affecting the ovaries (spinal, flank, hemiabdomen below the iliac crest, whole abdomen, inverted Y, pelvis, vagina, bladder, iliac lymph nodes, total lymphoid system, or total body) are at increased risk for ovarian failure.[81-83] Doses to the ovary exceeding 10 Gy are associated with a very high risk of ovarian failure.[82] When ovarian transposition is performed before radiotherapy, however, many younger women retain ovarian function.[79] Irradiation at an older age confers a greater risk of ovarian failure.

Women who have normal ovarian function at the end of treatment with potentially gonadotoxic therapy remain at risk for premature menopause later in life and should be counseled accordingly.[82]

Although female survivors treated with high-dose alkylators and/or pelvic irradiation have been shown to be less likely to experience a pregnancy when compared with sibling comparators,[85,86] those who do achieve pregnancy after treatment with chemotherapy alone do not appear to have adverse pregnancy outcomes.[87] Survivors treated with pelvic irradiation, who become pregnant, however, are at a higher risk of stillbirth and neonatal death and having offspring who are premature, have low birth weight, and are small for gestational age.[85,88]

Among survivors of childhood cancer who achieve a successful pregnancy, their offspring do not appear to be at increased risk of congenital anomalies or genetic defects.[85,89,90]

If ovarian failure occurs before pubertal onset, delayed puberty and primary amenorrhea will result. In those in whom ovarian function is lost during or after puberty, pubertal arrest, secondary amenorrhea, and symptoms of menopause will occur. If these symptoms are noted along with elevated gonadotropins, a referral should be made to an endocrinologist or gynecologist for consideration of hormone replacement therapy.

All women treated with the gonadotoxic therapies mentioned above should have periodic screening with LH and FSH levels, as well as careful Tanner staging, to monitor pubertal progression (Table 2). Elevated gonadotropin levels are consistent with primary ovarian dysfunction. Although plasma levels of anti-mullerian hormone (AMH) have been shown to correlate with ovarian reserve in adult women, there are no long-term data correlating AMH levels in children and adolescents and subsequent ovarian function and fertility.[91] Therefore, measurement of AMH levels is not currently recommended in the clinical management of survivors under age 25.

CONCLUSION

Research on survivorship-related issues has identified important associations between certain therapeutic exposures and long-term complications in survivors of childhood cancer. This has facilitated the development of a number of recommendations for early screening in asymptomatic sur-

vivors. Ongoing studies exploring gene-environment interactions[92] continue to refine our understanding of high-risk categories. Studies are needed to integrate emerging information on genetic susceptibility with established clinical risk factors. Novel interventions aimed at reducing the long-term burden in survivors at highest risk for treatment-related late effects also are needed. Multidisciplinary collaboration between primary care providers, oncologists, and other medical specialists is integral to the successful implementation of these interventions.

Disclosures of Potential Conflicts of Interest

Relationships are considered self-held and compensated unless otherwise noted. Relationships marked "L" indicate leadership positions. Relationships marked "I" are those held by an immediate family member; those marked "B" are held by the author and an immediate family member. Institutional relationships are marked "Inst." Relationships marked "U" are uncompensated.

Advances in Website Information Resources to Aid in Clinical Practice

Matthew J. Rioth, MD, Travis J. Osterman, DO, and Jeremy L. Warner, MD, MS

OVERVIEW

The World Wide Web, which has been widely implemented for roughly two decades, is humankind's most impressive effort to aggregate and organize knowledge to date. The medical community was slower to embrace the Internet than others, but the majority of clinicians now use it as part of their everyday practice. For the practicing oncologist, there is a daunting quantity of information to master. For example, a new article relating to cancer is added to the MEDLINE database approximately every 3 minutes. Fortunately, Internet resources can help organize the deluge of information into useful knowledge. This manuscript provides an overview of resources related to general medicine, oncology, and social media that will be of practical use to the practicing oncologist. It is clear from the vast size of the Internet that we are all life-long learners, and the challenge is to acquire "just-in-time" information so that we can provide the best possible care to our patients. The resources that we have presented in this article should help the practicing oncologist continue along the path of transforming information to knowledge to wisdom.

The World Wide Web, proposed by Tim Berners-Lee and Robert Cailliau on November 12, 1990, and widely implemented since 1994, is humankind's most impressive effort to aggregate and organize knowledge to date (Fig. 1).[1] Although the total number of Internet sites is constantly changing, a recent survey estimated that there are 876,812,666 sites with a total information content of 5-million terabytes of data.[2] The medical community was slower to embrace the Internet than others but has now caught up. The current generation of medical students may not recall a world before the Web, mobile telephony, and cheap computing power.[3] As an example of the Web's pervasiveness, a 2009 study found that a majority of junior physicians were using Google (80%) or Wikipedia (70%) in their daily clinical practice.[4]

BACKGROUND: THE ORGANIZATION OF KNOWLEDGE

At its core, the Internet operates by organizing knowledge, both intentionally and informally. There are many useful paradigms for understanding knowledge organization (e.g., explicit versus tacit; individual versus organizational; novel versus learned). The Internet could be framed in any of these dimensions, but for our purposes the data, information, knowledge, wisdom (DIKW) framework, which was introduced in a rudimentary form as early as 1955, offers a very useful starting point.[5,6] This schema is usually represented by a pyramid, where the foundation is raw *data*. For the Inter-

net, this might be an Internet Protocol (IP) address (e.g., 23.21.100.117) or the American Standard Code for Information Interchange codes representing individual characters on a webpage. The next level in the pyramid is *information*, which introduces basic meaning to data, such as "what," "where," and "how much." For example, the IP address 23.21.100.117 points to the uniform resource locator (URL) www.cancer.net. *Knowledge* is the introduction of context and content to information. This is sometimes referred to as "know-how" and is the core goal of many Internet-based resources, which are often referred to as *knowledge bases* (this term is formally used to refer to a machine-readable knowledge resource but in practical terms is used more broadly). Finally, *wisdom* is the most difficult part of this schema to describe, as there is some disagreement on what exactly wisdom represents and whether it can only be manifest as a human endeavor, as opposed to a collective experience such as the Internet.[7]

For the practicing oncologist, the Internet resources most useful in day-to-day practice will have some overlap across the DIKW framework but will be primarily in the knowledge sphere. As described below, the sheer volume of information related to cancer is impossible to master, yet most practitioners desire to have the final say in their practice of medicine (i.e., the application of wisdom to knowledge). We now turn to an overview of some of the current resources available to the practicing oncologist, in three parts: (1) general medical knowledge bases; (2) oncology-specific resources; (3) social

media outlets of interest to the medical practitioner. Although we have attempted to be exhaustive in this overview, we apologize in advance for any unintentional oversights or omissions.

GENERAL MEDICAL KNOWLEDGE BASES

Online medical compendia and knowledge bases are among the most popular resources for clinical queries. Although not specific to oncology, resources such as UpToDate, Ovid, PubMed, Google, Medscape, and Wikipedia contain information pertaining to many topics relevant to practicing on-

---

KEY POINTS

- The Internet is vast and is now used on a regular basis by the majority of physicians, especially those that were born into the "digital generation."
- The organization of the Internet can be understood by applying the data, information, knowledge, wisdom management framework.
- General medical knowledge bases (e.g., PubMed, UpToDate, and Wikipedia) each have advantages and disadvantages for the practicing oncologist.
- There are an increasing number of oncology-specific website resources, including those maintained by professional organizations such as the American Society of Clinical Oncology and unaffiliated entities.
- Social media will take a role of increasing importance for the practicing oncologist, although it must be approached with caution, especially given the for-profit nature of many of the current endeavors.

---

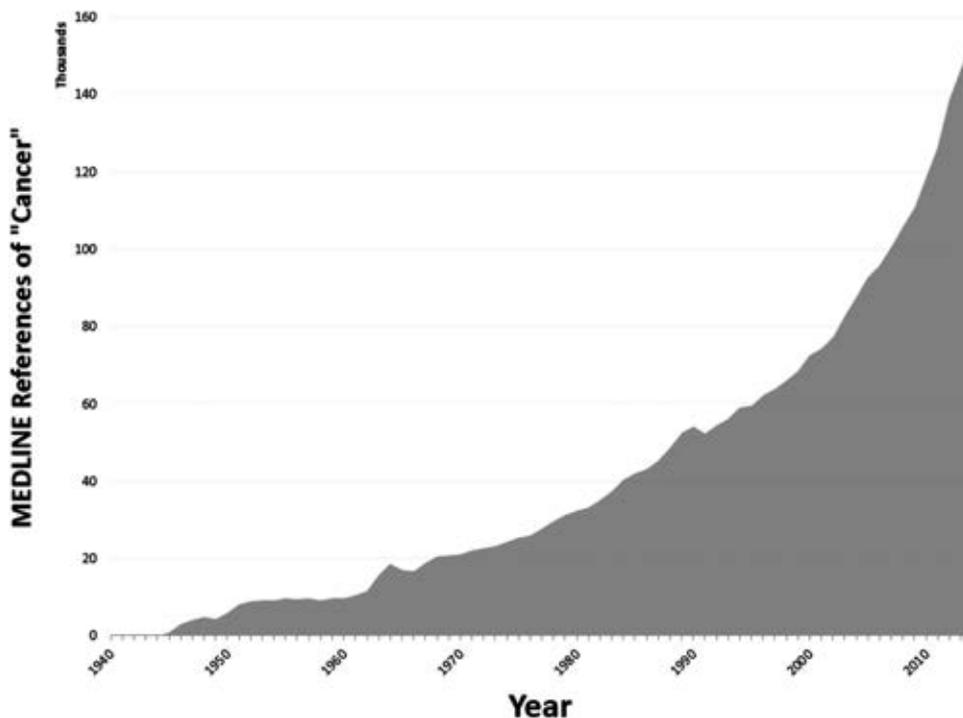
cologists. Each resource uses different models to create, organize, aggregate, and present information. Google and Wikipedia are free for use (although Google is supported by advertisements); Medscape is free but requires an account for access; and Ovid and UpToDate require paid subscriptions. With the vastness of oncology literature and the diversity of potential information needs, no one information resource or search strategy is consistently superior.[8] Resources with higher-level reviews (knowledge and wisdom in the DIKW paradigm) will lack the depth and immediacy of primary literature; literature searches (data and information) are more time consuming as the reader must sift through irrelevant results. A savvy information consumer will be familiar with the advantages of multiple knowledge bases. We describe some of the more well-known resources in detail.

PubMed

Developed and maintained by the National Center for Biotechnology Information, PubMed is a free online search engine of the MEDLINE database containing over 24-million citations of biomedical and health literature.[9] The primary user interface consists of a single search field, but multiple advanced search options are possible using specific filters and syntax. Given the vast size of the MEDLINE database (Fig. 2), searches to produce only relevant articles are difficult. Using multiple search terms, Booleans, and additional search tools will produce more relevant results.[10] Some training programs, such as the University of California, San Francisco's Program in Medical Education for the Urban Underserved,[11] explicitly teach searching strategies. For most currently practicing clinicians, optimizing the use of PubMed is an example of "on-the-job training." PubMed indexes large amounts of biomedical literature in near real time; therefore, it is likely to outperform other information resources when searching for recently published information, primary literature, or uncommon questions. However, for general questions other information resources could be considered.

Google

The most popular search engine in the world, Google (Google Inc. Mountain View, CA), is a common starting point for medical queries. The algorithm by which Google produces search results, PageRank, performs numerical weighting to websites based on the number and authoritativeness of webpages that link to them.[12] This produces search results based on relevancy to the entire population of Internet users. Google Scholar (scholar.google.com) restricts searches to scientific literature, such as conference proceedings (which are not generally indexed in MEDLINE). Since a physician-specific version of Google does not exist, using generic terms would be more likely to return websites without information directed specifically at clinicians.[13] A savvy "googler" would use technical terminology for search terms that would be specific to sources directed at clinicians.

FIGURE 2. Growth of "Cancer" References Indexed in MEDLINE


In 2014, 154,654 articles referencing cancer were added to MEDLINE. This amounts to a new article approximately every 3 minutes for the entire year. Extracting utility from this deluge of information for a clinician is impossible without the help of digital searches and information aggregators. Depending on the resource used and the information sought, different strategies must be employed to efficiently find accurate information.

UptoDate

The subscription service UpToDate (Wolters Kluwer NV, Alphen aan den Rijn, the Netherlands) provides original content rather than aggregation of existing resources. The oncology content is provided via two editors in chief, three deputy editors, 35 section editors, and approximately 1,100 authors.[14] Article content draws from primary articles, national guidelines, text books, and expert opinion to generate knowledge and wisdom. Insomuch as there is variation in clinical practice; articles can also represent these regional, institutional, or personal variations. Although articles are updated continuously, the human authors do not necessarily update content immediately on newly published evidence. The trade-off for this content curation is a filtering of irrelevant information that encumbers searches of the primary literature, such that searching content in UpToDate results in satisfactory answers faster than a search engine such as PubMed.[15,16] For clinicians who have access to UpToDate, it can serve as an efficient means of reviewing clinical content but would require additional searching to find "breaking news" information or primary literature.

Ovid

Another Wolters Kluwer subscription service, Ovid is a content aggregator that provides searches across 307 books, 74 journals, 12 databases, and nine collections of oncology content predominantly published by Wolters Kluwer.[17] Additionally, OvidMD is a curated resource for clinician queries optimized to return clinically relevant results. The OvidMD platform also links to UpToDate content for individuals with accounts on both platforms. As such OvidMD operates as something of a hybrid between a content aggregator as well as a curated source of primary content.

Medscape

Similar to Ovid, Medscape (WebMD, New York City, NY) is a hybrid of content aggregator with authors of reviews and literature synopses; however, in contrast it is free to use but requires a login. Additionally, Medscape and its parent company, WebMD, exist in a content zone targeting somewhere between medical professional and lay audience. Medscape has not been evaluated against other information resources in the published literature.

Wikipedia

Wikipedia (Wikimedia Foundation, Inc., San Francisco, CA) is a free online encyclopedia and has 4,704,035 articles in English (as of January 25, 2015). Any individual can edit articles on any topic, although in practice the number of contributors compared to users is quite small.[18] It is neither medical- nor oncology-specific in its content. Initially, based on several high-profile inaccuracies mostly pertaining to malicious individuals or state actors, there was skepticism about the accuracy and reliability of Wikipedia as a knowledge source.[19] Outside of this concern over factual inaccuracy, concerns about incompleteness, especially in the medical arena, have also persisted.[20] For example, a study comparing Wikipedia to the Medscape Drug Reference in 2008 found a

lack of information such as dosing (0% versus 90%, respectively). However, several recent studies have demonstrated that Wikipedia has markedly improved with regards to health information. In 2014, Kräenbring et al systematically compared the accuracy and completeness of drug information in the German and English language versions of Wikipedia to several standard pharmacology textbooks. They found that the accuracy of the drug information in Wikipedia was 99.7% ± 0.2% when compared with the textbook data.[22] Completeness was less robust but still reasonable, at 85%. To our knowledge, no published article has systematically addressed the information content of clinician-oriented, cancer-related articles in Wikipedia (patient-oriented content has previously been examined).[23] Some have suggested that medical Wikipedia articles be subject to formal peer review,[24] although this is unlikely to become commonplace. Given the uneven content coverage and the lack of editorial controls, answers from Wikipedia for clinical queries would likely need cross-validation from other sources to be accepted confidently.

ClinicalTrials.gov

As opposed to the resources described above, which are primarily educational, ClinicalTrials.gov is devoted to the identification of clinical trials. At first a voluntary registry, registration for most types of clinical trials became mandatory after the passing of Section 801 of the U.S. Food and Drug Administration Amendments Act of 2007 on September 27, 2007. Once a trial is registered, it is given a National Clinical Trials (NCT) number that can then be used to trace the trial's status and associated published results. With some practice, a clinician or patient user can quickly locate open trials by region, and scan at least the basic eligibility criteria. Less robust are the "results" section of each trial, although an notice of proposed rule making was recently issued to encourage more transparent reporting of trial results.[25] Thus, this portal will become increasingly useful to practicing oncologists both as a means of identifying clinical trials outside of their home institution and learning about results of completed trials.

ONCOLOGY-SPECIFIC WEBSITES
American Society of Clinical Oncology Websites

Founded in 1964, the American Society of Clinical Oncology (ASCO) represents more than 35,000 members, making it the largest professional organization representing medical oncologists. In addition to its mission statement of "conquering cancer through research, education, prevention and delivery of high-quality patient care," ASCO has been a proponent of adopting technology solutions, including the Web, to fulfil its vision.[26] Along with portals to its well-known journals, the *Journal of Clinical Oncology* and the *Journal of Oncology Practice*, ASCO has several Web-based initiatives of interest to practicing oncologists.

ASCO Connection (connection.asco.org). This multimedia, professional networking portal includes a commentary blog written by many well-known oncologists; links to the *ASCO Connection* magazine; a number of discussion groups on specific topics; forums designed to foster interactive conversations; and a number of resources specifically for trainee and early-career oncologists.

ASCO University (university.asco.org). This learning portal was established "to provide a comprehensive eLearning Center that supports lifelong learning."[27] The target audience is oncology professionals, and topics are organized by cancer type as well as by goal of the audience: continuing medical education, maintenance of certification, and ASCO's self-study publication for board examinations, *ASCO-SEP*. The site also contains the Meeting Library from past ASCO meetings, an embedded bookstore, and a link to *Journal of Clinical Oncology*'s career center.

Cancer.Net (cancer.net). Although Cancer.Net is focused toward patients and their caregivers, it contains a wealth of information that could be of use for patient education materials. The site recently underwent a complete redesign and is now very user friendly. In addition to links to factual information on the diagnosis and treatment of 124 types of cancer and cancer syndromes, the site contains multimedia content and an active blog. Content is reviewed and approved by an appointed editorial board.

Institute for Quality (instituteforquality.org). This recently debuted website consolidates ASCO's multiple quality improvement efforts into one portal. This includes the Quality Oncology Practice Initiative (commonly known as QOPI®), templates for chemotherapy planning and summarization, and clinical practice guidelines. The latter area in particular is undergoing rapid growth, aided by a collaborative wiki site, the ASCO Guidelines Wiki. Housed within the Institute but also distinct is CancerLinQ™ (cancerlinq.org), which will take on increasing relevance as the project goes live later in 2015.[28]

ALLIED ORGANIZATIONS' SITES

ASCO is but one stakeholder in the very large space of clinical oncology, and there are many others. Although an exhaustive overview of resources offered by allied organizations is out of scope of this article, we provide Table 1 as an overview of some of the major allied organizations. All of these organizations have educational resources available through their websites, with varying applicability to various practice environments. A more extensive list, including subspecialty organizations, can be found online at hemonc.org/wiki/Professional_organizations.

UNAFFILIATED SITES

There are many efforts by individuals, institutions, and other collaborations that aim to bring oncology information to

TABLE 1. Major Organizations with Content Useful to Practicing Oncologists

Organization Name	Acronym	URL	Notes
American Cancer Society	ACS	cancer.org	
American College of Surgeons	AcoS	facs.org	Includes the Commission on Cancer and the National Cancer Data Base
American Joint Committee on Cancer	AJCC	cancerstaging.org	Staging rules for most solid and some hematologic malignancies
American Society for Radiation Oncology	ASTRO	astro.org	
American Society of Hematology	ASH	hematology.org	ASH Image Bank; access to ASH proceedings
Centers for Disease Control and Prevention	CDC	cdc.gov/cancer	Information about cancer statistics and more
College of American Pathologists	CAP	cap.org	Resources about genomics and molecular medicine
European Hematology Association	EHA	ehaweb.org	Free online access to EHA proceedings
European Society for Medical Oncology	ESMO	esmo.org	Free online access to ESMO proceedings
National Cancer Institute at the National Institutes of Health	NCI	cancer.gov	
National Comprehensive Cancer Network	NCCN	nccn.org	Extensive set of regularly updated guidelines for most cancer subtypes
Oncology Nursing Society	ONS	ons.org	
Radiological Society of North America	RSNA	rsna.org	

practitioners. Unfortunately, oftentimes the result is a needless duplication of effort. Here, we focus on a few mostly not-for-profit endeavors that offer a fairly unique, extensive, or centralized source of information.

HemOnc.org

This knowledge base for chemotherapy regimens and antineoplastic drugs began 2011 as a freely available collaborative resource for oncologists and oncology professionals. Similar to Wikipedia, users can edit, create, and delete pages at will. Unlike Wikipedia, an additional stipulation that users be oncology professionals is required; there are currently 26 users with editing privileges. As of this writing, there are 1,390 chemotherapy regimens (1,865 when including variants) covering 70 benign and malignant disease conditions. To our knowledge, HemOnc.org is the largest freely

FIGURE 3. A Screenshot from HemOnc.org of R-CHOP for Untreated Follicular Lymphoma[35]

For each regimen variant, a table has a link directly to the original published article and links to comparator regimens in the case of randomized trials (as shown here). Level of evidence and comparative efficacy as reported in the original literature (for randomized trials) are shown using a simple green-yellow-red schema. Below this table, the regimen details are shown with links to individual drug pages for each drug. When relevant, additional links to external sites are provided, such as the link to the ASCO guidelines for the use of G-CSF. Not shown are five additional R-CHOP variants, 10 references to the original studies, and two references to updates of the original studies.

TABLE 2. Calculators, Dosing, and Conversion Tools

Name	URL	Description	Access Restrictions
Adjuvant Online	adjuvantonline.com/index.jsp	"…to help health professionals and patients with early cancer discuss the risks and benefits of getting additional therapy…"	Requires registration of free account
BloodRef.com	bloodref.com	Summary of key diagnostic, scoring, and prognostic systems relevant to hematology	Free to use
Body surface area calculator	www-users.med.cornell.edu/~spon/picu/calc/bsacalc.htm	Calculates BSA using DuBois and DuBois formula	Free to use
CancerMath.net	cancer.lifemath.net	Clinical outcomes calculators for breast, colon, head and neck, melanoma, and renal cancer	Free to use
ePocrates	epocrates.com	Several medical calculators, some oncology-specific	Free with installation of ePocrates
ePrognosis	eprognosis.ucsf.edu	Estimate prognosis for elders (not cancer-specific)	Free to use
Fox Chase Cancer Center nomograms	labs.fccc.edu/nomograms/	Nomograms for a variety of genitourinary cancers	Free to use with acceptance of agreement
Geriatric Assessment Tools	www.healthcare.uiowa.edu/igec/tools/	A collection of calculators relevant to geriatric patients (e.g., fall risk, weight loss, etc.)	Free to use
GlobalRPh Medical Calculators	globalrph.com/medcalcs.htm	A large collection of calculators mostly concerning dosing and laboratory parameters	Free to use
Knight Cancer Institute Cancer Survivor Predication Calculator	skynet.ohsu.edu/nomograms/	Cancer survival prediction calculators for a variety of cancer types	Free to use
Life Expectancy Calculator	socialsecurity.gov/OACT/population/longevity.html	Calculator shows the average number of additional years a person can expect to live, based only on the gender and date of birth you enter (USA only)	Free to use
MCW Health Calculators	.mcw.edu/MCW-Health-Calculators.htm	A small collection of calculators, two relevant to oncology: BMI and eGFR	Free to use
MD Anderson Clinical Calculators	mdanderson.org/education-and-research/resources-for-professionals/clinical-tools-and-resources/clinical-calculators/index.html	Nomograms for breast, colorectal, esophageal, and pancreatic cancer	Free to use
MDCalc	mdcalc.com	A large collection of calculators that are organized by specialty and system	Free to use
Medal	medal.org	"The largest international knowledge base of medical algorithms and computational procedures for medical diagnosis, treatment and administration"	Requires registration of free account
Medscape	reference.Medscape.com/guide/medical-calculators	A large collection of calculators, some of which are hematology specific	Free to use
Melanoma prediction tool	melanomaprognosis.org/	Individualized melanoma patient outcome predictions, based on the American Joint Committee of Cancer Melanoma Database	Free to use
Memorial Sloan Kettering Cancer Center prediction tools	mskcc.org/nomograms	A large number of nomograms for varying solid tumor types	Free to use with acceptance of disclaimer
QxMD	qxmd.com/calculate-online/hematology	A large collection of calculators that are organized by specialty. Also available as apps	Free to use
Stanford BMT Calculators	bmt.stanford.edu/calculators	A small collection of calculators: BSA, date from transplant, and height/weight conversions	Free to use
WolframAlpha	https://www.wolframalpha.com/	A general computational knowledge engine that does unit conversions in addition to many other things	Free to use

available chemotherapy regimen resource and has been evaluated as highly usable and relevant by its users.[29] HemOnc.org also contains extensive information on 439 chemotherapeutic or supportive medications, 127 of which are in clinical trials. New content and functionality is constantly being added; an example of a recent enhancement is shown in Fig. 3.

ChemoRegimen.com and Cancer Therapy Advisor

ChemoRegimen.com is also a freely available source of chemotherapy regimen information. However, the site partnered with Monthly Prescribing Reference (Haymarket Media, London, United Kingdom) in 2008, and new content has not been added since that time. It is thus increasingly out of date, although it does include many commonly used regi-

mens with references to the original article(s). Another site also owned by Haymarket Media is Cancer Therapy Advisor (cancertherapyadvisor.com).

MyCancerGenome.org

MyCancerGenome.org was established in 2011 by the Vanderbilt-Ingram Cancer Center as part of their personalized cancer medicine initiative.[30,31] The goal is to provide a portal for genotype-specific cancer information, along with links to genotype-directed clinical trials. The site contains extensive information on 21 types of cancer and many associated genes; it is regularly visited by a worldwide audience. The content of MyCancerGenome.org is now licensed through GenomOncology LLP (Cleveland, OH).

Oncolink.org

This website was established by the University of Pennsylvania in 1994 and contains a wealth of information that is primarily patient-oriented. However, there are also some useful resources for the practicing oncologist, including links to continuing medical education activities and prebuilt teaching sheet bundles for common chemotherapy regimens.

eHealth Initiative (ehidc.org)

This is a nonprofit organization "that brings together leaders from across the healthcare industry."[32] Among other efforts, they maintain a Cancer Resource Guide. This useful list includes tools for decision making, education, treatment management, social support, and lifestyle management. It is regularly updated.

Online Calculators

In addition to the more extensive sites described above, there are many purpose-built resources such as online calculators for diagnosis, prognosis, chemotherapy dosing, and other areas that may be of interest to the practicing oncologist. Some sites, for example, Cleveland Clinic's R-Calc (r-calc.com) let

users create their own nomograms through a simple interface. Table 2 lists several of these resources.

SOCIAL MEDIA

The implications of social media for the practicing oncologist are just beginning to be realized. These include both the benefit of networking with colleagues as well as the challenge of presenting a professional identity and of interacting with patients in this arena. Tips on how to best use social media and links to some of the most important social media outlets can be found on the ASCO social media microsite (asco.org/about-asco/social-media). Table 3 lists the social media portals likely to be of most interest to practicing oncologists. Note that in distinction from the previously mentioned resources, a majority of these sites are for-profit, although a majority are also free to join, with some (notably LinkedIn) providing a "basic" and "premier" access tier. A recent content analysis of health-related content on Facebook raises a red flag: the most common type of page (32.2% of results) was marketing or promotional.[33] Another study of Twitter prostate and breast cancer communities (defined through the social relationships of community members) found that health organizations and news media, despite their focus on health, did not play a significant role in the core communities, suggesting a disconnect between patients and practitioners.[34] It is not clear at this time which of these many social media outlets will become the "preferred" site for oncologists, and whether oncology-specific social media outlets will emerge.

CONCLUSION

As the complexity of cancer care accelerates, the need for knowledge has never been greater. Fortunately, the Internet offers a wealth of knowledge. In fact, the problem is not a lack of information but the ability to quickly identify the best

TABLE 3. Social Media Outlets of Interest to Practicing Oncologists

Website	URL	Notes
doc2doc	doc2doc.bmj.com	A community of doctors and health care providers run by the British Medical Journal
Doximity	doximity.com	Claims 50% of U.S. doctors are verified members; the single largest physician-specific social network
ecancer.org	ecancer.org	Claims to be "the leading oncology channel;" mainly a source of oncology news with some social media features
Facebook	facebook.com	The world's largest social network
Google+	plus.google.com	Social networking by Google
Linkedin	linkedin.com	The world's largest professional network; hosts many oncology-specific groups
OncLive	onclive.com	"Bringing the Oncology Community Together"
Ozmosis	ozmosis.org	In addition to social networking, the site also provides "virtual grand rounds," "clinical cases," and "journal club"
ResearchGate	researchgate.net	Mission is stated as "to connect researchers and make it easy for them to share and access scientific output, knowledge, and expertise"
SERMO	sermo.com	Claims 40% of U.S. doctors are verified members. They focus on allowing anonymous discussions between physicians.
Storify	storify.com/ASCO	ASCO-curated social media stories
Twitter	twitter.com/	The world's largest microblogging platform; dedicated community of cancer clinicians
YouTube	youtube.com/	Many cancer-specific videos; has some rudimentary networking capacity

sources of information and how to derive wisdom from the content. It is clear from the vast size of the Internet that we are all life-long learners, and the challenge is to acquire "just-in-time" information so that we can provide the best possible care to our patients. The resources that we have presented in this article should help the practicing oncologist continue along the path of information to knowledge to wisdom.

Disclosures of Potential Conflicts of Interest

The author(s) indicated no potential conflicts of interest.

Using Social Media to Learn and Communicate: It Is Not About the Tweet

Michael A. Thompson, MD, PhD

OVERVIEW

Social media can be defined as the use of media to interact with social networks. Social media is not about the content of the tweet, inasmuch as the technologies and social media platforms influence how content is generated, disseminated, and used. Social media is not dead, but rather it offers rapid incoming and outgoing forms of communication, which may be utilized in a variety of "use cases" in medicine and oncology.

The prominent social media–savvy physician Bryan Vartabedian, MD, FAAP (@Doctor_V) asked, "Is Social Media Over?" on his blog, 33charts.[1] To that provocative title he added, "Or is it just part of the background?" suggesting that the novelty of social media is wearing off and that invited talks or expert opinion on "social media" may be reaching a decline. Just as we do not have American Society of Clinical Oncology (ASCO) Education Sessions on "What Is Email?" we may now focus less on the communication tool itself and more on the content and contextualization. We understand that educational content reaches us by multiple mechanisms including social media. Also, many of us are now able to interact with social media rather than just consume it. In another post titled, "Social Media Has Been Introduced to Physicians,"[2] Vartabedian noted several salient points:

- "At some point we must go beyond the introduction and into application."
- "Repeatedly pitching the terminally skeptical does not work."
- "While newbie public physicians need to be educated, there are great resources available."
- "We've reached a point where social media is now part of the professional workflow."
- "The genuinely curious and motivated will figure it out just like we did."

With this in mind, I will not over elaborate on what social media is or why physicians should use it, but rather focus on social media use cases. I would suggest to my social media–using colleagues that instead of "the cocktail party [being] over,"[3] social media use by physicians is just starting to get interesting.

WHAT IS SOCIAL MEDIA?

Social media is not a "thing" that has reached an endpoint. Rather, it is a constellation of processes. Some old and tired, some new and failing, and some already well interwoven into our digital lives. Social media is not a monomorphic phenomenon. It consists of a spectrum of the most trivial human interests as well as news, highly curated thoughts, and small and large communities.

I have previously discussed that "Social Media is a Form of Media,"[4] and that social media represents tools that may be used to store and deliver information and content disseminated through social interactions or networks. Social media includes various forms such as Facebook, blogs (e.g., ASCO Connection), forums (e.g., Doximity, Sermo, HealthTap), LinkedIn, image/video (e.g., YouTube, Vine, Instagram, SnapChat), and Twitter. There is increasing blurring between these various tools, and the social media platforms have evolved and will continue to evolve. They will not be the same years from now.

Social media differs from "traditional" media in several respects. Social media is generally faster, permanent (archived), interactive, and searchable. In addition, the conversations that emerge around a specific topic or piece of content on social media means that there can be amplified effect beyond the initial "broadcast" audience. Different social media tools may be more appropriate for various venues. My favorite social media platform is Twitter, so that is where I will focus. However, others have used video, blogs, and other social media effectively.

Social media is no longer new. We have moved beyond the early adopter phase in medicine. At previous ASCO and other meetings, a group of social media proponents have promulgated signing up and using social media. At the 2014 ASCO Annual Meeting (hashtag #ASCO14), cancer advocates noted that their lung cancer hashtag (#LCSM) was not being promoted by ASCO via its social media URL

(www.asco.org/about-asco/social-media) and by designated social media curators. To me, this was an inflection point transitioning from early users "pushing" social media use to a milieu where a broader community could "demand" use and recognition on social media. Many didactic and pragmatic reviews of social media in medicine are available.[5,6] A few useful slides and posts from Matthew Katz, MD (@subatomicdoc) and others can help the social media beginner and are provided in Table 1. In addition, a group of ASCO staff and members of the ASCO Integrated Media and Technology Committee developed the "Ten Tips for Use of Social Media," a resource available at www.asco.org.

WHY SOCIAL MEDIA?

Physician use of social media is increasing. Reid et al[7] reviewed cancer-specific Twitter conversations among physicians and found a growing number of Twitter conversations about oncology among doctors, and some have suggested "Every Young Physician Should Have a Professional Twitter Account."[8] Some physicians adopted social media long ago, others never will, and many physicians, hematologists, and oncologists who have joined social media networks are looking for the next step.

Farris Timimi, MD, at the Mayo Clinic Center for Social Media noted "In medicine, comprehension is more critical than content." This is important for patients and for sharing between health care professionals. Herein, we'll review some "use cases" for social media.

USE: INCREASE SIGNAL-TO-NOISE RATIO

Information exchange via social media is often faster than traditional media sources including online news channels.

KEY POINTS

- Social media is a form of media.
- Social media is not dead.
- Social media offers rapid incoming and outgoing forms of communication.
- Twitter and other forms of social media are tools.
- Tools are only tools if they are useful.

However, the information on social media can be overwhelming. Choosing sources to follow, including Twitter users that create context for content, is one method. Katz et al have created an oncology/cancer hashtag system or ontology, allowing users to watch one specific topic and avoid the overwhelming crush of irrelevant content, thereby boosting the signal-to-noise ratio.[9-14] This may be especially helpful when the cancer type is not obvious in the title of a publication or for cross-disciplinary posts such as Cardio-Oncology (#CardioOnc).

These hashtags were in widespread use at the 2014 ASCO Annual Meeting (e.g., #bcsm for breast cancer social media). Boolean searches (with an implied "AND"), such as #ASCO14 #bcsm, can find #bcsm tweets at the 2014 ASCO Annual Meeting. This can help track conversations about topics over time. According to Katz, "Twitter may be relevant to how effective professional societies are at sharing research and the organizational mission."[15] Another example of improving social media content delivery came from Ekins and Perlstein in "Ten Simple Rules of Live Tweeting at Scientific Conferences."[16]

There is a suggestion that physician social networks may be more effective than medical journals at spreading information about clinical decision making.[17] However, a randomized trial of social media published in *Circulation* seemed contrary to that conclusion, suggesting that a journal's use of social media did not increase views to a given article.[18] Christian Assad-Kottner, MD, countered that conclusion by noting "Social Media is not about just posting, sharing and retweeting. There are many variables that play an important role on how social media would impact a particular outcome," and that "We live in an empowering world, with intelligent patients that also want to learn about medical advances and many are more than fit to understand our articles even without a medical degree, this I guarantee."[19]

Some have remarked "If [William] Osler were alive today, we're confident he'd be on Twitter."[20] Dr. Meyskens noted in his ASCO Connection blog post "White Coat Conversations" that he had "deep concern about the disappearing 'physician scientist'" and "I became aware that to move forward, I needed to be engaged in the national dialogue."[21] Others have asked, "Are physicians obligated to share their knowledge online?"[22] This may be critical in creating useful information

about public health issues such as vaccinations as well as understanding the risk/benefit of cancer screening, the complexities of cancer treatments, the role of research in medicine, and end-of-life decisions. In contrast, many physicians feel, regarding doctors and social media, we are "damned if you engage, damned if you do not."[23]

USE: EDUCATION NETWORKS

Beyond annual conferences and peer-to-peer communication, social media has a potential role in informing patients, families, and the public about hematology and oncology. At the 2012 American Society of Hematology (ASH) Annual Meeting and Exposition, Matthias Weiss, MD, and colleagues in the National Cancer Institute (NCI) Myeloma Steering Committee Accrual Working Group described the substantial barriers to accrual to NCI-sponsored clinical trials on multiple myeloma,[24] and subsequently identified strategies to overcome those barriers at the 2013 ASCO Annual Meeting.[25] One of those strategies was to "educate patients and providers about the significance of a new [clinical trial] using social media." Cynthia Chmielewski (@myelomateacher) and I developed the #mmsm (multiple myeloma social media) Twitter discussion group based on the example of the breast cancer social media (#bcsm) and other groups. Over the past 2 years, the following discussions have occurred at our group:

- September 15, 2013: Online patient resources and smoldering multiple myeloma (@VincentRK and @Myeloma_Doc)
- October 20, 2013: Induction; VRd versus CfzRd (@myelomaMD)
- November 16, 2013: ECOG-ACRIN Meeting (@mtmdphd)
- January 26, 2014: Allogeneic stem cell transplant in myeloma (@phari)
- February 23, 2014: Racial disparities in multiple myeloma (@VincentRK)
- March 16, 2014: Clinical trials in multiple myeloma (@Myelomateacher)
- May 18, 2014: Can we cure multiple myeloma? (@Rfonsi1)
- June 29, 2014: Amyloidosis (@brendanweiss)
- July 27, 2014: Minimal residual disease (@DrOlaLandren)
- August 24, 2014: Multiple myeloma risk assessment (@szusmani; transcript available at: ow.ly/AKVTJ)
- September 7, 2014: Crowdfunding for multiple myeloma research (@mpatientmyeloma)
- November 23, 2014: Advocating for yourself and others (@MyelomaTeacher)

Mrs. Chmielewski and I moderate and facilitate the health care provider, patient, and advocate discussions. Further information on how this started can be found on the ASCO Connection blog.[26] Many patients with multiple myeloma and thought leaders on this disease have contributed to questions and discussions in a rapid push/pull of information exchange. This would be difficult to perform with the same input and availability before social media.

This, in part, may explain why physician conversations about multiple myeloma on Twitter more than quadrupled between 2012 and 2013.[27] Many other disease-specific support groups use Twitter or Facebook to communicate. A Facebook example is the page run by Dana Holmes titled, "Asymptomatic 'Smoldering' Multiple Myeloma 'aka'-SMM – Information Exchange."[28] Although clinicians cannot participate in every online discussion group (and may not want to participate in any), knowing they exist and what information is exchanged can be enlightening. Many patients and advocates are highly educated, highly informed, and can help drive public perspective, funding, and clinical trial accrual.

USE: CROWDSOURCING/CROWDFUNDING

A group of highly informed patients (i.e., crowd) may help brainstorm ideas (i.e., source) for drug development including clinical trials (i.e., crowdsourcing). Additionally, patients and the public may help fund research by crowdfunding. The concept of "Can We Build A Kickstarter For Cancer?" has been explored by *Forbes* as a way of funding a "virtual biotech" for a single patient.[29] *Oncology Times* also asked, "Should clinical trials be crowdsourced?"[29] and *The Lancet Oncology* looked at "#trial: clinical research in the age of social media."[31]

Although not everyone is ready for these concepts, especially those with established research funding via traditional mechanisms, engaging with patient communities can help us understand the patient perspective. An educated and engaged public (via social media and in real life) is necessary to sustain a national clinical trials infrastructure. This has been embraced by the clinical trial cooperative group Alliance for Clinical Trials in Oncology (@ALLIANCE_Org; #AllianceNCTN) to crowdsource its cancer clinical trial concepts from the general public.[32]

The generalizability and utility of such social media efforts will become clearer over time. Other medical crowdfunding sites include Experiment, MedStartr, and (the now dead?) Petridish. A patient advocate–central model of crowdfunding with crowdsourced ideas vetted/curated by scientific and patient advisory boards is underway with the Myeloma Crowd Research Initiative (MCRI, www.myelomacrowd.org/mcri/). This hybrid approach may allow new ideas with thought-leader input.

USE: COLLABORATION

Although patients may share medical information on social media without legal ramifications, patient confidentiality complicates discussions among professionals. We lack a strong Health Insurance Portability and Accountability Act (HIPAA)-compliant mechanism for open online multidisciplinary conferences/clinics (MDCs). For rare tumor types, physicians have gone social with older media, such as the 2013 ASCO Annual Meeting presentation "A Model for Multi-Institutional, Multidisciplinary Sarcoma Videoconferencing."[33] At an institutional level, options include proprietary applications such as Yammer or corporate email with possible encryption. HIPAA-compliant online discussion fo-

rums are available, including from Doximity, to allow only authenticated users.

In a recent YouTube video, Linda Burns, MD, (former ASH president) reviewed a collaborative tool called MedTing (http://medting.com/).[34] MedTing is used by Best Doctors for internal use,[35] but was previously used throughout Spain to share patient case discussions. It is now being used by various groups to micro-crowdsource information exchange among selected experts (i.e., micro), forming the components of an online MDC with time- and location-shifting ability. This means not everyone needs to be in the same place and online at the same time—one limitation of current in-real-life videoconferencing either locally or nationally. This reveals likely untapped potential to extend MDCs and further enable peer-to-peer case questions such as ASH's "Ask a Hematologist" (www.hematology.org/Thehematologist/Ask/) or "Consult a Colleague" (www.hematology.org/Clinicians/Consult.aspx) features. The ASCO membership directory (www.asco.org/membership-directory) may be used for colleague contact information, and ASCO Connection Forums allow for online tumor boards, such as the "ROS1 Rearrangement: Molecular Oncology Tumor Boards."[36]

USE: PROMOTION

Many individuals, hospitals, and other groups use social media to promote myriad business interests such as increasing referrals to a private practice or to a second opinion program, raising awareness of a cancer center, or disseminating disease-specific or general cancer information. The NCI Clinical Trials Network (NCTN) groups have used social media to share annual meeting information, clinical trial information, and educational resources.

Institutions have embraced social media with various levels of enthusiasm, engagement, and effectiveness. Some push promotional information derived from other marketing materials, whereas others have an active and vibrant online presence. The best efforts engage in interactive discussions and highlight their faculty and staff.

The pharmaceutical industry has for the most part moved slowly into social media, but interest has increased since the release of some U.S. Food and Drug Administration guidance on the use of social media.[37,38] A noncomprehensive listing of entities and examples of specific uses, including some with multiple channels used for very specific purposes by a given entity (e.g., NCI), are shown in Table 2. By following users or hashtags, either individually or by combining Boolean searches, one can filter the near infinite volume of information down to something usable.

Social media is not perfect and not every platform is ideal for every use, but using social media can add a valuable com-

plement to learning and communicating about hematology and oncology. Just following @ASCO, @theNCI, and @US_FDA would provide low tweet volume and highly informative content.

CONCLUSION

Social media is a growing form of health communication and is still evolving. Social media offers rapid incoming and outgoing forms of communication. Twitter and other forms of social media can be valuable learning and information-sharing tools. However, these tools are only helpful if they are found useful by the user. A book chapter or lecture can not determine that. Only you can. Find a social media mentor and see what you can learn.

The Past, Present, and Future of Patient-Reported Outcomes in Oncology

Laura E. Strong, PhD

OVERVIEW

Patient-reported outcomes capture a unique and important perspective of oncology therapy. Surveys to properly capture patient-reported outcome measures have been under development for more than 2 decades. More recent efforts to understand the clinical significance of patient-reported outcomes, called performance measures, are underway. Patient-reported outcomes can be used in a variety of ways, including therapy decisions for an individual patient, payment for treatment, research into disease progression, or new drug development. Technology has already enabled electronic systems to capture and search patient-reported outcomes and in the future will assist in capturing everyday activities, which, in combination with improved informatics to sort the meaningful and actionable information, will reduce the time commitment for both patients and providers.

Although the conversation about patient-centered medicine gained traction in the United States with the formation of the nonprofit Patient-Centered Outcomes Research Institute as part of the Affordable Care Act in 2010, the discussion was started within several organizations 2 decades ago.[1-4] These, and other, organizations have facilitated processes that allow patients to contribute their voice.

A critical step in involving patients in their care is to capture their experience, but historically this information has not been captured in a format that can be broadly useful. The U.S. Food and Drug Administration (FDA) has described four ways in which a patient's condition can be assessed:

- Patient-reported outcome (PRO)
- Clinician-reported outcome (ClinRO)
- Observer-reported outcome (ObsRO)
- Performance outcome (PerfO; e.g., timed walk test)

These assessments focus on the physical, mental, and social health of the patient and can be used to evaluate disease symptoms or adverse events caused by intervention such as drugs or surgery. The major distinction of the PRO is the direct involvement of the patient rather than indirect reporting by others. Although often thought of as symptoms or functional status, PROs can also include satisfaction with care and treatment adherence. The significance of the patient's voice in oncology has been demonstrated in studies comparing reporting of symptoms by patients and clinicians. Patient reporting of Common Terminology Criteria for Adverse Events (CTCAE) is more strongly associated with measures of daily health status than that of clinicians.[5,6] The direct potential benefits of PROs for patients include improved management of symptoms and side effects that would likely result in a higher quality of life and greater satisfaction with care providers.

Two common settings for PROs are in general clinical practice or in the FDA approval of new interventions, typically drugs. In both cases, the questionnaires used to collect PROs are generally referred to as PRO measures (PROMs). A variety of PROMs are available, from the National Institutes of Health's PRO Measurement Information System (PROMIS) to the European Organization for Research and Treatment of Cancer's QLQ-C30, which is focused on patients with cancer and has disease-specific PROMs.[7,8] The National Cancer Institute has pushed for the development of a PRO version of the CTCAE called PRO-CTCAE.[9] PROMs need to be reliable (get the same answers repeatedly), valid (measure what they are designed to measure), and sensitive/responsive (show differences between patients or within patients over time). In addition, the PROM needs to fit the specific purpose, meaning that some tools may need to be tailored to specific disease symptoms and/or stage of disease.[10] Although the FDA has provided guidance on the use of PROs to support approval, the agency has also described the disadvantages of using PROs as an endpoint in cancer drug development, which include uncertainty about the clinical significance of small changes in PROs.[11,12]

Recently, a new concept has emerged that could address questions of clinical significance: the PRO-based performance measure (PRO-PM). With funding from the Centers for Medicare & Medicaid Services, the National Quality Fo-

Corresponding author: Laura E. Strong, PhD, Quintessence Biosciences Inc., 3300 Commercial Ave., Madison, WI 53714; email: lstrong@wisc.edu.

rum (NQF) convened workshops of stakeholders and provided a report defining the concepts. The NQF report also provides a detailed pathway for the development of PRO-PMs starting with PROs and working through the PROMs.[13] The Quality of Care Committee of the American Society of Clinical Oncology (ASCO) has reported on their efforts to develop outcome measures for pain associated with bone metastases and postchemotherapy nausea (Table 1).[14] As these measures work through the delivery of health care, payers will likely to take an interest in measures that correlate to drug use. Although PROs have been used for drug approval in the United States, their utility in drug cost and reimbursement decisions has not been tested.[15,16] As better measures and systems are developed, the E.U. experience may provide useful insight.[17]

HOW AND WHY ARE ONCOLOGISTS USING PROs IN CLINICAL PRACTICE?

A variety of PROMs are available and the last few years have seen many of the paper-based tools translated into electronic versions, resulting in dozens of academic and commercially available electronic PRO (ePRO) systems. A comparison of 33 systems in clinical use revealed the need to consider a variety of features in selecting a solution, including ease of use by patients and providers, ability to change assessments, interpretation of results, and electronic health record integration.[18]

A review of ePROs in use in oncology clinics provided examples of their implementation.[19] Two examples of academic systems are noted here: Patient Viewpoint from Johns Hopkins, and Symptom Tracking & Reporting (STAR) Prostatectomy Project from the Memorial Sloan Kettering Cancer Center (MSKCC; Table 2). These systems can be used to manage both general patient populations and very specific goals for well-defined patient populations. In both systems, patients were able to fill out surveys via the website and monitor their progress over time, and clinicians received reports via the electronic medical record. Interestingly, the MSKCC project also provided benchmarks for patients relative to others in this narrow group. Additional features of other systems

TABLE 1. Oncology-Specific PRO-PMs Developed by the ASCO Quality of Care Committee for Pilot Testing

	Pain	Postchemotherapy Nausea
PRO	Pain	Nausea
PROM	Brief Pain Inventory, worst pain	PRO-CTCAE nausea items
PRO-PM	Proportion of patients with radiographically detected metastatic disease in a given practice with worst pain of 4	Proportion of patients receiving moderately or highly emetogenic systemic cancer treatment who experience moderate or worse nausea within a week

Abbreviations: PRO, patient-reported outcome; PM, performance measure; PROM, patient-reported outcome measures; CTCAE, Common Terminology Criteria for Adverse Events.

included sending alerts to clinicians and/or providing educational material or care advice to patients.[19]

Although the potential benefits of PROs in general practice are clear, a recent review of 24 controlled clinical trials suggests that additional work is necessary to translate PROMs into clinically meaningful and actionable tools.[20] The authors evaluated three types of outcomes from these trials: patient outcomes, health service outcomes, and processes of care, which was the most frequently studied in the trials. The authors came to the following conclusion:

"The routine use of PROMs increases the frequency of discussion of patient outcomes during consultations. In some studies, PROMs are associated with improved symptom control, increased supportive care measures, and patient satisfaction. Additional effort is required to ensure patient adherence, as well as additional support to clinicians who will respond to patient concerns and issues, with clear system guidelines in place to guide their responses. More research is required to support PROM cost-benefit in terms of patient safety, clinician burden, and health services usage."[20]

This review supports the efforts described above to develop outcome measures that properly evaluate the success or failure of PROs in changing outcomes for patients, providers, and health care systems.

KEY POINTS

- Patient-reported outcomes provide a unique and important perspective in oncology.
- PROs are used in clinical practice, including via electronic capture.
- U.S. Food and Drug Administration–approved drugs can include patient-reported outcomes in their label claims.
- Patient-reported outcomes can be used for research, including studies of disease progression.
- The future of patient-reported outcomes will include technology to help patients capture data and help providers identify the information that is meaningful and actionable.

TABLE 2. Two Examples of ePRO Systems in Use at Oncology Clinics[19]

System	Patient Viewpoint (Johns Hopkins)	STAR Prostatectomy Project (MSKCC)
Population	Treatment and survivorship	Postsurgery for radical prostatectomy
Goal	Flexible system of patient monitoring	Monitor recovery of urinary and sexual function
Survey Content	Topics and schedule chosen for patient by clinician	Urinary and sexual function and quality of life
Information to Patient	Patient can see score reports showing changes over time	Changes in function over time compared to other patients and expected improvement based on prediction model

Abbreviatons: ePRO, electronic patient-reported outcomes; STAR, Symptom Tracking & Reporting; MSKCC, Memorial Sloan Kettering Cancer Center.

HOW ARE PROs USED IN ONCOLOGY DRUG DEVELOPMENT?

PROs can be used as endpoints in oncology clinical trials, resulting in symptom improvements that may be listed in label claims of drugs approved by the FDA.

Endpoints used for FDA approval of new cancer drugs from January 1990 to November 2002 were reviewed.[21] Changes in symptoms related to tumors were responsible for 4 of 57 approvals including the use of mitoxantrone in hormone-refractory prostate cancer (HRPC), approved solely for pain relief. From January 2002 to September 2006, 6 of 70 new or revised oncology drug labels included PRO assessments.[22] These drugs included gemcitabine, imatinib, abarelix, leuprolide acetate, interferon alfa-2b, and palifermin.

While noting challenges (e.g., missing data), the FDA's Guidance to Industry in 2007, "Clinical Trial Endpoints for the Approval of Cancer Drugs and Biologics," included symptom endpoints as sufficient evidence for regular approval.[23] Based on draft guidance in 2006, the FDA published a guidance document in 2009 called "Patient-Reported Outcome Measures: Use in Medical Product Development to Support Labeling Claims."[12] Although an oncology-focused review is not available, an overview of the PROs in labels from 2006 to 2010 reveals that the Biologic Oncology Products and Drug Oncology Products divisions at the FDA did not grant any PRO labels claims.[24]

Separately, a review of the drug approval packages for New Molecular Entities and Biologics License Applications for drugs approved from January 2006 through December 2010 was performed to evaluate the use of PROs.[25] A total of 116 approvals across all therapeutic areas were evaluated. Although there are alternative reasons to include PROs, this review assumed that all PROs included in a drug approval package were intended for approval. Among 52 drugs for which PROs were included in pivotal studies, 28 had one or more PRO claim approved. Eight cancer drugs were "denied" PRO claims in this time period. For comparison, 18 oncology applications were submitted over the same time period.[24] Across all sectors, but specifically in oncology, the major reasons that PROs did not support claims included "fit for purpose" and study design/data quality/interpretation. As noted, providing detailed evaluations of the PROs and their use would allow sponsors to better meet FDA standards in the future.[25]

Prostate cancer provides a strong example of the use of tumor symptoms as endpoints in oncology drug development. Pain and skeletal-related events are among the major disease-related symptoms of HRPC. The supplemental approval of mitoxantrone in 1996 was for pain relief in HRPC.[21] The approval of docetaxel in 2004 was based on survival benefit as the primary endpoint. Two clinical trials comparing mitoxantrone and docetaxel with secondary endpoints of PROs were inconclusive as one study was positive and the other negative.[26,27] A review of PROs and chemotherapy in clinical trials of HRPC indicates that the PROMs were generally validated, even if they were often used as a secondary end-

point.[26] Although bisphosphonates have been approved for use in HRPC to reduce skeletal-related events, the corresponding improvement in pain did not lead to an improvement in function or quality of life, illustrating the challenges associated with these and other new agents.[21,27]

In a recent review of PROs in randomized clinical trials (RCTs) of prostate cancer from January 2004 to March 2012, the authors estimate that approximately 20% of the RCTs provided sufficient data to change clinical practice.[28] The authors compared their work to a similar review covering RCTs from 1980 to 2001 and indicate that the use of PROs in RCTs has improved. One area of improvement was that the number of trials with documentation of missing data increased from 48% to 72%. Unfortunately, only 18% of the newer trials addressed statistical treatment of the missing data. This issue reflects the concerns expressed by the FDA in the examples given above. Adding to the discussion, an organization called CONSORT (Consolidated Standards of Reporting Trials) has recently published specific recommendations to improve the reporting of RCTs that include PROs.[29]

The most recent generation of FDA-approved drugs for prostate cancer includes abiraterone, cabizataxel, enzalutamide, radium Ra 223 dichloride, and sipuleucel-T. Clinical registration trials for each of these products included PROs. Notably, the products were approved from 2010 to 2013, following release of the draft and final FDA guidance on PROs. In the United States, the FDA granted pain symptom claims based on PROs to two of the five drugs, enzalutamide and abiraterone.[30] A review has collected background information for the rejection of the remaining claims by the FDA, showing that the reasons largely overlap with those for rejections from 2006 to 2010 (e.g., validity of the instrument or missing data).[30]

ARE THERE OTHER USES FOR PROs?

In addition to providing direct benefit to patients, PROs can be used for a variety of other purposes. PROs can be captured to explore disease progression and could assist in the development of improved diagnostic tools or potentially even new interventions, including new targets for drug development. Large academic medical centers fit into this stakeholder category because they have electronic health records and often have access to existing PROMs. However, another intriguing example is Open Research Exchange, which is a collaborative project developed and run by the online patient community network PatientsLikeMe.[31,32] Their goal is to attract researchers to Open Research Exchange to develop and test health outcome measures within the patient communities of PatientsLikeMe. Although the company is for profit, the Open Research Exchange advisors include many of the leading academics involved in PROs, including Dr. Ethan Basch from the Lineberger Comprehensive Cancer Center at the University of North Carolina.

HOW CAN TECHNOLOGY HELP PATIENTS (AND PROVIDERS)?

Capturing and analyzing all of the data points for PROs can be cumbersome for providers and patients, particularly when the patients are experiencing decreased function as a result of disease or intervention. One of the negative consequences of this is the disadvantage of missing data noted above. The move from paper to electronic PROs has increased the flexibility of data capture. However, even seemingly small changes such as having patients use their own device rather than a device provided specifically for filling out the PROs can potentially influence results.[33]

In the future, technology may provide a means for everyday activities (performance outcomes) to essentially be captured as PROs. As an example, consider two common symptoms experienced by patients with cancer: fatigue and depression. For fatigue, PROMs ask questions about feelings of being run down, tired, or lacking energy. Alternatively, a wearable device or mobile application on a smartphone (most of which have sensors, including accelerometers) could directly gauge the daily activity levels of patients with cancer with the appropriate health status. The simplest marketed devices collect activity data, but newer products include sensors for additional factors, such as vital signs and heart rhythms. These devices range from consumer products to FDA-cleared devices. On the consumer front, the Fitbit and Jawbone are general activity trackers, and next-generation devices have emerged with sensors for heart rate, such as the Mio Link and TomTom Runner. Although consumer devices may not be appropriate for all purposes, there are suggestions from clinical trials that wearables have utility in specific cases, such as predicting recovery from surgery.[34,35] There are also FDA-cleared sensors with greater capabilities, such as skin temperature and body posture. For example, HealthPatch MD from Vital Connect and wGT3X-BT Monitor from ActiGraph have recently been tested for utility in clinical trials.[36] If a correlation between fatigue and activity is demonstrated, the devices or apps could collect more information while decreasing the patient reporting burden.

Multiple companies, including Ginger.io, Priori, and Cross-check, are developing mobile applications (apps) for smartphones that may allow them to correlate behavior with mood as determined by traditional survey instruments. These apps are tracking general activity such as volume of text messages and phone calls, voice analysis, and location tracking.[37] Ginger.io is currently running a randomized, controlled clinical trial of their app called Mood Matters, which would provide support for exploration in other settings such as oncology.[38]

As everyday activities (performance outcomes) become be captured as PROs, there will be additional concerns to address. A few of these concerns are noted here. First, the conversion itself does not address the increased informatics workload for providers. Methods for data visualization or other dashboards that could assist in identifying what is meaningful and might guide action would address this concern. Second, the reliance on technology would likely exacerbate the gap between patients with access to technology (smartphones with data packages) and those without. Although there are strategies to address these issues, consideration should be given to differences in technology solutions that affect the comparability of results. Finally, care should be taken that the technology does not change patient behavior unless that is an intended outcome. A recent example comes from an experiment by Jawbone to encourage their users to be more active on Thanksgiving.[39] The company found that even a holiday greeting that included a suggested step count modified behavior. Technology provides tremendous potential as another way to capture the "voice" of the patient, but great care and consideration are necessary to ensure the utility of the data.

Clinical Oncology Practice 2015: Preparing for the Future

Michael P. Kosty, MD, FACP, FASCO, Anupama Kurup Acheson, MD, and Eric D. Tetzlaff, PA-C

OVERVIEW

The clinical practice of oncology has become increasingly complex. An explosion of medical knowledge, increased demands on provider time, and involved patients have changed the way many oncologists practice. What was an acceptable practice model in the past may now be relatively inefficient. This review covers three areas that address these changes. The American Society of Clinical Oncology (ASCO) National Oncology Census defines who the U.S. oncology community is, and their perceptions of how practice patterns may be changing. The National Cancer Institute (NCI)-ASCO Teams in Cancer Care Project explores how best to employ team science to improve the efficiency and quality of cancer care in the United States. Finally, how physician assistants (PAs) and nurse practitioners (NPs) might be best integrated into team-based care in oncology and the barriers to integration are reviewed.

The ASCO National Oncology Census was originally launched in 2012.[1] The goals of the National Oncology Census were to help ASCO understand where oncologists were providing services, their practice characteristics, and their challenges. Before the launch of the census, some members of ASCO voiced concerns about substantial shifts in oncology care from private practices to university- or hospital-based practices. Also, it is projected that there will be increases in the number of patients and decreases in the supply of oncologists.[2] Therefore, it was important for ASCO to try to clarify if the apparent shifts were actually occurring throughout the nation and, ultimately, whether this was affecting delivery of cancer care in United States.

For the 2014 census, there were 1,252 respondents comprised of 974 practices, representing more than 10,000 oncologists in the United States. The number of practices and oncologists represented in the 2014 National Oncology Census were much greater than the 530 practices and nearly 8,000 oncologists responding in 2013.[3]

More practices from the South and West regions of the United States responded in 2014 (Fig. 1). The largest number of respondents was from physician-owned practices, with the second highest being from hospital/health-system–owned practices, and the third being from academic practices. There were respondents from industry and those in international and government settings, as well as retired practitioners. For the purposes of analysis, we focused on the physician-owned, hospital/health-system–owned, and academic practices.

As would be expected, a majority of the practices focused on hematology and oncology services with many also providing radiation oncology, gynecology oncology, and surgical oncology. Fewer respondents were part of multidisciplinary practices that included internal medicine, gynecology, or pediatrics.

The census survey tool asked the respondents questions about plans for their practice in the next 12 months, including selling/merging their practice or buying another practice. More than 70% of respondents were unlikely to plan any major shifts in the upcoming 12 months, with only about 4% of practices planning to close or sell their practice and only about 5% planning to purchase another practice. With regards to physician-owned groups, about 6% planned to close or merge, about 7% planned to sell, and about 4% planned to purchase another practice.

Hospital/health-system–owned practices and physician-owned practices were more likely to indicate that financial pressures were because of payers, costs, competition, and drug pricing issues. Meanwhile, academic practices cited research issues, staffing issues, and competitive pressures as their most important concerns. Overall, the pressures cited by practices responding to the National Oncology Census during the past 3 years seem to focus around payer issues, cost pressures, competitive pressures, and drug pricing. The overall payer mix remains the same, with a trend toward an increasing percentage of patients on Medicaid and Medicare in 2014 compared with 2013 and 2012. The majority of the practices are still not participating in accountable care organizations. Academic practices, by far, use more advanced practice nurses and PAs (Fig. 2). Respondents also indicated that for potential layoff considerations, that administrative staff and other clinical staff are more likely to be affected in their practices (Fig. 3).

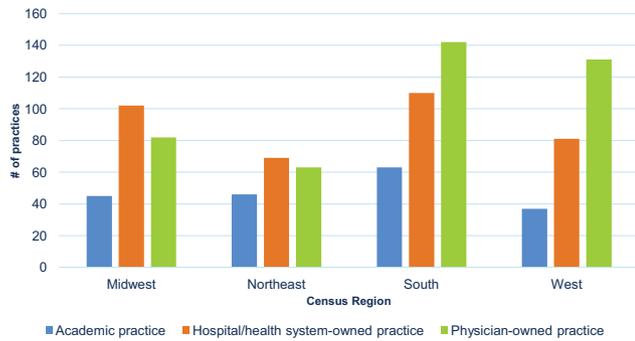
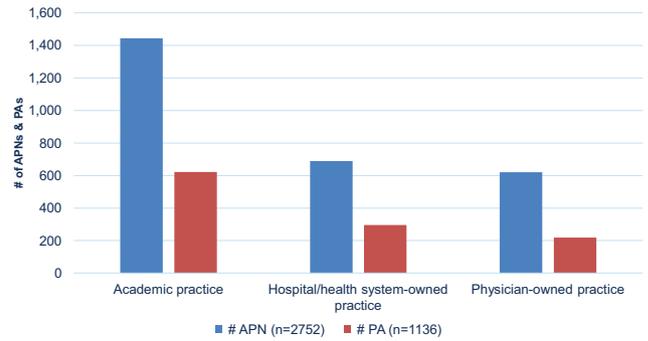
FIGURE 1. Practices by Census Region and Practice Setting (971 patients)

FIGURE 2. Number of Advanced Practice Nurses and Physician Assistants by Practice Setting


With each successive year of the ASCO National Oncology Census, it is clear that the shifts away from private practice to more alignment/consolidation or moves to hospital-based practices has occurred.[1,3] These findings seem consistent with other studies that note size growth of oncology practices.[4] Ultimately, it is unclear whether the pendulum has come to a rest or whether there will be further consolidation or shift. ASCO has already begun preparing for the 2015 census, with plans to identify additional data or sources to support and validate this census process. The information from this effort informs ASCO's work in supporting its membership, including policy efforts and shaping legislation and regulation, payment reform, and workforce needs. Ultimately, understanding the practice environment surrounding the providers who care for patients with cancer is important to ensure increasingly complex therapies are delivered to some of our most vulnerable patient populations in the United States and that all patients have access to high-quality cancer care.

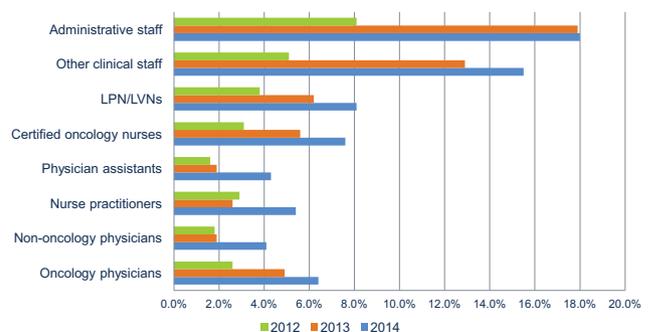
KEY POINTS

- ASCO Oncology Census continues to show shifts away from private practice to more alignment/consolidation.
- Practices are concerned about payer issues, cost pressures, competitive pressures, and drug pricing.
- True team-based approaches to oncology care may provide a means of optimizing resource utilization and improving the quality of care.
- Utilization of advanced practice providers in oncology will help meet workforce needs, although significant importunities still exist to improve the engagement of providers, national organizations, and policy makers.
- Restrictive barriers in legislation, reimbursement, provider bias, and educational infrastructure reduce the benefits of utilizing advanced practice providers in oncology and inhibit the ability to expand and effectively employ advanced practice providers in the workforce.


TEAM-BASED CARE IN ONCOLOGY

At the risk of sounding trite, high-quality cancer care takes a village. Multimodality therapy requires coordinated care delivery among several groups of clinicians as patients move along the continuum of cancer care—from risk assessment, prevention, diagnosis, treatment, and surveillance to survivorship and advanced cancer. Within any given clinic, increasingly complex therapies require clinicians with advanced, specialized training. Clear communication and transparent, defined roles and responsibilities help ensure that care needs are addressed and timely decisions are made. Placing prompts in electronic health records, sending reminders to patients, and requiring detailed notes at transfers of care are important strategies to improve communication. Embedding tools in the process helps address issues in the immediate, but more lasting change can come from explicitly helping to transform individual clinicians and separate groups into a team that works together.

In March 2015, the *Journal of Oncology Practice* presented an overview of cancer care team effectiveness[5] and used a case-based vignette[6] to discuss the importance of delivering cancer care as a team. These manuscripts marked the beginning of collaboration between NCI and ASCO bringing clinicians, patient advocates, and researchers together to explore application of the evidence of team effectiveness to clin-

FIGURE 3. Potential for Staff Layoffs by Year


ical practice. The NCI-ASCO Teams in Cancer Care Project will unfold at a 2016 workshop.

Teams are defined as two or more people who "interact dynamically, interdependently, and adaptively" to accomplish a shared goal.[6] Weaver et al assessed the role of interprofessional teams in an inpatient oncology setting and concluded that nurses and oncologists have disparate perceptions of the effectiveness of their collaboration and work as a team.[7] In an editorial to accompany the article, Childress questioned the need for additional studies to demonstrate "significant and well-documented" differences in perception of communication.[8] Taplin et al note that communication is one of the eight hallmark traits of effective teams. The hypothesis the NCI-ASCO project will discuss is that deliberately identifying and enhancing team interactions in oncology care will help improve cancer care delivery.

This project fits in the larger context of the transformation of health care delivery and payment models. The field of primary care has actively engaged in reinventing care to form a patient-centered medical home. Experiments are underway to apply the same concepts to specialty care delivery. At the same time, public and private payers and ASCO are proposing payment models that would move away from payment based on specific procedures and physician contributions and toward an approach that provides bundled payments for comprehensive care and allows greater flexibility in how care is organized and delivered. A team-based approach has potential to leverage these changes, provide an opportunity to reexamine clinician roles and responsibilities, and may enable the most efficient delivery of high-quality health care services.

Clinicians in oncology care may believe that their practice already involves working in teams. People with cancer often view their care as a seamless experience and most likely desire this approach from the many clinicians they engage across the care continuum—from diagnosis to surgery to therapeutic radiation to chemotherapy to palliation to rehabilitation. Do clinicians meet this standard or is the responsibility more often on the patient or their caregivers to connect the dots? If clinicians saw themselves through the patient's eyes as members of a single team coordinating care, could quality, access, efficiency, and clinical outcomes improve? Should the person with cancer have an explicit role and set of responsibilities within the treatment team? If clinicians approach patients with this question, would they embrace a role in the team or believe the clinician is trying to avoid responsibility? Could working in teams with well-recognized and valued roles for all members of the team improve job satisfaction and reduce provider burnout?[9,10] These questions have many possible answers.

The literature in health care and many other fields demonstrates that effective teamwork takes time and intentional focus to nurture, develop, and sustain. To this end, it is the hope that a collaboration of clinicians involved in cancer care, advocates who have been patients, and researchers engaged in studying teams will highlight successful models and identify areas for future research. Leaders of the initiative will invite applicants to serve on writing groups to apply principles of team-based care to specific case scenarios. The writing groups will meet in person and work by conference call and email to develop a presentation for an NCI-ASCO workshop in February 2016 at the ASCO Quality Care Symposium. Presenters will engage in discussion with workshop attendees to enrich their work and submit final manuscripts for publication in the *Journal of Oncology Practice.*

ADVANCED PRACTICE PROVIDERS WORKFORCE IN ONCOLOGY

As a key member of team-based care in oncology, the use of advanced practice providers (APPs) to help meet the workforce demands has been one of the proposed solutions since the initial workforce strategic plan was approved by the ASCO Board of Directors in 2008. The utilization of APPs in oncology practices can increase practice efficiency and productivity as well as the professional satisfaction of collaborating oncologists.[11] However, the degree to which the use of APPs will help meet future demand is unclear, as the current and projected workforce of APPs in oncology has been challenging to report. Based on census data from 2013, the American Academy of Physician Assistants (AAPA) reported that there were an estimated 2,140 clinically practicing PAs in adult medical, surgical, and radiation oncology subspecialties.[12] This represented a 25% increase compared with 2010 census data.[13] However, important characteristics such as age, geographic distribution, education, years of experience, and years to expected retirement are unknown. Similar challenges are faced when trying to describe the NP workforce in oncology. The American Association of Nurse Practitioners (AANP) also publically reports survey data for licensed NPs. In 2013, of the more than 205,000 licensed NPs, approximately 2,050 worked in oncology and had been in practice for an average of 7.7 years with a median age of 48.[14]

MODELS OF APP INTEGRATION INTO TEAM-BASED CARE

There are three models of care utilizing APPs in the team-based care setting: (1) the independent-visit model (IVM) in which APPs predominantly see patients independently in clinic but still under the collaborative practice agreement with their physicians, (2) the shared-visit model (SVM), for which patients are seen by both the APP and the physician during the clinical encounter, and (3) the mixed-visit model (MVM) in which both the independent and shared visit model is utilized to manage the clinical volume but neither is the predominant encounter used.

To examine the differences between the different models, Buswell et al reported the effect of the practice models on productivity, fees, and provider and patient satisfaction in an academic cancer center.[15] They found that productivity for the IVM, MVM, and SVM, as measured by the number of new and established patients, was similar between the models

(6.8, 6.7, and 7.0 patients seen per 4-hour session, respectively). Both physician and APPs were very satisfied with the IVM and reported patient-centered and productivity-based reasons influencing the decision to use their chosen model. For the SVM, physicians were still very satisfied with the model, whereas, APPs were only moderately satisfied. Reasons for utilizing the SVM were more physician-centered, focusing on physician preferences and perceptions. Importantly, there were extremely high levels of patient satisfaction for both models (100% satisfaction with care received from either model).

In a much larger study of the private practice setting, the results of the ASCO study of collaborative practice arrangements also noted high levels of patient and provider satisfaction with the APP models.[11] The most common model in the survey was the independent model. The IVM was also 19% more productive (based on relative value units, [RVUs]) when the APP worked with the entire group of physicians as compared with an IVM when the APP worked exclusively with a limited number of physicians. However, one should be cautious to conclude that the more productive RVU model is the ideal model to utilize APPs. Further insight into measures of quality and continuity of care of the two models would be important to distinguish. In addition, RVUs as the sole productivity measure is a limited assessment of the value an APP adds to a practice. The study did not take into account the non-revenue generating activity performed for each model, which would be important in defining the preferred models.

BARRIERS TO INTEGRATION
Provider and Patient
ASCO's study of the collaborative practice arrangements of APPs identified physician lack of interest in working with APPs as the most common reason not to utilize them in their practice.[11] To determine how to best motivate attitudinal change, it is important to explore the reasons for lack of interest. As the ASCO report was primarily physician-owned private practices (73%) with only 8% surveyed in academic practice, it is possible that the lack of interest is based on the fear of decreased personal compensation for the physician. It has been shown that the private-practice model has significantly more oncologists compensated on an incentive-based model compared with academic models (39.3% vs. 3.1%; p < 0.001).[16] Therefore, it may be important to focus on the increased practice productivity when using APPs to encourage utilization in private practice. Furthermore, as a pure incentive-based model is associated with the highest rate of burnout, the increased professional satisfaction when working with APPs can be another educational point to change perceptions.

There are other challenges to incorporating APPs into clinical practice that are largely historic or based more on personal bias than fact.[17] For example, the belief that utilizing APPs will negatively affect the physician/provider relationship or that patients will not accept APPs as part of the care team is not founded. Studies have demonstrated high levels

of patient and provider satisfaction with the collaborative practice model with increased utilization nationally.[11,15,18,19] It is likely that a portion of the workforce that is nearing retirement is also the same group that has less experience and understanding of the PA and NP profession and, therefore, more perceived bias. This barrier, however, is likely to end as oncologists entering the workforce develop experience working with PAs and NPs during their fellowship. In a survey of fellowship program directors in 2011, 90% of medical directors reported that their fellows work with NPs or PAs.[20] What is not well known is how well prepared oncologists entering the workforce will be to lead a medical team that incorporates APPs. It will be important moving forward for oncologists to understand the different models for APP utilization, as well as the regulatory and reimbursement requirements to effectively lead the medical team. Ideally, this educational need could be incorporated into the fellowship training programs before entering the workforce and then further refined at the practice level based on state laws and institutional policies.

Legislative
With modern medicine should come modern legislation. Unfortunately, despite widespread acceptance of PAs and NPs, there remain substantial historic and dated legislative barriers that limit the effect that APPs have in providing quality care. Despite differences in regulations between PAs and NPs, there is common ground in the interest to ensure that PAs and NP are practicing to the highest level of their degree and professional training. Both the AANP and AAPA have written position statements and established policy priorities to improve access to health care through removing barriers in federal and state regulations. Specifically, some of the shared priorities nationally for APPs that will directly affect oncologic care include authorizing APPs to provide hospice care and allowing APPs to certify home care services and order durable medical equipment. At the state level, limitations on the prescriptive authority and scope of practice are also shared concerns between PAs and NPs. For example, 14 states still prohibit PAs from prescribing schedule II narcotics. Practice productivity is highest when APPs are used for advanced activities.[21] Therefore, by expanding the prescriptive privileges and allowing APPs to practice at the highest level of their scope of practice will help ensure that quality and efficient care will continue for patients with cancer.

To highlight the benefits of improving legislation for APPs, a study was conducted to simulate the effect that enacting policy changes would have on the supply of PAs and NPs in primary care in Alabama.[22] This simulation was based on policy changes that facilitated obtaining licensure, expanded prescriptive privileges, and removed several limitations on scope of practice. The results demonstrated the potential for substantial health care savings and increased access to care in Alabama with simple policy changes. The specific results of this study cannot be directly applied to the current and projected work demands in oncology. However, the proof of principle should be helpful to policymakers and advocacy

groups in further examining the role of utilization of APPs in oncology.

Productivity and Reimbursement

It is generally accepted that practices that incorporate APPs are more productive and efficient in providing quality care to patients than practices that do not. However, as practices work to integrate APPs into clinical practice they have been challenged with accurately assessing the productivity and value of individual APPs. Practices that utilize a system strictly based on RVUs will likely underestimate the productivity and value of APPs because of the inability to accurately measure RVUs. For example, global surgical visits and the SVM will render the time and effort of the APP invisible.[23] Even in the IVM, all incident-to visits as well as visits for many commercial payers are billed under the physician's National Provider Identifier, despite all care being provided by the APP. In addition, there are numerous activities in clinical care that APPs provide that are not billable encounters but bring quality and value to the practice. Importantly, these nonrevenue generating activities, if not completed by the APP, would have to be completed by the physician. The challenges in assessing the productivity of APPs and the limited benchmarking data available affects the ability to not only improve productivity of the APPs but will hinder the ability to increase utilization. Practices will struggle to determine when to hire new APPs and how their time should be allocated to support the clinical enterprise. Also, practice managers will inherently be unable to determine equitable compensation, comparison, and accountability of APPs within a practice.

Moving forward, it will be important for administrators and APPs to work together to ensure that productivity assessments accurately reflect the overall value that the APP brings to the care team. Options should include continued use of claims data, but also use of practice management and health records software to measure care rendered by an APP. Using a team-based approach to productivity where the physician and APP RVU are combined may be a reasonable alternative to the independent model of assessment. To augment the measurement of productivity, time and effort studies can be completed on a regular basis to track both the billable and nonbillable effort. This exercise will not only provide a greater understanding of the value of the APP, but it may highlight opportunities to improve practice efficiency and ensure that APPs are working up to the level of their degree.

In regard to reimbursement, there are several common myths and misconceptions that can stymie the expansion of APPs in oncology. Several myths such as "APPs cannot see new patients" or "APPs cannot bill above a certain level" are easily debunked with a little education and, if needed, support from the national advocacy organizations. However, one of the more challenging misconceptions is the over estimation that the 85% reimbursement rate of the APPs compared with the physician rate will have on the cost-effectiveness of APPs. Numerous studies on PAs and NPs have demonstrated that APPs are cost-effective health care

providers. This can be explained by physician salaries being consistently 30% to 50% higher than APPs, incident-to billing reimbursed at 100%, and the savings on reduced recruitment and retention costs of APPs.

Educational Systems

One of the biggest barriers to utilizing APPs to help meet the oncologic workforce demands may be in the educational infrastructure in place for the education of APPs. The education of APPs generally provides a general medical education with limited time dedicated to oncology in the curriculum. In a survey of PA programs, cancer prevention and diagnosis were the primary focus of the oncologic curriculum with no or little focus on acute management, oncologic emergencies, and supportive and survivorship care.[24] In addition, although nearly all PA programs offer locally available, elective rotations in oncology, less than 15% of students participate in such opportunities. Similarly, in a survey of the educational experience of oncology NPs, most reported being poorly prepared to provide cancer care and not at all prepared to perform oncologic procedures or manage oncologic emergencies.[25] Once APPs enter the oncologic workforce, the majority report on-the-job training through mentorship with supervising/collaborating physicians, as well as, self-study as the means to obtaining the core competencies for their position.

To overcome the educational barriers to expanding the APP workforce will require efforts both during and immediately after the graduate training of APPs. With less than 15% of students pursuing elective rotations in oncology, the current workforce of APPs in oncology should help engage students during their didactic year to increase participation. This could be done by developing relationships with local APP programs and educating students about a career in oncology. The national organizations that represent APPs in oncology should also engage new student members to help increase interest in the field. As an example, the Association of Physician Assistants in Oncology has created a student day seminar at the annual continuing medication education (CME) meeting that offers students a free day of participation in the conference, as well as seminars for students about pursuing a career in oncology.

To help APPs gain the knowledge they need to meet the demands of caring for patients with cancer will require improvements in the core curriculum in graduate education. Unfortunately, it will be hard to expand the curriculum given the limited time available during the didactic year. It is possible that a flipped-curriculum model may be helpful to meet this challenge. In this model, standardized lectures can be viewed outside of the classroom and time spent in the classroom can be used for more active learning opportunities such as teamed-based learning and skills training.[24] The active classroom time would also be another opportunity for clinical preceptors and other APPs in oncology to engage students in oncology. The core curriculum for the flipped-curriculum model could be provided through standardized programs similar to ASCO's Curricula for Advanced Practice

Provider's (ACAPP), but with a focus on expanding the core curriculum of students in current APP programs.

Once an APP enters the oncologic workforce, the majority of education occurs during on-the-job training and self-study. To help meet the educational needs of APPs, programs such as ACAPP were developed and annual CME meetings for APPs in oncology are offered. These programs help offset the burden of individual practices in onboarding new graduates and provide ongoing education to APPs in oncology. As the number of APPs in oncology continues to increase, educational providers and industry have become increas-

ingly interested in engaging this emerging market. Certainly, programs that provide certificates of completion and educational credits will be welcomed. However, educational programming for the intent of certification in oncology should be met with caution. Utilization of APPs in oncology is variable and differs in practice setting, discipline, and patient population. An individualized approach to ensuring the competency of APPs in oncology is, therefore, the best approach. Promoting the certification of APPs in oncology could be a substantial barrier to increasing the APP workforce and should not be endorsed as a requirement to practice.

Adjuvant Chemotherapy for Soft Tissue Sarcoma

Paolo G. Casali, MD

OVERVIEW

Adjuvant chemotherapy is not standard treatment in soft tissue sarcoma (STS). However, when the risk of relapse is high, it is an option for shared decision making with the patient in conditions of uncertainty. This is because available evidence is conflicting, even if several randomized clinical trials have been performed for 4 decades and also have been pooled into meta-analyses. Indeed, available meta-analyses point to a benefit in the 5% to 10% range in terms of survival and distant relapse rate. Some local benefit also was suggested by some trials. Placing chemotherapy in the preoperative setting may help gain a local advantage in terms of the quality of surgical margins or decreased sequelae. This may be done within a personalized approach according to the clinical presentation. Attempts to personalize treatment on the basis of the variegated pathology and molecular biology of STS subgroups are ongoing as well, according to what is done in the medical treatment of advanced STS. Thus, decision making for adjuvant and neoadjuvant indications deserves personalization in clinical research and in clinical practice, taking profit from all multidisciplinary clinical skills available at a sarcoma reference center, though with a degree of subjectivity because of the limitations of available evidence.

Adult-type soft tissue sarcomas are a variegate group of malignancies. They are highly heterogeneous, because they are made up of several histologies and arise from virtually all body sites.[1] In addition, they are rare, and their incidence is approximately 4 per 100,000 per year.[2] This incidence does not prevent controlled trials, but pooling together different histologies and possibly different primary sites is often the price to pay. It is true that more than half of STS cases are high-grade and undifferentiated pleomorphic sarcomas, liposarcomas, leiomyosarcomas, myxofibrosarcomas, synovial sarcomas, or malignant peripheral nerve sheath tumors, and more than half of them arise in the limbs. However, a high degree of heterogeneity remains, even after selecting a group of patients with these types of STS, and other relevant subgroups (e.g., uterine sarcomas) are left behind. This contributes to major limitations of available evidence on adjuvant chemotherapy in STS and, thus, a considerable degree of uncertainty on its clinical value, although several randomized clinical trials have been performed in the last 40 years.

When one singles out high-grade STS, the mortality rate exceeds 50%. In addition to the malignancy grade, other main prognostic factors are size and presentation—for example, deep fascial extension. By combining these three factors, it is easy to select a population in which two-thirds of patients may die of their disease. Prognostic nomograms are available to refine the prognosis with a view toward adjuvant decisions.[3-6]

Currently, the treatment of metastatic disease is unsatisfactory. Surgery of lung metastases is the main option when secondary lesions are isolated in the lungs, and the number of such lesions is relatively low. A cure may be achieved in a minority of patients with these metastases, and the course of disease may be slowed down in a subgroup of others; however, most patients will experience relapse in a matter of months. Chemotherapy is based on anthracyclines and ifosfamide, though other cytotoxics and even molecularly targeted agents are available, which have interesting antitumor activity in selected histologies. Indeed, there is currently a trend in favor of an histology-driven approach in the medical therapy of STS. However, the effect of medical therapy in the metastatic setting is essentially palliative, though improving over the last years. The median survival of patients with metastatic disease often has been reported to be in the range of 1 year. Undoubtedly, there are subgroups who benefit from surgery of lung metastases and currently available medical therapies, but a cure is essentially precluded in most cases, and—though possibly higher than once reported— overall survival remains unsatisfactory, if one leaves aside the tails of curves.

In addition, STS often pose challenging problems regarding surgery of localized disease. In a minority of cases, one may hope to convert mutilating surgery into limb-sparing procedures by means of preoperative cytoreduction. In several other cases, cytoreduction is felt by the surgeon to be potentially useful to minimize sequelae and improve the local control rate. This is why chemotherapy is resorted to preoperatively in a proportion of patients, which may vary from an

institution to another, with a view toward local cytoreduction, in addition to its possible systemic effects.

In conclusion, there is a huge need for effective adjuvant and/or neoadjuvant treatments in STS. The proportion of potentially amenable patients may roughly amount to one-half of cases. This applies to adult-type STS, because extraskeletal Ewing sarcomas and embryonal or alveolar rhabdomyosarcoma fall in a distinct group of sarcomas, even when they occur in the adult, which deserves chemotherapy in all cases as a key component of the standard treatment.

AVAILABLE EVIDENCE

Several randomized, controlled trials have been performed with adjuvant chemotherapy for STS, starting from the 1970s, when chemotherapy was shown to be crucial in revolutionizing the prognosis of childhood sarcomas, (i.e., osteosarcoma, Ewing sarcoma, and rhabdomyosarcoma). Trials performed in STS can be divided into two generations. First-generation trials used anthracycline-based regimens—that is, either doxorubicin alone or combinations that today would be regarded as exploiting doxorubicin as virtually the only, or nearly only, active drug. Second-generation trials have been based on combinations of anthracyclines and ifosfamide. Doses varied substantially, but at least the two main active drugs in STS were incorporated. A high degree of heterogeneity can be found in all these studies also, as far as the patient populations are concerned, and the number of patients ranged from a few dozens to hundreds.

A meta-analysis of these randomized clinical trials, published in 2008, confirmed the benefit that a previous meta-analysis, done on individual patient data, had already shown in terms of local and distant relapse rate; the 2008 publication also noted a statistically significant benefit in terms of overall

survival for doxorubicin plus ifosfamide (p = 0.01).[7,8] The magnitude of benefit was in the 5% to 10% range. Although small, this could well justify the choice of using chemotherapy in high-risk patients, and a meta-analysis of several randomized clinical trials could be regarded as sufficient evidence to back this choice. Methodologically, the last meta-analysis was not done on individual patient data. However, the main limitation of any meta-analysis of adjuvant chemotherapy in STS is that the pooled trials are conflicting, and the largest trials point to a lack of benefit. Clearly, this substantially undermines any positive conclusion. Conversely, small trials were less heterogeneous in their patient population and/or were carried out by single institutions with more expertise with the disease. In rare cancers, large trials enrolling patients from a variety of institutions with different expertise levels may pose substantial problems in terms of quality of care. Random assignment is not a guarantee that this clinical bias is offset just because it is operating in both arms, because the most effective treatment may be more penalized by shortcomings in quality of care (e.g., in the adjuvant setting, by surgical treatment).

In 2012, a large, randomized trial was published by the European Organization for Research and Treatment of Cancer (EORTC) Soft Tissue and Bone Sarcoma Group, which provided a negative result by using a regimen of doxorubicin plus ifosfamide at full doses, though the latter was given at 5 g/m^2 in 24 hours.[9] The relapse rate of the study patient population was in the 50% range; thus, it was at a level that may be slightly lower than the one selected by some positive studies. By updating the meta-analysis using aggregate data for overall survival of this and other new studies, a statistically significant benefit was still apparent in terms of survival in favor of chemotherapy (p = 0.02).

A randomized trial performed by the Italian Sarcoma Group (ISG) and the Spanish Sarcoma Group (GEIS), published in 2008, compared five cycles (three preoperatively and two postoperatively) of full-dose epirubicin (an analog of doxorubicin) plus ifosfamide with 3 preoperative cycles of the same regimen.[10] Both relapse-free survival and overall survival were superimposable, but they also were superimposable to the treatment arm (five postoperative cycles of the same regimen) of a previous randomized trial carried out by ISG that had a no-chemotherapy control arm.[11] That trial had been closed in advance because of an early major benefit in survival in favor of the adjuvant treatment arm. With a longer follow-up time, the statistical significance was lost, though a trend was preserved.[12] The patient population of the ISG trials was definitely in the high-risk group, and it was calculated that the prognosis expected without chemotherapy for patients enrolled on the most recent trial, estimated through available nomograms, was compatible with the performance of the control group in the first study. This may be taken as indirect evidence that three courses of a full-dose regimen of anthracycline plus ifosfamide can give some prognostic benefit in a truly high-risk STS patient population.

It is interesting that several trials on adjuvant chemotherapy in STS detected some benefit in terms of local relapses.[8,13]

KEY POINTS

- Adjuvant chemotherapy is not standard treatment in soft tissue sarcoma (STS), but it is an option to share with the patient in conditions of uncertainty when the risk of relapse is high.
- Controlled evidence is available, and was also pooled in meta-analyses, but its weakness is that studies have been conflicting.
- If the decision is to resort to chemotherapy in the patient with localized high-risk STS, chemotherapy can be administered preoperatively if cytoreduction is felt to help improve the quality of surgical margins and/or sequelae.
- Personalization of adjuvant chemotherapy across diverse STS subgroups is worth testing in clinical research as a way forward, to improve its efficacy.
- Personalized, rational decision making in conditions of uncertainty on adjuvant treatment for patients with STS is the every-day challenge that multidisciplinary tumor boards face at reference sarcoma centers or within sarcoma networks.

This observation is difficult to explain, especially in the presence of a questionable benefit for distant relapse. However, one should recall that the local control in some patients with high-risk STS may be challenging. In addition, some local relapses in STS may well lead to death. This might explain the differences in survival in the absence of comparable differences in distant relapses. In addition, this could add to the rationale of placing chemotherapy preoperatively, as long as the decision has been made in the single case to use it as an adjunct to surgery. The ISG trial allowed the combination of neoadjuvant chemotherapy with preoperative radiation therapy, and this proved to be tolerable in the proportion of patients in whom it was used.

With an incidence in the range of 0.5 per 100,000 per year, uterine sarcomas are a relevant subgroup in the STS family. They entail a significant risk of relapse. Leiomyosarcoma is the main subgroup, if one excludes mixed mullerian tumors (carcinosarcomas), which are currently held to be epithelial in nature. Other highly malignant subgroups are high-grade endometrial stromal sarcomas and undifferentiated uterine sarcomas. Recent, uncontrolled evidence was provided on a regimen employing four cycles of gemcitabine plus docetaxel and another that was based on four cycles of the same chemotherapy followed by four cycles of doxorubicin.[14,15] The latter regimen was associated with an interesting relapse-free survival rate compared with external controls, though the rate decreased with a longer follow-up time. A randomized trial is ongoing to compare this regimen to a no-chemotherapy arm in uterine leiomyosarcomas.

CURRENT RECOMMENDATIONS

The 2014 National Comprehensive Cancer Network (NCCN) clinical practice guidelines state that adjuvant chemotherapy for STS greater than 5 cm and intermediate to high grade in the extremities, superficial trunk, or head and neck, can be viewed as an appropriate intervention on the basis of lower-level evidence marked by limited and conflicting data.[16] Thus, adjuvant chemotherapy is a legitimate option, but is not standard. In essence, the same applies to uterine leiomyosarcomas or undifferentiated sarcomas.

The 2015 European Society for Medical Oncology (ESMO) clinical practice guidelines state that chemotherapy can be regarded as an option for patients with high-grade, deep STS that is greater than 5 cm as adjuvant or neoadjuvant treatment, but they acknowledge no consensus on its role, given the conflicting results of available studies.[17] In uterine leiomyosarcomas, the value of adjuvant chemotherapy also is said to be undetermined.

In brief, clinical practice guidelines must take into account that some evidence was provided on the potential value of adjuvant chemotherapy in STS but that this evidence is insufficient to make chemotherapy standard practice. Thus, a clinical decision shared with the patient to resort to adjuvant chemotherapy in the presence of a high risk of relapse is fully justified according to current consensus recommendations, provided that the patient is aware that it is not standard treatment.

ISSUES

Available studies mainly refer to the most typical presentations, that is, limb and superficial trunk STS. Their results are conflicting, and uncertainty has not been settled, but at least they can help by providing direct evidence. In clinical practice, one may be challenged by patients with STS who fall outside the average STS patient. In general, the primary site can be regarded as a minor source of discrepancy for the efficacy of systemic therapy, because there is no major reason, ultimately, why the same histology should benefit differently depending on the primary site. Sometimes, an atypical site entails an additional risk of relapse. For example, a pleural synovial sarcoma is likely to entail a higher risk than a limb synovial sarcoma because of the additional locoregional risk of pleural spread. Thus, one may estimate that an additional reason for selecting adjuvant chemotherapy is in place. It goes without saying that the reverse may be true as well; that is, the additional risk is even less likely to be covered by available adjuvant treatments.

Some rare histologies may pose further uncertainty, because their behavior may be less known and, most important, their chemotherapy sensitivity may deviate from that of average STS. Indeed, some histologies (e.g., epithelioid sarcoma, or alveolar soft part sarcoma) are less sensitive to standard chemotherapy for STS, and this may be a good reason to refrain from using adjuvant chemotherapy for them, when the lack of any tumor lesion prevents one from the opportunity to check tumor response (i.e., tumor sensitivity). In these cases, delaying chemotherapy to the time of relapse may be a reasonable choice, though the pursued effect of chemotherapy as an adjuvant would be different by definition. Sometimes, these histologies are less sensitive to anthracyclines plus ifosfamide but may be sensitive to other agents (e.g., leiomyosarcoma is less sensitive to ifosfamide and more sensitive to dacarbazine). In these cases, one may try to personalize the choice of the medical therapy. Of course, this adds to the uncertainty of adjuvant chemotherapy in STS, and the patient needs to be informed accordingly within a deeply shared decision-making process. In general, because the approach to the medical therapy of STS is increasingly histology driven, the assessment of whether an histology-driven approach to the adjuvant therapy of STS may improve its effectiveness is a priority for clinical research. However, when single histologies are considered, the number of eligible patients for clinical studies further diminishes, and conventional statistics faces major challenges.

With regard to the regimen choice in the adjuvant setting, aside from the possible role of histology-driven options, full-dose anthracycline-plus-ifosfamide combinations should be regarded as standard. Certainly, this conclusion may be challenged by the unclear superiority of the combination of these two drugs over single-agent doxorubicin in advanced disease, as recently suggested by a randomized trial.[18] How-

ever, this trial showed a clear superiority of the combination in terms of antitumor activity (response rate and progression-free survival). Thus, it is logical to resort to most active regimens in the adjuvant setting, aside from their superiority in terms of survival in the setting of advanced disease. Therefore, if the decision is made to use adjuvant chemotherapy in the single patient, in the absence of a personalized choice in favor of an histology-driven regimen, a full-dose combination of an anthracycline and ifosfamide can be regarded as the most logical selection today. In many institutions, this means doses of doxorubicin in the range of 60 to 75 mg/m^2, or equivalents, plus ifosfamide in the range of 6,000 to 7,500 mg/m^2.

CONCLUSION

The rarity and the heterogeneity of STS have been formidable obstacles to generating reliable evidence in favor of or against adjuvant and neoadjuvant chemotherapy. Available data are consistent with a limited degree of effectiveness, but a lack of benefit cannot be ruled out. In fact, several institutions worldwide propose systemic therapy to selected patients with STS in a shared decision-making process in conditions of uncertainty.

Eligible patients are those with a high risk of relapse, which largely is dictated by the malignancy grade and the clinical presentation. There are some rare histologies that are poorly sensitive to chemotherapy: in patients who have these histologies, adjuvant chemotherapy usually is not proposed, even when the risk would be high enough to justify adjuvant treatment, if available.

There is some evidence that systemic therapy may be placed before or after surgery with similar results, with the obvious advantage for preoperative chemotherapy to exert a local effect, which sometimes may be beneficial for the qual-ity of surgical margins. Chemotherapy may be combined with radiation therapy preoperatively so that the local effect is maximized. Evidence provided by one randomized trial would support a short course of three cycles of chemotherapy, which clearly is more acceptable for decision making in a setting of so much uncertainty over its efficacy.

Overall, chemotherapy has a limited antitumor activity in STS. Although this explains the difficulty in finding any major effect of adjuvant chemotherapy, it is clear that systemic therapy is undergoing improvements in STS. A major way forward seems to lie in histology-driven approaches. Thus, an ongoing, randomized trial is comparing three cycles of full-dose epirubicin plus ifosfamide with three cycles of an histology-driven chemotherapy regimen (i.e., gemcitabine plus dacarbazine in leiomyosarcoma; trabectedin in myxoid liposarcoma; high-dose continuous-infusion ifosfamide in synovial sarcoma; ifosfamide plus etoposide in malignant peripheral nerve sheath tumors; gemcitabine plus docetaxel in pleomorphic sarcomas). Likewise, an above-mentioned randomized trial that is ongoing in uterine leiomyosarcoma is histology-driven. In principle, molecularly targeted agents shown to be active in STS might be tested in the adjuvant setting, though they face all of the limitations that targeted therapy may encounter in solid tumors when used as an adjuvant, as demonstrated with gastrointestinal stromal tumors.[19,20]

Thus, there is room to test the effectiveness of more variegated medical therapies in the adjuvant treatment of STS, but standard practice continues to face a high degree of uncertainty. All the rules of rational decision making in conditions of uncertainty should be exploited while we look forward to the implementation of new methods for clinical studies in rare cancers.[21]

Adjuvant Radiation for Soft Tissue Sarcomas

Colleen I. Dickie, MSc, Rick Haas, MD, PhD, and Brian O'Sullivan, MD, FRCPC

OVERVIEW

Over recent decades, limb-preservation surgery in combination with radiotherapy achieves local control rates exceeding 90% for extremity soft tissue sarcoma (STS). Local control is not as successful for retroperitoneal sarcoma (approximately 60%) despite aggressive surgical approaches including en bloc resection of uninvolved adjacent organs combined with intensity modulated radiotherapy (IMRT). This review will discuss the indications for adjuvant radiation therapy (RT) for primary presentation of soft tissue sarcoma: "What," referring to the type and manner of planning and delivery of RT; "When," referring to the timing and scheduling of RT; and "Why," referring to the rationale for the use of RT will be addressed. From a practical stand point, this Educational Chapter on "adjuvant RT" will focus on pre- and postoperative RT in the context of gross total resection for extremity and retroperitoneal soft tissue sarcoma, the two most frequent paradigms for the use of adjuvant RT.

Various types of RT can be used in the treatment of STS and require attention to the application of appropriate principles for their implementation. Especially important are issues surrounding the choice of target volumes, the treatment of normal anatomy termed "organs at risk," and processes to ensure reliability in treatment delivery. Most experience in adjuvant RT of STS is based on external beam radiotherapy (EBRT). Nevertheless, other modalities exist including brachytherapy, intraoperative RT, and hadrons (i.e., protons and carbon ions).

TYPES AND METHODS OF RADIOTHERAPY DELIVERY: THE "WHAT" COMPONENT
Intensity Modulated Radiotherapy

Target coverage and protection of normal tissues appear to be superior for IMRT compared with traditional techniques in extremity STS (ESTS).[1,2] A recent retrospective review spanning noncoincident treatment time periods compared surgery combined with either IMRT (165 patients) or conventional EBRT (154 patients). Allowing for known limitations associated with studies involving treatments deployed over different eras, IMRT demonstrated significantly reduced local recurrence (LR) for primary ESTS (7.6% LR for IMRT vs. 15.1% LR for conventional RT; p = 0.02).[3]

Two recently completed prospective phase II trials, from Princess Margaret (NCT00188175) and the Radiation Therapy Oncology Group (RTOG 0630; NCT00589121), investigated if preoperative image-guided radiotherapy (IGRT) using conformal RT/IMRT can reduce RT related morbidities. The characteristics of the Princess Margaret Hospital (PMH) and RTOG 0630 trials are not identical in several ways and are contrasted (Table 1).[4,5]

The PMH trial showed less wound healing complication rates (30.5%) in lower extremity compared with the 43% risk in the previous Canadian Sarcoma Group NCIC SR2 trial that only used two-dimensional and three-dimensional RT.[6] The need for tissue transfer, RT chronic morbidities, and subsequent secondary operations for wound complications was reduced while maintaining good function and local control (93.2%). The recently published results of the RTOG-0630 trial reported a significant reduction of late toxicities compared with the NCIC-SR2 trial (10.5% vs. 37% in SR2), which is very similar to the IGRT PMH trial. Importantly, both trials defined the clinical target volume (CTV) differently (longitudinal margin of 3 cm from the gross tumor for high-grade lesions and 2 cm for low-grade lesions vs. 4 cm longitudinal margins in the PMH trial). Potentially, the reduction in CTV margins of this degree could explain the improvement in limb function with comparable local control, although, an alternative possibility is the reduction in normal tissues receiving the target dose in all dimensions that is shared by both studies.

Brachytherapy

Brachytherapy has several theoretical advantages. With appropriate selection, local dose intensification to target structures with surrounding normal tissue protection is feasible. The treatment time is shorter, theoretically limiting tumor

TABLE 1. Difference between Two Prospective IMRT Trials for Extremity Soft Tissue Sarcoma

Characteristic	RTOG 0630[4]	PMH[5]
Technique	3D conformal or IMRT	IMRT alone
Anatomic Site	Upper and lower extremity	Lower extremity only
Chemotherapy	Cohort A received induction chemotherapy plus RT (50 Gy) and concurrent chemotherapy wiht RT (44 Gy). Cohort B did not receive chemotherapy.	No chemotherapy
Postoperative Boost- R2 Surgical Margins	EBRT or BRT (LDR, HDR, IORT)	No postoperative boost
Primary End Point	Reduction of late morbidity at 2 years by RTOG/EORTC criteria ($\geq$ grade 2 lymphedema, subcutaneous fibrosis, joint stiffness)	Reduction of wound complications by the NCIC SR2 criteria at 120 days
Secondary Endpoints	Similar between both studies	Similar between both studies
Target Definitions	CTV: 3 cm longitudinal; 1.5 cm radial for high-grade lesions,	CTV: 4 cm longitudinal; 1.5 cm radial
	2 cm longitudinal; 1.0 cm radial for low-grade lesions	Surgical resection site contoured as an avoidance organ

Abbreviations: IGRT, image guided radiotherapy; RTOG, Radiation Therapy Oncology Group; PMH, Princess Margaret Hospital; 3D, 3-dimensional; IMRT, intensity modulated radiotherapy; RT, radiotherapy; EBRT, external beam radiotherapy; BRT, brachytherapy; LDR, low dose rate; HDR, high dose rate; IORT, intraoperative radiotherapy; EORTC, European Organisation for Research and Treatment of Cancer; CTV, clinical target volume; NCIC SR2, National Cancer Institute of Canada SR2 trial.

cell repopulation. Moreover, brachytherapy permits radiation volumes to be mapped according to intraoperative findings. The American Brachytherapy Society Guidelines differ from those for EBRT and also advise that brachytherapy as a sole treatment modality is contraindicated in the following situations: (1) the CTV cannot be adequately encompassed by the implant geometry, (2) the proximity of critical anatomy, such as neurovascular structures, is anticipated to interfere with meaningful dose administration, (3) the surgical resection margins are positive, and (4) there is skin involved by tumor.

> ## KEY POINTS
>
> · Trials investigating adjuvant radiotherapy for extremity soft tissue sarcoma have demonstrated a substantial benefit in local disease control for high-grade, deep seated, large tumors with control in excess of 90%.
> · A paucity of clinical trial evidence for retroperitoneal sarcoma is available. The preoperative radiotherapy approach is associated with favorable local control and overall survival with low treatment related toxicity rates.
> · Pre- and postoperative radiotherapy prospective trials questioning historic clinical target volume concepts have been completed and results are anticipated.
> · Toxicity profiles associated with the timing of radiotherapy must be considered for the individual patient and in the decision algorithm for the different approaches and types of adjuvant radiotherapy, including brachytherapy, external beam, intraoperative radiation therapy, and particle treatment.
> · Emerging evidence from prospective intensity-modulated radiation therapy trials and retrospective series demonstrate comparable local disease control with reduced acute and late morbidities including wound complication rates, limb edema, fibrosis, joint stiffness, and bone fracture incidence.

A randomized trial of 164 patients reported from Memorial Sloan Kettering Cancer Center evaluated adjuvant brachytherapy versus surgery alone and showed 10-year actuarial local control rates of 81% in the brachytherapy group and 67% in the nonbrachytherapy group (p = 0.03).[7] This improvement in local control was limited to histologically high-grade tumors without effect on low-grade lesions, which remains a matter of conjecture and uncertainty. Brachytherapy also seems less useful where implant geometry is not optimal, such as in the upper extremity or more proximal limb regions.[8] In addition, brachytherapy has been compared retrospectively with IMRT in 134 high-grade early STS[9] with similar adverse features. The 5-year local control rate was 92% for IMRT compared with 81% for brachytherapy (p = 0.04). Unfortunately, although the results of brachytherapy, including its more restrictive criteria for use, suggest lower efficacy compared with EBRT, there is no randomized, controlled trial comparing these seemingly effective local adjuvants.

Traditional brachytherapy studies, including those mentioned above, used low-dose rate techniques. High dose-rate brachytherapy has potential logistic advantages including lower radiation staff exposure, outpatient delivery, and optimized dose distributions by varying dwell times. However, wound healing complications may occur in sarcoma management and caution is also recommended when placing catheters adjacent to neurovascular structures. As yet, no large series evaluating high-dose rate brachytherapy for STS is available, nor has it been directly compared with low-dose rate, partly because of technical differences.

Particle Therapy
Emerging approaches using hadrons have putative efficacy advantages over conventional photon therapy because of their physical and radiobiologic properties. However, their

use has generally been restricted to the management of bone tumors, pediatric sarcomas, and especially skull-base and spinal lesions. Protons, intensity-modulated, and/or intraoperative electron RT targeting areas of anatomic attachment in retroperitoneal sarcoma combined with aggressive anterior surgical resection has been reported and may minimize radiation-related morbidity and reduce local recurrence, especially in patients with primary disease.[10] Further progress is awaited included the use of hadron therapies in other sarcoma sites.

Altered Fractionation

Altered fractionation can deliver doses in a shorter time period, often using higher than normal doses per fraction, or smaller than usual dose fractions more than once daily as a protracted course.

Preoperative hypofractionated RT for extremity and trunk wall STS was recently evaluated in a series of 272 patients. RT was delivered preoperatively for five consecutive days in 5 Gy per fraction. The local recurrence rate was higher (19.1%) with the hypofractionated schedule compared with many contemporary series.[11] Longer follow-up of this novel strategy is warranted.

A contrasting strategy used twice daily 1.2 Gy fractions to a total dose of 50.4 Gy in predominantly high-grade, large tumors, to exploit smaller dose per fractions in mitigating local toxicity.[12] The local control rate was 91%, with a wound complication rate of 16%, and bone fracture rate of 7.7% in an era (1978 to 1987) before IMRT or conformal techniques.

Neither hyperfractionation nor hypofractionation are likely to replace conventional daily fractionation in the short term for a combination of reasons that include the small nonrandomized nature of studies, resources needed for some protocols, concerns about efficacy and toxicity, and the fact that modern targeting techniques with IMRT may offset some of the potential benefits that underpin the choice of altered fractionation protocols.

Intraoperative Radiotherapy

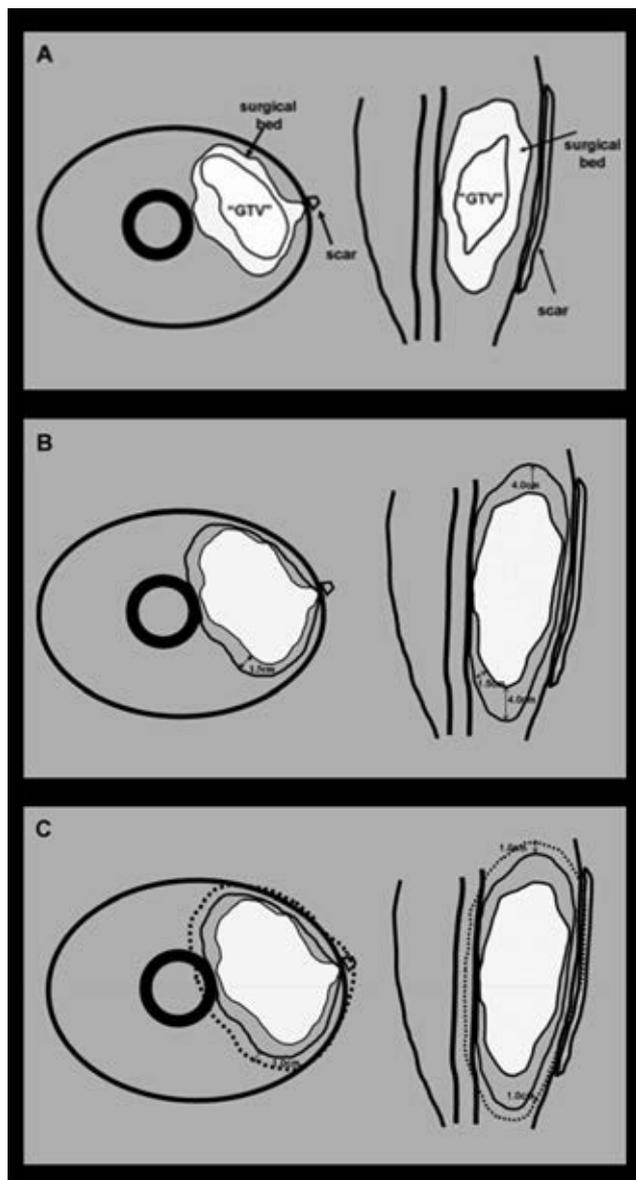
Intraoperative radiotherapy (IORT) or intraoperative electron radiotherapy (IOERT) refer to the delivery of RT, including electrons, to a targeted region while the area is exposed during surgery. Most experience has been in combination with fractionated EBRT. A small subgroup (34 patients) analysis of a prospective phase II trial of IOERT, etoposide, ifosfamide and doxorubicin, and postoperative EBRT in high-grade extremity STS suggested excellent local control and overall survival (97% and 79%),[13] though superiority to large series receiving conventional EBRT is not obvious.

Interest in IORT originated in retroperitoneal sarcomas (RPS) as a result of its challenging anatomic nature. As discussed later (see Rationale for the Use of RT), an early report was a randomized trial at the National Cancer Institute that used postoperative EBRT.[14] Later the strategy evolved to combinations with preoperative EBRT as a result of toxicity imperatives. The Massachusetts General Hospital reported the long-term results of IOERT following preoperative external beam therapy (median dose of 45 Gy) and gross total resection for RPS in a selected subgroup (16 patients) receiving 10 Gy to 20 Gy of IOERT (83% local control and 74% OS) compared with no IOERT (61% local control and 30% OS). Complications in four patients included hydronephrosis, neuropathy, vaginal fistula, and uretero-arterial fistula.[15] Notably, a small number of patients were excluded because of tumor progression (two patients), partial resection (four patients), or for unresectable disease secondary to sarcomatosis (two patients). This underscores the need for prospective trials with intention-to-treat, and preferably addressing questions through randomization. The Mayo Clinic used a similar approach and also considered local control to be improved.[16] These studies were not randomized, and potentially more favorable lesions may have been chosen for IORT so that its true contribution remains unclear. In addition, although early interest appeared to focus on the potential contribution of IORT, they were also characterized by the use of preoperative EBRT which may have contributed at least as much as IORT to the apparently favorable results compared with historic series. Moreover, the likely contribution of improved surgical approaches and imaging techniques in guiding decisions and treatment may also have contributed to apparently improved outcomes. Like the efficacy results, the early toxicity results were also difficult to interpret when trying to unravel separate effects of IORT compared with preoperative RT in these retrospective series. Eventually, prospective trials discussed later (see Timing and Scheduling of Radiotherapy) became available with evidence that preoperative EBRT alone is very well tolerated acutely and led to the development of an important ongoing randomized trial (STRASS; NCT01344018) addressing the efficacy issue by comparing preoperative EBRT against surgery alone in RPS (see later discussion in Rationale for the Use of RT).

METHOD OF DELIVERY
RT Dose and Volume Definition

The most traditional method of delivering adjuvant RT is postoperatively. Guidelines have been published on how to address the technical design of the radiation volumes.[17]

Traditionally, the surgical bed is irradiated to a dose of 45 to 50.4 Gy in 1.8 to 2.0 Gy once daily fractions followed by a smaller boost volume to the tumor bed (phase II). For the latter, typically doses of 10 to 16 Gy are subsequently applied, resulting in a total dose of 60 to 66 Gy. The surgical bed is expanded with a 1.5-cm radial margin and a 4-cm craniocaudal margin to encompass microscopic disease in the surrounding tissues; the boost is applied to the original sarcoma localization with a 1.5-cm radial margin and a 2-cm craniocaudal margin (Figs. 1 and 2).

FIGURE 1. Schematic Descriptions of Target Definitions for Postoperative RT


(A) Patient to receive postoperative RT. Both original sarcoma extensions (gross tumor volume [GTV]) visualized, as well as surrounding surgical bed. (B) Margins for postoperative RT elective clinical target volume (CTV) are shown; these margins were 1.5 cm in transverse plane onto, but constrained at, surfaces of bones and fascia, unless involved with tumor at surgery. Note, elective CTV remains inside the skin. Furthermore, the elective CTV is longer than the marker of the skin scar. If 4 cm expansion of reconstructed surgical volume in longitudinal direction is shorter than surgical scar, elective CTV will need to be expanded to include the surgical scar. (C) Expansion of 1 cm in all directions to produce postoperative elective planning target volume (PTV), although PTV can vary by local institutional protocols, as described in text.

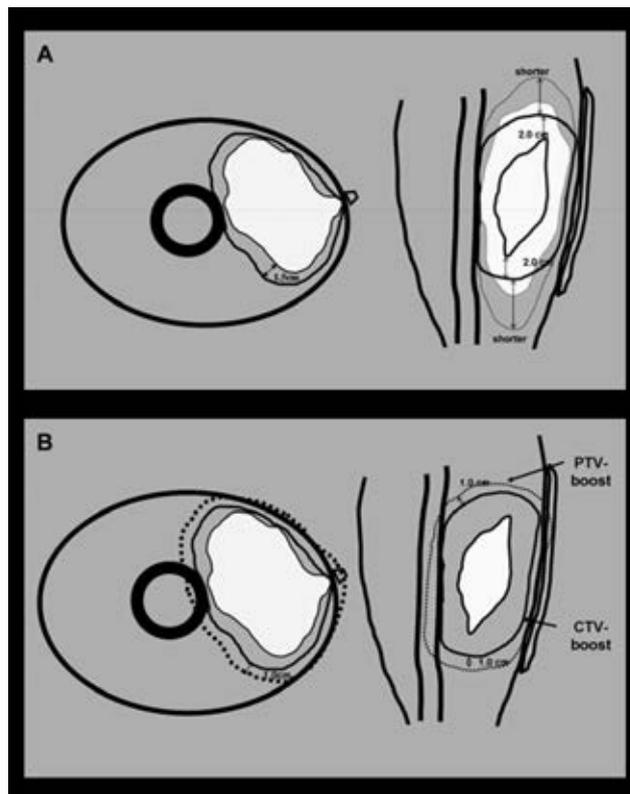
In preoperative RT, historically more recent but potentially the most prevalent approach used today, the gross tumor (GTV) is treated to a dose of 50 Gy in 25 fractions over 5 weeks with surgery following 4 to 6 weeks later. In general, the clinical target volume (CTV) encompasses the GTV with a 4-cm cranio-caudal and a 1.5-cm to 2.0-cm radial margin for microscopic disease coverage (Fig. 3). CTV should also

FIGURE 2. Schematic Descriptions of Target Definitions for Postoperative RT Boost


Postoperative boost clinical target volume (CTV) was the same volume as the postoperative elective CTV, except cranio-caudally. (A) In the longitudinal direction, elective CTV is 2 cm longer on both sides than the reconstructed sarcoma GTV before surgery. (B) Expansion of 1 cm in all directions of boost CTV to produce boost PTV, although PTV can vary by local institutional protocols, as described in text.

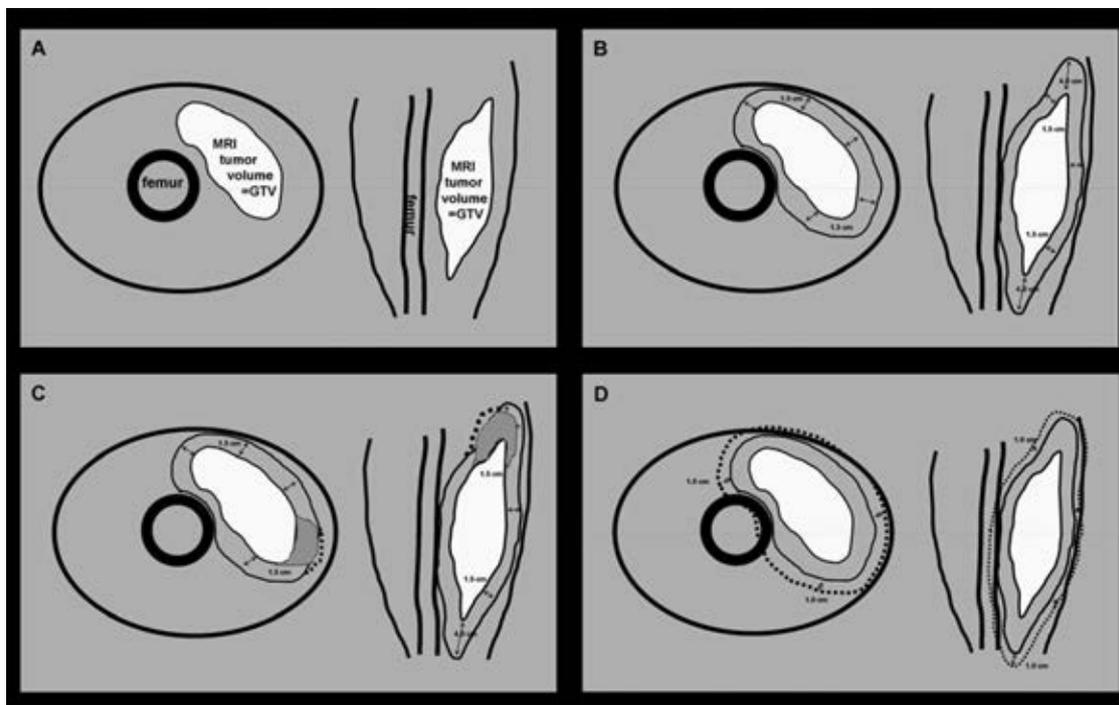
include peritumoral edema since it may harbor tumor cells at some distance from the GTV.[18]

The defined external beam volumes for extremity STS reflect those of the prospective Canadian Sarcoma Group randomized clinical trial.[6] However, the recently completed postoperative U.K. phase III randomized VORTEX trial (NCT00423618) compared a 5-cm longitudinal margin from GTV in the standard arm to a 2-cm margin and results are awaited. The completed RTOG-0630 trial (NCT00589121) mentioned earlier defined slightly smaller preoperative RT volumes (longitudinal 3 cm), although its results may be less easily interpreted because of its nonrandomized nature. In any event, the size of the RT volume margins is not appreciably smaller than the 4-cm longitudinal margin noted above.

For RPS RT volumes, a CTV margin of 1.5 to 2.0 cm could be considered but may be reduced to protect vital radiosensitive anatomy. A typical dose of 45 to 50.4 Gy is given in 1.8 to 2.0 Gy fractions. When evaluating patients for RT planning, the functional capacity of the liver and differential function of the kidneys is paramount, as they may need to be resected or irradiated. A study that evaluated the spatial and volumetric changes of RPS during preoperative RT also as-

FIGURE 3. Schematic Descriptions of Target Definitions for Preoperative RT


(A) Patient to be treated with preoperative RT. Sarcoma delineated using T1-weighted, postgadolinium MRI scan fused to planning CT scan. This gross tumor volume (GTV) does not include peritumoral edema, generally best seen on T2-weighted MRI scan. (B) GTV transversely expanded with 1.5 cm, but constrained at surfaces of fascia and bones, unless invaded. Longitudinally, expansion was 4 cm. Note, this was a sarcoma case without peritumoral edema. (C) Sarcoma case with peritumoral edema, with GTV also transversely expanded with 1.5 cm and constrained at surfaces of fascia and bones, unless invaded. Longitudinally, expansion was 4 cm. Note, CTV has been manually edited (bold dashed line) to encompass edema zone in both transverse and coronal planes. Peritumoral edema indicated by striped zone. (D) Delineation of final preoperative planning target volume (PTV) by expansion of CTV with 1 cm in all directions, although PTV can vary by local institutional protocols, as described in text.

sessed target volume coverage during inter- and intrafractional breathing.[19] Four-dimensional CT simulation and planning was suggested for superiorly located tumors (GTV centroid above the L2/3 junction) to account for respiratory motion most pronounced in the superior to inferior dimension (maximum of 14 mm).

Features of RT Planning and Delivery

Techniques such as IMRT, brachytherapy, and particle therapies, or a combination of techniques (i.e., brachytherapy combined with EBRT), are able to tailor the dose distribution to avoid vulnerable normal tissue structures with superior coverage of the CTV, even where vital anatomy is juxtaposed.

In a study of 363 patients with extremity STS treated with EBRT and surgery, a dose-related fracture rate was apparent with a median of 50 months of follow-up. Radiation induced fractures were identified in 27 patients (crude fracture risk of 6.3%), 20 of whom received 60 to 66 Gy (fracture rate, 10%), and three received 50 Gy (2% risk).[20] A separate retrospective dosimetric review of bone fractures (that occurred in 21 patients) was compared with a random sample without fractures (53 patients) to determine fracture risk factors. Bone fracture risk was reduced if the volume of irradiated bone to

40 Gy or greater was less than 64%, the mean bone dose was less than 37 Gy, or the maximum dose along the bone length of bone was less than 59 Gy.[21] This study provides evidence-based dose volume bone avoidance objectives for RT planning, which was further investigated in additional patients (176 patients with lower and 54 patients with upper extremity STS) with a median follow-up of 41.2 months.[22] The overall risk of fracture was 1.7% (four out of 230 patients), which compares favorably to the previous reported incidence of 6.3%, and suggests that efforts to achieve bone avoidance are meritorious.

Quality Assurance of Dosimetry

In addition to employing evidence-based dose volume objectives for optimal RT planning, preoperative RT also requires additional considerations. As previously discussed (see RT Dose and Volume Definition), volumetric changes occur during preoperative RT in RPS suggesting that imaged-guided tracking of GTV size and position may improve preoperative RT quality and prompt replanning.[19] Similarly, volume changes in extremity STS occur during preoperative RT[23] and adaptive RT may need to account for these changes. A 1 cm tumor volume change on imaging is a reliable threshold to identify potential GTV underdosage for increasing tumor volumes during extremity

STS IMRT, indicating the need for reliable on-board imaging to detect target volume changes.[24]

TIMING AND SCHEDULING OF RADIOTHERAPY: THE "WHEN" COMPONENT

The two most common methods of EBRT delivery are preoperatively or postoperatively. Postoperative delivery is associated with increased limb fibrosis, edema, joint stiffness, and bone fractures. Preoperative RT results in an increased rate of acute wound complications.[6]

Several studies have reported the late morbidities following pre- and postoperative RT in extremity STS. Long-term follow-up of patients treated in the Canadian Sarcoma Group NCIC trial (SR2) showed that, of 129 patients evaluable for late toxicity, 48.2% in the postoperative group compared with 31.5% in the preoperative group had grade 2 or greater fibrosis (p = 0.07).[25] Edema was more frequently seen in the postoperative group (23.2% vs. 15.5%), as was joint stiffness (23.2% vs. 17.8%). Patients with these complications had lower function scores (all p values < 0.01) on the Toronto Extremity Salvage Score and the Musculoskeletal Tumor Society Rating Scale. Field size predicted greater rates of fibrosis (p = 0.002) and joint stiffness (p = 0.006), and marginally predicted edema (p = 0.06). Acute wound healing complications were twice as common with preoperative compared with postoperative RT. The increased risk was almost entirely confined to the lower extremity (43% associated with preoperative vs. 21% with postoperative timing; p = 0.01).

The influence of time interval between preoperative EBRT and surgery on the development of wound complications in extremity sarcoma has been studied. Although the interval had little influence, the data still suggest that the optimal interval to reduce potential wound complications was 4 or 5 weeks between RT and surgery.[26]

Although toxicity is a known accompaniment of the combination of EBRT and surgery, these problems and considerations do not preclude the use of RT in the management of ESTS. In fact, the gain in local control is at least as large as the benefit of adjuvant RT in breast conserving therapy for invasive breast cancers.[27] Furthermore, for high-grade sarcomas, a survival benefit has been suggested.[28]

Whether a radiation therapy boost is needed following preoperative RT and surgery with positive resection margins has been questioned in a retrospective review of 216 patients with ESTS; 52 received preoperative RT (50 Gy) alone and were compared with 41 who received preoperative RT with a postoperative boost (generally 16 Gy). A portion of the population did not receive radiotherapy at all, or received post-operative RT and were excluded (123 of 216 patients). Patients who received the postoperative boost had lower 5-year local recurrence-free rates (73.8% vs. 90.4% for preoperative RT only), indicating that the postoperative boost provides no obvious advantage.[29] A similar study of 67 patients yielded almost identical results.[30] These results suggest that a benefit from a delayed postoperative boost following preoperative RT and surgery is at best debatable, and the increased risk and challenges of managing later RT morbidity (e.g., radiation-induced fractures) resulting from the higher radiation doses involved should be considered.

Finally, preoperative EBRT may be particularly suited to the management of RPS. Its potential role was mentioned briefly in the discussion of IORT because of the way these approaches evolved. Radiotherapy delivered to an in situ tumor has the advantages of treating a well-defined and undisturbed tumor volume where the tumor also acts as a tissue-expander to displace small bowel and other radio-sensitive viscera from the radiation volume. Preoperative external beam radiotherapy for RPS was associated with minimal acute toxicity in two prospective clinical trials from the Princess Margaret Hospital and The University of Texas MD Anderson Cancer Center[31,32] with no increase in wound healing complications. Long-term follow-up of both trials combined indicated that preoperative radiotherapy may be associated with favorable local control and overall survival.[33] This has been further addressed in the very long-term follow-up of the PMH study.[34]

The minimal early toxicity reports of preoperative EBRT were further confirmed in an additional trial where only one of 20 patients experienced gastrointestinal toxicity of grade 2 or greater and one additional patient experienced leucopenia during the EBRT phase.[35] Additional toxicity manifesting later[35,36] included a 33% severe postoperative complication rate and may relate to the subsequent IORT phase. This underlines the importance of prospective data collection in addressing complex toxicity reporting from sequential phases of adjuvant local therapy that is difficult to interpret in retrospective studies such as those reported earlier from the Mayo Clinic and MGH.[15,16] In such retrospective studies where toxicity is reported remotely (often years later), only aggregated toxicities can realistically be reported, since differential toxicities from separate treatments are generally neither defined nor attributed distinctly at the time of occurrence.

RATIONALE FOR THE USE OF RT: THE "WHY" COMPONENT
Adjuvant Radiotherapy

Even in large, deep seated, intermediate- to high-grade sarcomas, the combination of limb sparing surgery with RT permits more conservative surgical resections and results in high local control results of approximately 90%.[6,17] The gain should be balanced against the costs. The scope of this domain is broad and includes RT treatment planning and delivery, patient expenses including travel and work leave, and the cost to health care when managing acute and late radiation-induced morbidities.

To fully appreciate the role of RT in STS, it is also informative to reflect on the outcome in randomized trials of patients in whom RT was either not applied or was of only moderate

dose intensity for the given circumstance (e.g., the RPS setting for the Sindelar trial outlined later).

Rosenberg et al randomly assigned patients to either receive an amputation (16 patients) or limb-sparing surgery plus adjuvant RT (27 patients). There were no local recurrences in the amputation group, but four in the limb-sparing group (local control 85% vs. 100%, p = 0.06), with no difference in overall survival.[37]

Two subsequent trials compared conservative surgery alone with similar surgery combined with adjuvant RT in predominantly ESTS. The first study was discussed earlier, and patients were randomly assigned to receive adjuvant brachytherapy or surgery alone (see Types and Method of RT Delivery, Brachytherapy).[7]

Yang et al at the NCI randomly assigned 141 patients to receive postoperative RT or not. They reported that high-grade lesions (present in 91 patients) benefited from adjuvant EBRT (10-year local control rates of 78% vs. 100%; p = 0.03) as did low-grade sarcomas (present in 50 patients; 10-year local control rates of 68% vs. 95%; p = 0.067).[38] The gain in local control by the addition of RT resulted in a substantial and persistent reduction in joint motion. The earlier data was recently confirmed with a median follow-up of 17.9 years.[39]

The high risk of local failure following surgery has made adjuvant RT an attractive option for RPS, but its role remains controversial and there is a paucity of trials available. At the National Cancer Institute, Sindelar et al reported the prospective, randomized trial discussed earlier (see Intraoperative Radiotherapy). In the study, 35 patients with surgically resected RPS were randomly assigned to receive postoperative EBRT (50 to 55 Gy) versus postoperative EBRT (35 to 40 Gy) and IORT (20 Gy). The median follow-up was 8 years. Locoregional recurrence was substantially lower with IORT (40% vs. 80% with external beam alone), but with high toxicity and no survival difference. However, only modest EBRT doses (35 to 40 Gy) delivered postoperatively without IORT resulted in very high recurrence rates.

Withholding Adjuvant Radiotherapy

Although the benefit of adjuvant RT is apparent in phase III trials, guidelines and several published series also recommend withholding RT in subsets of patients. Patients with early-stage disease, including small size, superficial location, and/or low-grade histologic subtypes are candidates. The caveat underpinning the decision is that a resection should be undertaken with oncologically appropriate margins and/or intact fascial planes.[40] Such favorable presentations do not eliminate local recurrences after surgery alone, but the risk is low. For example, in the randomized study from Yang et al, six of 19 low-grade cases experienced local recurrence without RT versus one of 22 with RT (p = 0.067), but other anatomic factors (size and depth) also influence outcome.[38,39] In two other series in which patients were selected not to receive RT based on small size, favorable histology of extremity/trunk STS, and wide margin resections, the

10-year local recurrence rate was 7% to 16.2% for the entire group, and 0% to 10.6% for the subgroup after R0 surgery.[41,42] Nevertheless, recurring cases did not fare worse with respect to disease specific- and overall survival compared with similar patients without local disease recurrence. The decision algorithm includes factors that address the ability to salvage recurrence and the likelihood that metastasis will not develop. Morbidity as a result of recurrent disease management is an additional concern and not readily accounted for.

A published nomogram based on 684 patient clinico-pathologic factors estimated the risk of local recurrence after limb-sparing surgery without postoperative RT.[43] For example, a patient younger than age 50, with a smaller than 5 cm high-grade extremity pleomorphic malignant fibrous histiocytoma resected with negative margins, would have a 3-year local recurrence rate of less than 10%. This patient could undergo surgery alone if the tumor location permits potential limb salvage surgery in the event of subsequent local recurrence. Despite the inherent bias in a retrospective review of this nature, this nomogram shows promise as a clinical tool for assessing the risk of local recurrence and the need for adjuvant therapy with specific attention to whether RT can be omitted.

In the management of RPS, the role of adjuvant RT is much less clearly defined as compared to the treatment of ESTS. A number of large institutional studies[44,45] provide superior results with modern and/or more aggressive surgery alone than were obtained historically, thereby questioning the contribution of RT in this setting. Based upon these considerations, the European Organisation for Research and Treatment of Cancer (EORTC) is currently conducting a phase III, randomized study of preoperative RT plus surgery versus surgery alone for patients with RPS (STRASS Trial; NCT01344018).[46] This is a multi-institutional trial addressing preoperative RT specifically compared with surgery only. We await the results of this important and well-accruing trial that has shown a 54% global recruitment to date and is on target for completion.[46]

CONCLUSION

The local recurrence of ESTS following limb-sparing surgery alone is in the range of 30% to 50%. In contemporary series employing highly conformal RT including IMRT, the addition of pre- or postoperative RT improves local control to approximately 90% or greater with excellent functional outcome. For RPS, the benefit of RT has not yet been proven, but if considered, preoperative RT seems to be the safest process of delivery. An ongoing multi-institutional randomized trial should confirm its role. As experience evolves, including a better understanding of pathology and underlying molecular disease characteristics, as well as imaging modalities, additional strategies should further improve the therapeutic ratio following RT for local control of STS in all anatomic sites.

Systemic Therapy for Osteosarcoma and Ewing Sarcoma

Paul A. Meyers, MD

OVERVIEW

Curative therapy for both osteosarcoma and Ewing sarcoma requires the combination of effective systemic therapy and local control of all macroscopic tumors. Systemic therapy for osteosarcoma consists of multiagent chemotherapy. The most common regimen uses cisplatin, doxorubicin, and high-dose methotrexate. Addition of ifosfamide and etoposide to treatment for patients with poor initial response to therapy does not improve outcome. Addition of interferon to treatment for patients with favorable initial response does not improve outcome. Addition of liposomal muramyl tripeptide to chemotherapy may improve overall survival. Systemic therapy for Ewing sarcoma consists of multiagent chemotherapy including doxorubicin, vincristine, etoposide, and cyclophosphamide and/or ifosfamide. Increased dose intensity of therapy, either by shortening the intervals between cycles of chemotherapy or by increasing doses of chemotherapy, improves outcome. Regimens such as irinotecan/temozolomide or cyclophosphamide/topotecan have shown activity in metastatic recurrent Ewing sarcoma. Trials are ongoing to evaluate the addition of these drugs to existing multiagent regimens in order to test their ability to improve outcome. High-dose systemic therapy with autologous stem cell reconstitution is being tested for patients at high risk for recurrence; definitive results await completion of a prospective randomized trial.

Osteosarcoma and Ewing sarcoma are the two most common primary tumors of the bone seen in children, adolescents, and young adults. Both diseases almost always present with systemic metastasis and attempting to cure them by local measures alone is very unlikely. Successful treatment for both diseases requires the combination of effective systemic therapy and local measures directed at all sites of clinically detectable disease. Substantial progress has been made in the cure rate of these primary bone sarcomas when they present without clinically detectable metastatic disease. Curing patients who present with metastasis is much less likely.

OSTEOSARCOMA

Before the introduction of systemic therapy, cure rates for osteosarcoma were less than 20%, even among patients who presented without clinically detectable metastatic disease.[1] The introduction of multiagent chemotherapy improved the probability for cure to 60% to 70%.[1] There are only four chemotherapy agents with evidence of objective responses in osteosarcoma.[2] Anninga et al summarized the results of single-agent phase II trials of these agents in osteosarcoma, as shown in Table 1.

The reported objective response rates are probably an underestimate of true response, as osteosarcoma tumors can exhibit substantial necrosis following chemotherapy without change in size because of the osteoid matrix produced by the tumor.

Various combinations of the four active agents have been employed in clinical trials for the treatment of osteo-sarcoma—some with the addition of etoposide. Anninga et al summarized all published cohorts of patients with osteosarcoma.[2] Any trial that employed three of the active agents had a better outcome than any trial that employed only two. Trials that used all four active agents did not have outcomes superior to trials that employed any three.

When osteosarcoma is treated before definitive surgery, necrosis in the primary tumor can be assessed at the time of definitive surgical resection and strongly correlates with subsequent event-free survival (EFS) and overall survival.[3] Less necrosis in the primary tumor is associated with a higher probability of recurrence and death. Many trials have employed the strategy of tailoring: altering chemotherapy following definitive surgery to intensify therapy for patients with less necrosis following initial chemotherapy. The European and American Osteosarcoma Study Group (EURAMOS) performed the definitive prospective randomized trial to test the strategy of tailoring therapy.[4] All patients received initial therapy with cisplatin, doxorubicin, and high-dose methotrexate (MAP). Necrosis was assessed in the definitive surgical resection after 10 weeks of initial therapy. Patients with favorable necrosis were randomly selected to receive continuation of MAP and MAP with the addition of interferon-alfa. Patients with less necrosis were randomly selected to receive either continuation of MAP or MAP with the addition of high-dose ifosfamide and etoposide. Chemotherapy with MAP continued for 20 weeks following definitive surgery. The addition of interferon to MAP did not improve the prob-

Drug	Objective Response Rate
Doxorubicin	43%
Ifosfamide	33%
Methotrexate	32%
Cisplatin	26%

ability of EFS for patients with higher necrosis.[5] The addition of high-dose ifosfamide and etoposide to MAP did not improve the probability of EFS for patients with less necrosis.[6] The results of EURAMOS-1 suggest that MAP chemotherapy can be considered a standard approach to the treatment of osteosarcoma.

Substantial preclinical evidence suggests that bisphosphonates might be active against osteosarcoma, and a small pilot study explored the use of pamidronate in combination with MAP chemotherapy for the treatment of osteosarcoma.[7] This was a pilot trial. A larger prospective randomized trial carried out in France determined that the addition of zoledronate to chemotherapy did not improve outcome.[8] There does not appear to be a rationale for pursuing bisphosphonates as part of osteosarecoma thearpy.

Liposomal muramyl tripeptide (MTP) is a derivative of the Bacillus Calmette-Guérin cell wall, which stimulates macrophages to become tumoricidal. Clinical trials of MTP in osteosarcoma have decreased the probability of subsequent metastasis for patients with a first metastatic recurrence of osteosarcoma.[9] A prospective randomized trial of the addition of MTP to chemotherapy for the treatment of osteosarcoma demonstrated a trend toward improved EFS and a statistically significant improvement in overall survival (p = 0.03).[10] MTP is approved for use in combination with chemotherapy in the treatment of localized osteosarcoma for patients age 2 to 30 in the Europe, Mexico, Brazil, Israel, and Turkey. MTP is not approved for use in the United States.

Strategies under clinical investigation in osteosarcoma include the use of denosumab, monoclonal antibody therapy directed against the GD2 antigen, and investigational chemotherapy.

KEY POINTS

- The primary bone sarcomas of young patients require systemic therapy for cure.
- Systemic therapy for osteosarcoma can cure approximately 70% of patients who present with localized disease.
- Cure rates for osteosarcoma have not changed for over 20 years.
- Systemic therapy for Ewing sarcoma can cure approximately 70% of patients who present with localized disease.
- Increased dose intensity of therapy improves the outcome of treatment for Ewing sarcoma.

EWING SARCOMA

Before the introduction of systemic chemotherapy, Ewing sarcoma had a cure rate of less than 10%, even among patients who presented with localized disease.[11] The introduction of systemic chemotherapy improved the outcome for Ewing sarcoma. Treatment with multiagent chemotherapy will achieve long-term EFS for roughly 70% of patients who present without clinically detectable metastatic disease.[12-14] When patients present with lung metastasis, long-term EFS rates are 30% to 50%; when patients present with metastasis to distant bones or bone marrow, EFS is less than 20%.[12]

An intergroup study conducted by the Pediatric Oncology Group and the Children's Cancer Group demonstrated that the addition of ifosfamide and etoposide to cyclophosphamide, doxorubicin, and vincristine significantly improved outcomes for patients with localized Ewing sarcoma.[12] Following this study, the five-drug combination became the preferred background for treatment and for clinical trials in North America. In these trials, chemotherapy was administered as cycles of cyclophosphamide, doxorubicin, and vincristine and cycles of ifosfamide and etoposide. A single-institution study from the Memorial Sloan Kettering Cancer Center (MSKCC) reported a high rate of EFS with the use of very high-dose alkylating agent therapy given over a shorter duration (21 weeks).[15] The Children's Oncology Group (COG) performed a trial in which patients treated with the five-drug combination were randomly selected to receive conventional doses or higher doses of cyclophosphamide.[13] They reported no improvement in outcome with higher-dose cyclophosphamide, but the regimen called for higher doses of cyclophosphamide in only early cycles and did not equal the MSKCC in dose intensity over the duration of treatment. In a subsequent trial, COG studied dose intensification by shortening the interval between cycles of chemotherapy.[14] Administration of the usual five-drug combination every 2 weeks for 28 weeks achieved EFS (p = 0.048), which was statistically superior to the EFS observed with the five-drug combination administered every 3 weeks for 42 weeks. Increasing dose intensification by either increasing the dose of alkylating agents or by shortening the intervals between cycles of chemotherapy has been associated with improved outcome in the treatment of Ewing sarcoma (Table 2).

The demonstration of improved outcome with increased dose intensification for patients with localized Ewing sarcoma led to the concept that even further dose intensification of therapy might improve outcome for patients at higher risk for failure. A very dose-intensive regimen including higher doses of doxorubicin was tried with patients with Ewing sarcoma metastatic at initial presentation.[16] The regimen failed to improve EFS and was associated with a very high rate of secondary leukemia. Administration of chemotherapy in myeloablative doses followed by autologous stem cell reconstitution has been used for patients with Ewing sarcoma metastatic at initial presentation and for patients following

TABLE 2. Chemotherapy Dose Intensification: Planned Doses in mg/m^2/Week

recurrence of Ewing sarcoma. No regimen has conclusively demonstrated benefit for this strategy, and most reports are small series that do not adequately control for selection bias. The European Ewing sarcoma consortium began a trial in 1999 in which all patients received common initial therapy. Patients with lung metastases at initial presentation or patients with poor response to initial therapy were randomly assigned to either continue conventional chemotherapy or undergo consolidation with high-dose therapy and autologous stem cell reconstitution. As of 2014, the results of this study remained blinded because the accrual goals set at study initiation had not been met.

When Ewing sarcoma recurs following initial therapy, the prognosis is extremely poor, with less than 5% of patients remaining alive more than 2 years following recurrence.[17,18] Several chemotherapy regimens have shown activity in relapsed Ewing sarcoma, including cyclophosphamide/topotecan, irinotecan/temozolomide, and gemcitabine/docetaxel.[19-21] COG is conducting a randomized trial of the addition of cyclophosphamide/topotecan to the five-drug background. MSKCC is conducting a trial of the addition of irinotecan/temozolomide to the five-drug background.

Monoclonal antibodies against the insulin-like growth factor 1 receptor (IGF1R) showed activity in recurrent Ewing sarcoma.[22] Unfortunately, most pharmaceutical companies abandoned development of these antibodies because they failed to show activity in common adult cancers, and planned prospective randomized trials of these agents for patients with newly diagnosed Ewing sarcoma could not proceed.

One manufacturer transferred supply to the National Cancer Institute (United States), which became the sponsor for a COG trial studying the addition of a monoclonal antibody against IGF1R to the five-drug background for patients with newly diagnosed Ewing sarcoma metastatic at initial presentation. This trial is ongoing.

Strategies under clinical investigation in Ewing sarcoma include the use of PARP inhibitors as single agents and in combination with chemotherapy, as well as phase I and phase II trials.

Currently available clinical trials for patients with newly diagnosed Ewing sarcoma:

- Combination Chemotherapy in Treating Patients with Nonmetastatic Extracranial Ewing Sarcoma. COG AEWS1031. (www.cancer.gov/clinicaltrials/search/results?protocolsearchid=13732535)
- Combination Chemotherapy with or without Peripheral Stem Cell Transplantation, Radiation Therapy, and/or Surgery in Treating Patients with Ewing's Sarcoma. EURO-EWING-INTERGROUP-EE99. (www.cancer.gov/clinicaltrials/search/results?protocolsearchid=13732535)
- Combination Chemotherapy with or without Ganitumab in Treating Patients with Newly Diagnosed Metastatic Ewing Sarcoma. COG AEWS1221. (www.cancer.gov/clinicaltrials/search/results?protocolsearchid=13732535)
- A Phase II Study of Irinotecan and Temozolomide in Combination with Existing High-Dose Chemotherapy for Patients Newly Diagnosed with Ewing Sarcoma. MSKCC 13–068. (www.mskcc.org/cancer-care/clinical-trials/clinical-trial?keys=Ewing+sarcoma&field_trial_diseases_value=All&phase=All)

The Biology and Management of Cartilaginous Tumors: A Role For Targeting Isocitrate Dehydrogenase

Gabriel Tinoco, MD, Breelyn A. Wilky, MD, Ana Paz-Mejia, MS, Andrew Rosenberg, MD, and Jonathan C. Trent, MD, PhD

OVERVIEW

Chondrosarcomas are rare mesenchymal neoplasms defined by the production of abnormal cartilaginous matrix. Conventional chondrosarcoma is the most common histology. The management of primary conventional chondrosarcoma generally is surgical with the possible addition of radiation therapy. Treatment of conventional chondrosarcoma is problematic in unresectable or metastatic disease because the tumors tend to be resistant to standard sarcoma chemotherapy regimens. Previous attempts at targeted therapy, including inhibitors of Hedgehog signaling, the mTOR pathway, and platelet-derived growth factor receptor (PDGFR) have been largely disappointing. However, heterozygous mutations in isocitrate dehydrogenase (*IDH*) enzymes recently have been identified in chondrogenic neoplasms, with mutations reported in approximately 87% of benign enchondromas, 70% of conventional chondrosarcomas, and 54% of dedifferentiated chondrosarcomas. The normal *IDH* protein continues to produce alpha-ketoglutarate (alpha-KG) whereas the mutant IDH protein converts KG to the oncometabolite 2-hydroxyglutarate (2-HG). Clinical trials of novel IDH inhibitors are ongoing, with evidence of early activity in *IDH*-mutant leukemias. IDH inhibitors show antitumor effects against *IDH*-mutant chondrosarcoma cell lines, supporting the inclusion of patients with chondrosarcoma with IDH mutations on IDH inhibitor clinical trials for solid tumors. Targeting *IDH* mutations may offer hope of a novel antineoplastic strategy not only for patients with chondrosarcomas, but also for other solid tumors with aberrant IDH activity.

Chondrosarcomas constitute a diverse group of neoplasms with varied morphologic features and different clinical behaviors, defined by the production of neoplastic cartilage matrix by the tumor cells.[1] Chondrosarcomas are the second most frequent primary sarcoma arising in bone after osteosarcoma,[2-5] accounting for 20% to 27% of malignant bone neoplasms.[6] They may occur at any age, but typically they are seen more frequently in older adults.[7,8] The clinical behavior is quite variable, with low-grade tumors displaying slow growth and low metastatic potential, to high-grade tumors that can be highly aggressive with the propensity for distant metastases. Because of the avascular matrix and low percentage of dividing cells, most chondrosarcomas are inherently resistant to cytotoxic chemotherapy and are relatively radiation-resistant, with the exception of the mesenchymal subtype.[7] Thus, complete surgical resection with wide margins remains the most critical component of therapy, whenever possible, for patients with primary tumors.[9] Unfortunately, many patients present with inoperable disease at the time of diagnosis or recur with metastatic disease, and more than 10% of recurrent chondrosarcomas are of a higher grade than the original tumor.[7] Current research focuses on improving our understanding of chondrosarcoma biology and identifying new therapeutic approaches, especially for patients in whom curative surgery is not indicated.[10] Our objective in this review is to discuss classification of chondrosarcomas in the setting of standard treatments, and to review novel pathways that may lead to novel therapies in the future.

CLASSIFICATION

Cartilaginous tumors are categorized based on the *WHO Classification of Tumours of Soft Tissue and Bone* (Tables 1 and 2).[11] The importance of expert pathologist review in classification of all sarcomas cannot be overemphasized. These tumors may have overlapping histologic features and often require additional immunohistologic and genetic testing for definitive diagnosis. Various studies have suggested that histologic grade, size, stage, and anatomic location of the lesion are fundamental prognostic features.[12,13] In an analysis of 2,890 patients with chondrosarcoma from the Surveillance, Epidemiology, and End Results (SEER) database, only grade and stage were identified as independent prognostic factors

TABLE 1. Benign Cartilaginous Tumors of Bone

Benign	Molecular Features	Clinical Features
Enchondroma	*IDH1* or *IDH2* mutation	Ollier's disease or Mafucci syndrome; 50% risk of syndromic transformation; pain may herald malignant transformation
Osteochondroma	*EXT1* or *EXT2* deletion or inactivating mutation	Arise in long bones around knee or elbow; risk of fracture; 5% risk of transformation to peripheral conventional chondrosarcoma
Chondroblastoma	*H3F3B* Lys36Met	Arise around the knee or proximal humerus; younger individuals; more common in men; rarely metastasizes
Chondromyxoid Fibroma	*GRM1* gene fusion usually t(1;5)(p13;p13)	Arise in metaphysis of long bones; younger individuals; very rare malignant transformation

for survival.[14] However, as detailed below, histologic subtype is very important in guiding therapy.

Benign Cartilaginous Tumors

Benign cartilaginous tumors commonly are found in children and young adults. Many have a characteristic appearance on radiology films and are not biopsied. Although most tumors can be treated conservatively, enchondromas and osteochondromas have the potential to transform into a higher-grade chondrosarcoma, particularly in the setting of an underlying *IDH* mutation as seen in Ollier's disease and Maffucci syndrome.[15-18] Details of genetic and molecular abnormalities and clinical presentation can be found in Table 1.

Conventional Chondrosarcoma of the Bone

Conventional chondrosarcomas make up approximately 85% of all chondrosarcomas (Table 2). These tumors most commonly arise in the proximal femur, bones of the pelvis, and proximal humerus.[19,20] Clinical symptoms are nonspecific. Pain is the most frequent symptom, occurring in at least 95% of patients. Pathologic fractures are found at the time of diagnosis, affecting 3% to 17% of patients.[6] Conventional chondrosarcomas are divided into three histologic catego-

ries. Central conventional chondrosarcoma (CCC) represents approximately 75% of all chondrosarcomas. These cancers arise within the medullary cavity from previously normal-appearing bone. Although most are thought to arise de novo, as many as 40% of central chondrosarcomas may arise from a preexisting benign cartilage lesion (Table 1), or enchondroma.[7,8,11,21,22] These secondary chondrosarcomas often may be lower-grade with less metastatic involvement.[23] Malignant transformation has been described in patients with Ollier's disease (enchondromatosis) and Maffucci syndrome (enchondromatosis associated with soft-tissue hemangioma).[18] Most cases of chondrosarcoma in Ollier's disease and Maffucci syndrome are linked to *IDH1* or *IDH2* mutations.[24,25] Peripheral conventional chondrosarcoma (PCC) is rarer, occurs in younger patients, and by definition arises in an osteochondroma. PCC also is a tumor that is resistant to chemotherapy and relatively resistant to radiation therapy. A third type of chondrosarcoma is periosteal chondrosarcoma (also known as juxtacortical chondrosarcoma), which arises from the external surface of bone.[26] This tumor accounts for less than 1% of all chondrosarcomas.[14] Interestingly, despite high-grade histology, this subtype has a more favorable prognosis with adequate surgical management.[14,27] It tends to affect slightly younger adults, with slow growing masses arising from long bones, particularly the posterior distal femoral metaphysis or diaphysis.[6]

The other 10 to 15% of all chondrosarcomas are infrequent subtypes, such as dedifferentiated, myxoid, clear cell, and mesenchymal chondrosarcomas.[11,28] Mesenchymal chondrosarcoma is a high-grade malignant bone tumor that is comprised of biphenotypic well-differentiated cartilaginous cells and undifferentiated high-grade small round blue cells. These occur in younger patients, arise in the axial skeleton, and have a high propensity of metastasis at the time of diagnosis. The small round blue cell component of this subtype of chondrosarcoma may respond to conventional chemotherapy regimens used for Ewing sarcoma or rhabdomyosarcoma. Therefore, accurate diagnosis of the precise subtype is critical for appropriate management and best outcomes.

Dedifferentiated Chondrosarcoma

Dedifferentiated chondrosarcoma is an uncommon but aggressive subtype of chondrosarcoma that comprises approximately 10% of all chondrosarcomas.[6,11,14] The disease tends

KEY POINTS

- Treatment recommendations for chondrosarcoma depend heavily on histologic subtype, which predicts sensitivity to chemotherapy and radiation.
- RECIST response rates to anthracycline-containing chemotherapy regimens are less than 20% for the most common conventional and dedifferentiated subtypes.
- Isocitrate dehydrogenase (IDH) enzymes normally catalyze conversion of isocitrate into alpha-ketoglutarate during the citric acid cycle, a function impaired in mutant enzymes.
- Mutated IDH enzymes also possess a unique gain-of-function phenotype that converts alpha-ketoglutarate to an oncometabolite, 2-hydroxyglutarate, not present in normal cells.
- *IDH* mutations have been identified in numerous solid and hematologic cancers, including chondrosarcomas, which have led to ongoing clinical trials of novel IDH1 and IDH2 inhibitors.

TABLE 2. Malignant Cartilaginous Tumors of Bone

Malignant	Molecular Features	Clinical Features
Central Conventional Chondrosarcoma	IDH1 or IDH2 mutation	Most common type (approx. 70%); may arise from enchondroma or Ollier's disease; arises in pelvis, humerus, femur, or ribs; chemotherapy and radiotherapy resistant
Peripheral Conventional Chondrosarcoma	IDH1 or IDH2 mutation	Rare (approx. 10%); always arise from osteochondroma; younger individuals; arise in pelvis or shoulder; chemotherapy and radiotherapy resistant
Periosteal Conventional Chondrosarcoma	Not EXT, possibly Hedgehog pathway activation	Very rare (approx. 1%); younger individuals; distal femur or humerus; prognosis better than other histologies; chemotherapy and radiotherapy resistant
Mesenchymal Chondrosarcoma	HEY1-NCOA2	Very rare (approx. 2%); younger individuals, arise in head/neck, vertebrae, ribs, pelvis; round cell component is chemotherapy and radiotherapy sensitive
Dedifferentiated Chondrosarcoma	IDH1 or IDH2 (50% of cases)	Rare (approx. 10%); arise in conventional chondrosarcoma; older individuals; arise in femur and pelvis; High grade by definition; low response rates to chemotherapy

to affect patients between age 50 and 70, with no particular gender predilection. Clinically, patients present with pain (85% of cases), followed by pathologic fracture (31%) and a soft-tissue mass (29%).[29] The majority of tumors occur centrally in medullary bone usually affecting the pelvis, femur, and humerus.[6,30] Dedifferentiated chondrosarcoma is a high-grade malignant neoplasm usually with the histologic appearance of an osteosarcoma, an undifferentiated high-grade pleomorphic sarcoma or fibrosarcoma that arises in a pre-existing conventional chondrosarcoma.[11,31,32] Unusual histologies, such as squamous cell carcinoma, have been reported.[33] The pathogenesis of dedifferentiated chondrosarcoma remains incompletely understood. It has been postulated that the high-grade noncartilaginous component arises in a long-standing low-grade cartilaginous element.[33,34] Dedifferentiated chondrosarcomas are highly aggressive tumors with a grim prognosis. In a multicenter review of 337 patients, 71 (21%) had metastases at the time of diagnosis with only 10% survival at 2 years.[35] Systemic chemotherapy with poor-prognosis osteosarcoma regimens is often used, but unlike traditional osteosarcoma, response rates to chemotherapy are only 20%.[36] Moreover, therapy with high-dose ifosfamide-containing regimens are slightly superior with 33% survival at 2 years, but only 15% at 5 years.[37]

Mesenchymal Chondrosarcoma

Mesenchymal chondrosarcoma is a rare high-grade malignant cartilaginous tumor that may originate in either bone or soft tissue (dura).[6] These tumors are characterized by a bimorphic cellular pattern that is composed of islands of differentiated cartilage and highly cellular areas that are composed of undifferentiated small round blue cells.[11] Unlike other chondrosarcoma subtypes, the median age at presentation is age 25 and extraosseous tumors are observed.[38] The principal symptoms are pain and swelling. Mesenchymal chondrosarcoma most commonly arise in the craniofacial bones, ribs, ilium, and the vertebrae.[11,39] The meninges are one of the most common sites of extra skeletal involvement.[40] The overall prognosis is poor for conventional chondrosarcomas. Approximately 20% have metastatic disease at diagnosis.[39] Reported 10-year survival rates are 10 to 20%.[41] However, approximately 30% of mesenchymal chondrosarcomas will respond to Ewing sarcoma-type chemotherapy regimens, with evidence of improved survival as a result.[36,38,39]

Clear Cell Chondrosarcoma

Clear cell chondrosarcoma is a rare low-grade subtype of chondrosarcoma that is characterized histologically by bland clear cells in addition to hyaline cartilage.[6,11] Less than 2% of chondrosarcomas are classified as clear cell histology. Men are almost three times more likely to develop clear cell chondrosarcoma than women and most patients are between age 25 and 50.[42] Approximately two-thirds of lesions occur in the humeral or femoral head.[42] Although clear cell chondrosarcomas are low-grade tumors, partial excision or curettage leads to recurrence in at least 70% of the cases, and it should be avoided.[43,44] Local excision commonly is curative. The overall recurrence rate is 16%, and approximately 15% of patients die of the disease. Metastases to the lung, brain, and bones have been reported.[11] These tumors do not respond to chemotherapy or radiation; surgical resection is the only known therapy.

Myxoid Chondrosarcoma

Primary skeletal myxoid chondrosarcoma is a rare neoplasm. It remains unclear whether this constitutes a separate clinicopathologic entity or if it is part of the spectrum of conventional chondrosarcoma with prominent myxoid stroma.[23] Histologically, myxoid chondrosarcoma of bone has similar characteristics to the extraskeletal myxoid chondrosarcoma (EMC), but these are two distinct diagnoses.[45]

Extraskeletal myxoid chondrosarcoma is a malignant soft-tissue tumor characterized by a multinodular architecture, abundant myxoid matrix, and malignant chondroblast-like cells.[11,46,47] Typically, EMC has a characteristic translocation, t(9;22)(q22;q12.2), fusing EWSR1 to NR4A3 (genes formerly termed EWS and CHN, TEC, or NOR1, respectively).[48-51] A small proportion of EMC have a different translocation, t(9;17)(q22;q11.2), which results in a RBP56-NR4A3 fusion gene and neuroendocrine differentiation in some cases.[51] Given that these tumors can arise in the extremities and may mimic chondrosarcoma, this is an instance in which genetic testing for the translocation can affect therapy

greatly. A recent retrospective study showed prolonged overall survival in patients with extraskeletal myxoid chondrosarcoma despite high rates of local and distant recurrence.[52] Although anthracycline chemotherapy has not been effective historically, recent reports of clinical responses from sunitinib are encouraging for patients with metastatic disease.[53]

TREATMENT CONSIDERATIONS

As previously discussed, understanding the histologic subtype and grade of chondrosarcoma is helpful in predicting biologic behavior. However, regardless of subtype, surgical resection remains the cornerstone of therapy with the best potential for cure of primary chondrosarcoma.[9]

Several retrospective studies have shown that wide excision with negative margins is associated with higher event-free survival and overall survival rates for patients with large tumors and pelvic localization, regardless of the histologic grade.[54,55] A meta-analysis published in 2011 showed that in select patients with low-grade, nonpelvic chondrosarcomas, intralesional excision may be used as an alternative to wide excision without affecting outcomes.[56] In general, the recommended approach by the National Comprehensive Cancer Network Guidelines (Bone Sarcoma Version 1.2015) is wide local excision of the chondrosarcoma for any intermediate or high-grade histologies, large tumor size, pelvic locations, and intra-articular or soft-tissue involvement. This should be performed in a high-volume sarcoma center with experienced orthopedic oncologists.

Chondrosarcomas are relatively radiotherapy (RT)-resistant. Currently, there is not enough data to support its routine use in patients with this disease. However, RT may be considered if there is incomplete resection, for palliation of symptoms, in patients with advanced or unresectable tumors, or for mesenchymal chondrosarcoma.[57] In a large series involving 229 patients with chondrosarcomas of the skull base, the combination of proton and photon beam RT resulted in a sustained local control rate in most patients.[58]

The role of chemotherapy in the treatment of patients with chondrosarcoma remains unclear and should be considered on a case-by-case basis. At our center, we generally reserve chemotherapy for dedifferentiated and mesenchymal subtypes for patients with reasonable performance status.

Although the vast majority of patients with recurrent or metastatic chondrosarcoma do not respond to conventional sarcoma chemotherapy regimens, there are anecdotal reports of successful treatment with doxorubicin-based regimens, single-agent ifosfamide or methotrexate.[36,59-61]

The mechanisms contributing to resistant to chemotherapy that are seen in chondrosarcomas are not fully understood. It has been suggested that because of avascular matrix and often a low percentage of dividing cells, these tumors have a poor response to chemotherapy that targets cycling cells.[57] In the case of mesenchymal chondrosarcoma, the majority of the tumor may be composed of well-differentiated chondrosarcoma cells and cartilaginous matrix. Thus, there

may be little shrinkage even when the chemotherapy was efficacious against the small round blue cell component of the biphenotypic tumor cells. It also has been suggested that the expression of P-glycoprotein plays a role in resistance to chemotherapy. P-glycoprotein is encoded by the gene multidrug resistance-1 (*MDR-1*) and is expressed by chondrosarcoma cells.[62] It has been demonstrated that the expression of *MRD-1* in human chondrosarcoma cell lines results in resistance to doxorubicin in vitro.[63]

### Targeted Therapy for Chondrosarcoma

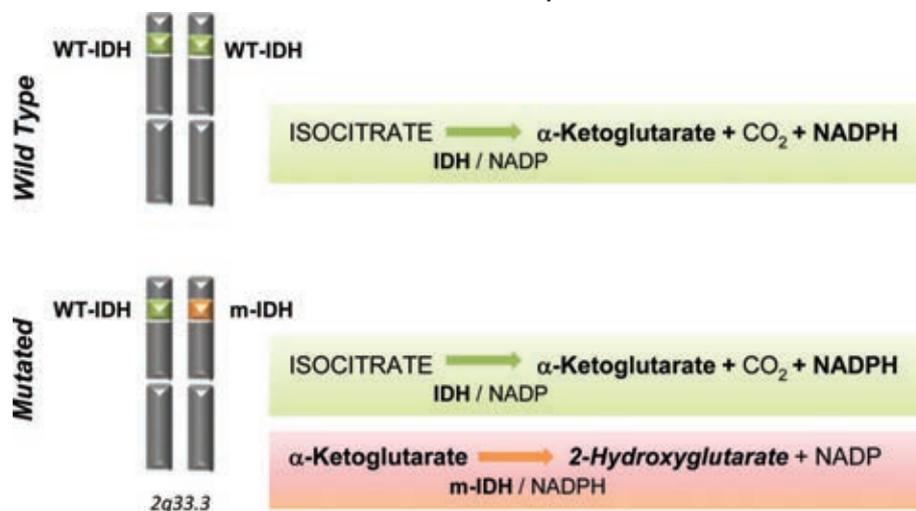
Within the last several years, there has been increased interest in exploring targeted therapies for chondrosarcomas. Our understanding of pathways implicated in chondrosarcomas is reviewed by Samuel et al.[64] As outlined in their work, one can consider the early and late genetic events that lead to the development of chondrosarcomas to design potential pathways that may be amenable to inhibition.

The indian hedgehog (IHH)/parathyroid hormone-related peptide pathway (PTHrP) is critical to chondrocyte maturation and development, and constitutive IHH signaling has been demonstrated in chondrosarcomas. Based on upregulation of intramembrane receptor patched (PTCH) and downstream transcription factors, including GLi, clinical trials were conducted with GDC-0449. Unfortunately, medical progression-free survival was short at 3.5 months and further enrollment on the study was halted.[65]

Another pathway of interest in chondrosarcoma was PI3K/mTOR, based on observations of increased receptor-type tyrosine kinase activity, including high levels of phosphorylated S6 and marked in vitro response to BEZ235, a PI3K/mTOR inhibitor.[66] In a recent retrospective analysis, 10 patients with unresectable recurrent chondrosarcoma received the combination of sirolimus/cyclophosphamide. The chemotherapy was well tolerated and resulted in a disease control rate of 70% (10% of patients had objective response and 60% of patients had stable disease for at least 6 months).[67] Based on these findings, further exploration of mTOR inhibition is warranted.

Activation and/or overexpression of PDGFR-alpha (PDGFRA) and PDGFR-beta (PDGFRB) has been described in conventional chondrosarcomas, but activating mutations have not been found.[68] Unfortunately, trials have failed to show significant clinical activity.[69]

Finally, another mechanism with interesting preclinical results in chondrosarcomas focuses on targeting epigenetic regulatory mechanisms via histone deacetylase inhibitors. Several studies have revealed the key roles played by acetylation or deacetylation in specific gene expressions of chondrocytes.[70,71] Further research revealed that HDAC inhibitors cause a variety of phenotypic changes, such as cell cycle arrest, morphologic reversion of transformed cells, apoptosis, and differentiation.[72,73] Sakimura et al recently reported the inhibition of tumor growth and the induction of differentiation of chondrosarcoma cells using the HDAC inhibitor depsipeptide.[74] Because of the promising results, several HDAC inhibitors currently are being used in clinical trials.

FIGURE 1. The Metabolic Effect of *IDH* Mutation in the Krebs Cycle


The wild-type IDH protein continues to produce alpha-ketoglutarate (KG); however, the mutant IDH protein converts KG to 2-Hydroxyglutarate (2-HG). HG then is able to function as an oncometabolite in chondrosarcomagenesis.

Inhibitors of IDH 1/2 Mutant Proteins

Perhaps the most exciting therapy on the horizon for patients with chondrosarcoma is the development of inhibitors of isocitrate dehydrogenase (IDH) enzymes. Isocitrate dehydrogenase proteins consist of three regulatory enzymes (IDH1, IDH2, and IDH3) that catalyze the $NADP^+$-dependent oxidative decarboxylation of isocitrate (ICT) into alpha-ketoglutarate (alpha-KG) in the Krebs cycle (Fig. 1).[75] IDH1 is found in both peroxisomes and the cytosol,[76,77] whereas IDH2 is a mitochondrial isoform of IDH.[78] The genes encoding IDH1 and IDH2 are located on chromosome 2q33.3[79] and 15q26.1,[80] respectively.

Mutations in the *IDH* family of genes recently have been described in patients with a variety of cancers. The mutation in the *IDH1* gene was first discovered in colorectal cancers.[81] Soon afterwards, somatic mutations affecting *IDH1* or *IDH2* were detected in more than 70% of grade 2 to 3 gliomas and secondary glioblastomas.[82] More recently, alterations in these genes were identified in many other types of cancers, including acute myeloid leukemia, cholangiocarcinomas, and chondrosarcomas.[83,84] Somatic mutations also have been identified in up of 87% of benign enchondromas, up to 70% of primary conventional central chondrosarcomas, and 54% of dedifferentiated chondrosarcomas.[28,85,86]

IDH1/2 mutations are heterozygous and affect a single arginine residue. The mutations in the IDH proteins frequently lead to changes affecting arginine-132 (R132H or R132C) in IDH1[87-89]; arginine-140 (R140Q) is the most common change seen in IDH2.[90] Mutated IDH1 or IDH2 are active catalytic enzymes. However, their mutations cause a reduced capacity to convert ICT to alpha-KG and an acquired ability to convert alpha-KG to delta-2-hydroxyglutarate (2-HG), which is considered an oncometabolite[75,91-94] (Fig. 1). Typically, the alterations in *IDH1* and *IDH2* are mutually exclusive and occur at very early stages of tumor development.[95]

The exact mechanism by which accumulation of 2-HG may lead to tumor formation remains unknown. However, recent publications suggested a possible epigenetic mechanism.[82,96-99] 2-HG inhibits the function of alpha-KG-dependent enzymes such as ten-eleven translocation gene family (*TET*) 2 by competing with alpha-KG.[100] Moreover, experiments using glioma lines showed that 2-HG inhibits both the TET of 5-methylcytosine hydroxylases and the H3K9 demethylase KDM4C, causing global DNA hypermethylation and leading to transcriptional blockages.[96,98] Also, it was recently described that IDH mutations induce a global hypermethylated phenotype that is distinctive of the gliomas with these mutations.[101]

In normal cells, 2-HG is present in low levels. However, IDH1/IDH2 mutations in cancer cells result in excess of production and accumulation of 2-HG.[92,99] Different tumor types, including glioma and acute myelogenous leukemia, have described elevated 2-HG compared to cells with wild-type alleles.[94,102] Fathi et al reported that 2-HG levels in serum, urine, bone marrow, and myeloblasts were significantly higher ($p < 0.0001$) in patients with acute myeloid leukemia with mutant *IDH* compared to wild type, and showed that serum and urine 2-HG decreased with response to treatment.[103] In chondrosarcoma, we have shown previously that 2-HG also can be detected in serum and urine of a patient with IDH2-mutant dedifferentiated chondrosarcoma (Li et al, unpublished data, November 2014). We also demonstrated that in vitro treatment of IDH1 mutant chondrosarcoma cell lines with an IDH1 inhibitor decreased production of 2-HG, induced apoptosis, and inhibited tumorigenic activity. Thus, it appears that 2-HG is a noninvasive biomarker of treatment response, and mutant IDH is being used as a predictive biomarker to select patients for enrollment in clinical trials of novel IDH inhibitors (NCT00989261, NCT02074839, NCT02073994, NCT02273739). Although, preliminary data in leukemia patients treated with IDH inhibitor suggests considerable efficacy, the results from the solid tumor study including chondrosarcoma are too early to characterize.

CONCLUSION

Chondrosarcomas are a unique, rare family of neoplasms that pose substantial treatment challenges, particularly in the metastatic and refractory setting. The next few years are likely to shed light on the unique biologic nature of these diseases, with development of novel therapies. Given the limited response to chemotherapy and other systemic drugs, referral of patients to clinical trials, particularly in the setting of documented *IDH*-mutated disease, should be a priority.

Chemotherapy for Bone Sarcomas in Adults: The MD Anderson Experience

Robert S. Benjamin, MD, Michael J. Wagner, MD, J. Andrew Livingston, MD, Vinod Ravi, MD, and Shreyaskumar R. Patel, MD

OVERVIEW

Increasing age is an adverse prognostic factor in the treatment of primary bone tumors. There are few published data on treatment of primary bone tumors in adults. This paper presents data from the Department of Sarcoma Medical Oncology at The University of Texas MD Anderson Cancer Center, summarizing our treatment results. To treat primary osteosarcoma, we used 90 mg/m^2 of doxorubicin as a continuous intravenous infusion over 48 to 96 hours and 120 to 160 mg/m^2 of cisplatin intravenously or intra-arterially. Initially, we found a marked difference in postoperative continuous disease-free survival (CDFS) between those with 90% or greater (i.e., good response) tumor necrosis and those with less than 90% (i.e., poor response) tumor necrosis. The sequential addition of high-dose methotrexate and ifosfamide to patients with poorly responding disease improved their CDFS to that of patients with good response. Older patients and those who have tumors with variant histology have inferior outcomes. Evaluation of subsequent patients revealed similar outcomes for those with good or poor response to induction therapy, supporting our practice of adaptation of postoperative chemotherapy to the results of preoperative chemotherapy. PET-CT is the best imaging modality to screen for a response with tumors inside bone. To treat Ewing sarcoma, we have employed 2 mg of vincristine, 75 to 90 mg/m^2 of doxorubicin as a 72-hour infusion, and 2.5 g/m^2 of ifosfamide over 3 hours daily for 4 doses (i.e., vincristine, doxorubicin, and ifosfamide [VAI]). Preliminary analysis indicates a higher CDFS when adjusted for patient age than seen with the standard alternating regimen used in pediatrics. A screening MRI of the pelvis and spine can detect subtle metastatic disease in bone or bone marrow that is missed by other imaging modalities or blind biopsy. Chondrosarcoma is treated surgically or on investigational protocols. Giant cell tumor of bone is usually managed surgically, but multiple options exist for medical treatment, and therapy is individualized with embolization, denosumab, and interferon.

Increasing age is an adverse prognostic factor in the treatment of primary bone tumors.[1-3] There are few, if any, randomized studies that address the treatment of primary bone tumors in adults, and no data support the common practice of extrapolating from the results of pediatric trials to the adult population. We know from pediatric studies that conclusions based on data derived from patients younger than 18 do not always apply to those age 18 or older. We know, for example, from the data presented at American Society of Clinical Oncology, that compressed VDC-IE (vincristine, doxorubicin, and cyclophosphamide alternating with ifosfamide and etoposide) was not more effective against Ewing sarcoma in patients older than age 17 than standard dosing, but, because those patients were included in the study, the overall results are extrapolated to apply to them.[3] The therapies that we will describe are derived from the experience of our group in the Department of Sarcoma Medical Oncology at The

University of Texas MD Anderson Cancer Center and are based on a sound rationale for individual regimens rather than on randomized trial data showing the superiority of any one regimen over another. Traditionally at our institution, adult patients were at least age 16. In recent years, the age of the pediatric service has expanded, and the majority of patients in the age range of 16 to 21 years are seen in pediatrics.

The two most common pediatric bone sarcomas, osteosarcoma and Ewing sarcoma, are seen in adults as well. In addition, chondrosarcoma, unclassified pleomorphic sarcoma (UPS, previously called MFH) of bone, and giant cell tumor of bone are seen mostly in adults.

CHONDROSARCOMA

Fortunately, because no systemic therapy has proven effective, most patients with conventional chondrosarcoma have

---

local disease only and can be treated effectively with surgery. Conventional chondrosarcomas are divided into central chondrosarcomas, which arise from enchondromas, and peripheral chondrosarcomas, which arise from osteochondromas. The majority of chondrosarcomas are central chondrosarcomas.[4] Patients with metastatic disease usually are treated only on investigational protocols, which have not yet generated positive data. Preclinical data implicate the hedgehog pathway in the development and proliferation of chondrosarcoma cells.[4,5] A clinical trial of the hedgehog inhibitor GDC-0449 did not meet its objectives, however.[6] The presence of frequent mutations of *IDH1* and *IDH2* in central chondrosarcomas[7] suggests a new target for therapy. We await clinical data.

We treat dedifferentiated chondrosarcoma, a composite tumor with a low-grade chondrosarcoma juxtaposed to a high-grade osteosarcoma or UPS of bone-like osteosarcoma. Dedifferentiated chondrosarcoma has a dismal prognosis when treated by surgery alone; all patients experienced disease relapse within 1 year, and all but one were dead within 2 years.[8] We noted a 51% relapse-free survival in a 15-patient series treated as if they had osteosarcoma (vide infra).[9] We treat mesenchymal chondrosarcoma, a composite tumor with a low-grade chondrosarcoma juxtaposed to a malignant small round cell tumor, like Ewing sarcoma. Although we have not analyzed our data, obvious responses to therapy have been noted. In support of our strategy, a recent review by Italiano et al,[10] which observed 180 patients treated with chemotherapy in 15 institutions in Europe and the United States, noted a response rate of 31% for mesenchymal chondrosarcoma, 20.5% for dedifferentiated chondrosarcoma, only 11.5% for conventional chondrosarcoma, and 0% for clear cell chondrosarcoma.[10]

KEY POINTS

- Older patients with osteosarcoma and Ewing sarcoma have inferior outcomes than pediatric patients.
- To treat osteosarcoma, induction chemotherapy with doxorubicin and cisplatin permits administration of full doses of both agents.
- Unlike some pediatric studies, our data support the addition of ifosfamide as well as high-dose methotrexate to poor responders but do not support the routine use of high-dose methotrexate for all patients.
- Our data suggest that vincristine, doxorubicin, and ifosfamide is a good choice of primary chemotherapy for Ewing sarcoma.
- PET-CT is the best imaging modality to assess response, especially in osteosarcoma, but MRI is the most sensitive method to detect subtle metastases in bone or bone marrow.

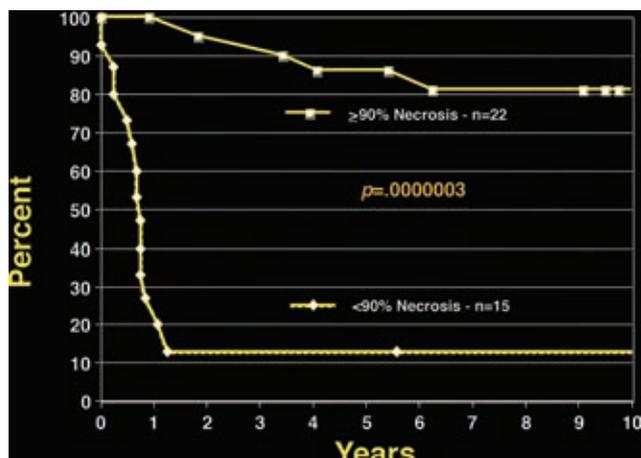
GIANT CELL TUMOR OF BONE

Giant cell tumor of bone is a fascinating tumor. Although histologically benign, approximately 2% of tumors can metastasize.[11] The metastases also are histologically benign. Histologic malignant transformation (dedifferentiation) may occur spontaneously or, more commonly, after radiation therapy. Although pathologists refer to giant cell tumor of bone as a benign tumor, we consider it a low-grade malignancy, analogous to (or worse than) well-differentiated liposarcoma or grade 1 chondrosarcoma, which cannot be distinguished histologically from their benign counterparts but which do not metastasize without further malignant change. In the majority of occurrences, intralesional resection (curettage and instillation of polymethyl methacrylate) is curative, whereas en bloc resection is preferred for lesions in expendable bones or those extending into soft tissue.[12] Until recently, medical oncologists have rarely been involved in the management of this tumor, seeing only the occasional patient with metastatic disease or with a primary tumor in the spine or sacrum, where resection would cause excessive morbidity. We prefer to avoid the use of radiation therapy because it has been associated with secondary malignancy, but we have used it when there are no reasonable alternatives. This should be even less necessary in the future.

Giant cell tumors are highly vascular lesions, and we have treated sacral lesions with arterial embolization since the 1970s.[13] Therapy is effective in approximately 50% of the cases, and long-term follow-up times show that most patients whose tumors respond are essentially cured.[14] Since 1992, we have treated patients who experience disease progression after embolization or those who have metastatic disease with interferon alfa.[15] It was the only antiangiogenic agent available at the time,[16] and, like embolization, it is effective in approximately 50% of the cases and has curative potential.[14] Interestingly, we have noted delayed responses to therapy after clear progression, sometimes only after the therapy has been discontinued.

The biology of giant cell tumor of bone is now much better understood.[17] The tumor cells (or malignant cells) are stromal cells with an immature osteoblast phenotype. These cells secrete RANKL (RANK ligand, a member of the tumor necrosis factor [TNF] family), a key mediator of osteoclast biology. Under RANKL signaling, the tumor cells recruit monocyte precursors that are transformed into osteoclast-like giant cells that represent the bulk of the actual giant cell tumor. Denosumab, a fully human monoclonal antibody that selectively binds RANKL, has been highly effective in the treatment of giant cell tumor of bone; 86% of patients experienced objective evidence of response in the initial phase II study[18] and, in the larger expansion study, 72% of patients responded likewise.[19] Because denosumab does not treat the malignant cell directly, however, it is unclear whether life-long therapy

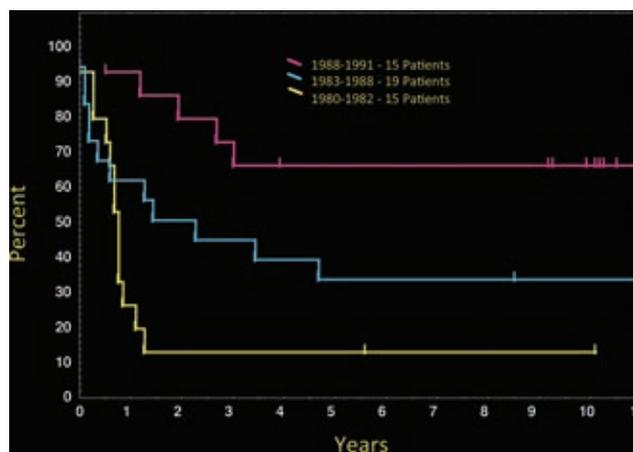
FIGURE 1. Continuous Disease-Free Survival by Tumor Necrosis

FIGURE 2. Continuous Disease-Free Survival with Tumor Necrosis of 90% or Less


will be needed in patients whose disease cannot be treated surgically.[17]

OSTEOSARCOMA

Our therapy for osteosarcoma is based on experience in a group of patients treated from 1980 to 1991 with induction therapy of 90 mg/m^2 of doxorubicin as a continuous intravenous infusion over 48 to 96 hours and 120 to 160 mg/m^2 of cisplatin intra-arterially. Initially, we found a marked difference in postoperative continuous disease-free survival (CDFS) between those with 90% or greater (i.e., good) tumor necrosis and those with less than 90% (i.e., poor) tumor necrosis.[20] (Fig. 1) We subsequently modified postoperative chemotherapy, first adding high-dose methotrexate and later, in addition, ifosfamide. We found no benefit from the addition of methotrexate to the good responders, but we observed an increased CDFS in the poor responders from 13% to 34%. The subsequent addition of ifosfamide to the postoperative regimen further increased the CDFS to 67% (Fig. 2), such that the difference between good and poor responders was no longer statistically significant.[21]

Because we have not had additional good drugs to add to our regimen, we have continued the practice established in our 1988 to 1991 series of adding ifosfamide and high-dose methotrexate to patients who have poor tumor necrosis. We recently reviewed a series of 46 patients with primary osteosarcoma of the extremities who were treated according to this approach. The median 10-year CDFS was 50%, and there was no difference between patients with good or poor necrosis. The recent EURAMOS study concluded that addition of ifosfamide was of no benefit to (largely) pediatric patients with osteosarcoma and poor necrosis.[22] The initial approach with modified adjuvant chemotherapy after poor response to neoadjuvant chemotherapy came from the sequential studies of Rosen et al,[23]


the inventor of the neoadjuvant approach.[23] Our data, together with the early studies of Bacci et al from the Rizzoli Institute,[24] support adaptation of postoperative therapy to preoperative response, despite the EURAMOS data. Our approach emphasizes maximum doses of the individual drugs in the initial doxorubicin-cisplatin doublet rather than adding methotrexate, which overlaps in nephrotoxicity with cisplatin and in mucositis with doxorubicin. We see no advantage to adding methotrexate in good responders, and it can be a difficult drug to use in older patients.

One factor that needs emphasis is that the spectrum of histologic appearance in adult osteosarcoma is quite different from that usually seen in pediatric series. Conventional osteosarcoma (osteoblastic, chondroblastic, and fibroblastic subtypes) makes up the vast majority of cases in typical pediatric series. Of the variants, only telangiectatic osteosarcoma has a similar response to therapy and prognosis. Patients with chondroblastic osteosarcoma had a lower rate of good necrosis but a better prognosis despite poor necrosis in our original series of patients, and that observation appears to be true in the subsequent group we analyzed, albeit with small numbers. Patients with variant histology (dedifferentiated parosteal osteosarcoma, high-grade surface osteosarcoma, small cell osteosarcoma) other than telangiectatic osteosarcoma represented 12% of our original series and had significantly worse CDFS. Perhaps because of the increasing age of patients currently seen on our pediatric service, variant histology was even more common in our recent group (28%). The patients in our current group were older than in our original series. In our current group, 46% are older than age 30, and 33% are older than age 40, compared with 23% and 11%, respectively, in our initial series.

PET-CT is the best imaging modality to assess response to therapy. MRI is the best modality to define an anatomic abnormality within bone, but it routinely overestimates the extent of residual viable tumor. CT shows details of cortical

structure and calcification in the soft tissue, so combining the CT images from the PET-CT with the MRI gives the best overall assessment.

Until recently, new agents with clear activity in the treatment of metastatic osteosarcoma have not been identified in the past 2 decades. Anecdotal evidence for the efficacy of gemcitabine with or without docetaxel was not confirmed in a clinical trial.[25] Recently, however, Grignani et al[26] reported a study from the Italian Sarcoma Group using the combination of sorafenib and everolimus.[26] The median progression-free survival (PFS) was 5 months, with a 6-month PFS rate of 45% despite an objective response rate of only 10%. It has long been known that primary osteosarcoma may not shrink when it responds. The use of PFS as an endpoint in this study is novel and important, and it throws into question some of the negative clinical trials of the past.[25]

EWING SARCOMA

It is even harder to find studies on Ewing sarcoma in adults than it is to find studies on osteosarcoma. Our initial data on the treatment of Ewing sarcoma in adults is, unfortunately, published only in abstract form,[27] and the logistics of transition from paper to electronic medical records and film to digital images makes a new review of the data cumbersome at best. The major lessons from our initial patients treated with VAdriaC (vincristine, doxorubicin, and cyclophosphamide) or CyVADIC (cyclophosphamide, vincristine, doxorubicin, and dacarbazine) were that any residual viable tumor in excess of scattered cells carried a high risk of recurrence and that, the more doxorubicin given, the better the patients faired. Therefore, it has become our practice to add additional postoperative chemotherapy with an alternative regimen to any patient who has less than 99% tumor necrosis.

The role of ifosfamide, questioned in the treatment of osteosarcoma, is well established in the treatment of Ewing sarcoma in pediatrics.[2,3] Because ifosfamide is one of the most active agents in the treatment of adult sarcomas, we have considerable experience in its use. The standard soft tissue sarcoma chemotherapy regimen is doxorubicin and ifosfamide, which we have studied extensively.[28] Ifosfamide is superior to cyclophosphamide in the treatment of sarcomas,[29] so we saw no reason to alternate cyclophosphamide with ifosfamide and have thus adopted VAI as our primary treatment regimen for Ewing sarcoma by simply adding vincristine to our standard soft tissue sarcoma regimen. We give 2 mg of vincristine on day 1, 75 to 90 mg/m^2 of doxorubicin as a 72-hour infusion, and 2.5 g/m^2 of ifosfamide over 3 hours daily for four doses.

We reviewed the data on a series of 24 patients with primary Ewing sarcoma of bone treated with VAI. The median age was 23 (range, 17 to 54); 17% of patients were younger than 20, and 17% of patients were older than 30. The 5-year CDFS was 70%, and all relapses but one occurred within 1 year of treatment. The primary sites of relapse were local recurrence in bone and adjacent soft tissue, with only a single case of pulmonary metastasis as

the first site. Two patients experienced relapse during induction therapy. No patient who experienced relapse survived. Twenty of the 24 patients underwent surgery after induction chemotherapy. Eleven patients (55%) who had more than 95% tumor necrosis in the resected specimen had an 80% 5-year CDFS compared with a 44% 5-year CDFS for the nine patients (45%) who had less than 95% tumor necrosis. All patients with more than scattered residual tumor cells after induction therapy underwent variable consolidation chemotherapy, including high-dose ifosfamide, ifosfamide/etoposide (IE), and irinotecan/temozolomide with or without vincristine. Although this is a small series, the results compare favorably with the commonly used regimen of alternating VAdriaC and IE used in the pediatric literature, for which event-free survival for patients older than age 18 was 44%[2] and was 47% in the study of compressed-interval dosing.[3]

MRI is the best modality to define an anatomic abnormality within bone or bone marrow. A screening MRI of the spine and pelvis can detect subtle metastatic sites missed by other imaging modalities, even PET-CT, or blind bone marrow biopsies. PET-CT is the best imaging modality to assess response to therapy, but it is not as critical as in osteosarcoma, because Ewing sarcoma tends to shrink or disappear as it responds.

New approaches to the therapy of Ewing sarcoma with insulin-like growth factor 1 receptor (IGF-1R) blockade with[30] or without[31] mammalian target of rapamycin inhibitors hold some promise, but thus far have been effective in only a minority of patients. Unfortunately, the IGF-1R target has relatively little interest to most pharmaceutical companies, and further studies to select the subset of patients who might benefit most have been stymied by the lack of drug supply and pharmaceutical support. Other new approaches, interesting from a theoretical point of view, have yet to undergo formal study.

CONCLUSION

Treatment of primary bone tumors in adults presents challenges and opportunities. The first challenge is finding effective therapy for chondrosarcomas. These tumors are like the gastrointestinal stromal tumors of the 1990s. We have no medical treatment. There are some interesting targets. How do we turn it around? For giant cell tumor of bone, we have a wonderful new agent, but is it curative? How long does therapy need to continue? How can we take advantage of the great activity of denosumab to design better treatments for the future? In treating osteosarcoma and Ewing sarcoma in adults, we do not do as well as our pediatric colleagues, perhaps because younger patients can tolerate more intensive chemotherapy and perhaps because of the differing mix of variant histologies. The VAI regimen for Ewing sarcoma seems promising, but formal studies and larger numbers will be required. The tragedy of near certain death with relapse in Ewing sarcoma needs to be addressed with better strategies, perhaps aimed at directly inhibiting the effects of its causative translocation.

Application of Molecular Biology to Individualize Therapy for Patients with Liposarcoma

Gulam Abbas Manji, MD, PhD, Samuel Singer, MD, Andrew Koff, PhD, and Gary K. Schwartz, MD

OVERVIEW

Liposarcomas are one the most common of over 50 histologic subtypes of soft tissue sarcomas that are mostly resistant to chemotherapy. Histologically, liposarcomas themselves are heterogeneous and fall into four distinct subtypes: well-differentiated/atypical lipomatous tumor, dedifferentiated liposarcoma, myxoid (round cell) liposarcoma, and pleomorphic liposarcoma. Surgical resection with negative margins remains the mainstay for definitive treatment for operable disease. For unresectable disease, retrospective studies have identified myxoid (round cell) and pleomorphic sarcomas to be relatively responsive to chemotherapy. Recent studies have identified distinct genetic aberrations that not only aid in the diagnosis of particular liposarcoma subtypes, but represent actionable targets as they are considered central to disease pathogenesis. Cyclin-dependent kinase 4 (CDK4) and murine double minute 2 (MDM2) are overexpressed in well-differentiated and dedifferentiated liposarcomas and offer tantalizing opportunities that are being pursued in clinical trials. Myxoid (round cell) liposarcomas appear to be sensitive to trabectedin, which is currently under U.S. Food and Drug Administration (FDA) review. Liposarcomas do not represent a uniform disease and understanding the underlying molecular mechanism will help not only in accurate diagnosis but in selecting the appropriate treatment.

Soft tissue sarcomas (STS) are a complex heterogeneous collection of more than 50 neoplasms of mesenchymal origin. According to the American Cancer Society, in 2015 approximately 11,930 patients in the Unites States will be diagnosed with STS, and nearly 4,870 will die from the disease. Surgery is the mainstay of therapy. For metastatic STS, cytotoxic chemotherapeutic agents such as doxorubicin or gemcitabine plus docetaxel have been used with response rates of approximately 25%, and overall survival (OS) of 12 to 18 months.[1,2] Whenever possible, treatments are now tailored to the histologic subtype, tumor characteristics, molecular signature, and patient performance status. Liposarcoma is among the most common sarcoma subtypes, with average annual, age-adjusted incidence of 0.4 to 1.1 per 100,000 persons dependent on gender and race.[3] Liposarcomas are a heterogeneous group of adipocytic neoplasms that are generally resistant to chemotherapy. This review will focus on management of liposarcomas and discuss novel targets and therapies directed toward them that are being tested in clinical trials.

LIPOSARCOMAS

Liposarcomas are neoplasms of adipocytes that normally grow slowly and present as a painless nonulcerated enlarging mass. They are subclassified into distinct categories dependent on their histology, molecular signature, and behavior[4]:

- Well-differentiated/atypical lipomatous tumor
- Dedifferentiated liposarcoma
- Myxoid (round cell) liposarcoma
- Pleomorphic liposarcoma
- Liposarcoma, not otherwise specified

Rarely, a specimen may have a combination of morphologic subtypes; this is referred to as mixed liposarcoma.

ATYPICAL LIPOMATOUS TUMOR/WELL-DIFFERENTIATED LIPOSARCOMA

Atypical lipomatous tumor (ALT) or well-differentiated liposarcoma (WDLS) is the least aggressive of the malignant forms of liposarcoma and represents 40% to 45% of the liposarcomas that are diagnosed.[5] Microscopically, they consist of scattered lipoblasts with a single atypical nucleus surrounded by large intracytoplasmic vacuoles in a background of adipocytes.[4] ALT/WDLS are usually indolent and tend not to metastasize, but can recur locally. However, if they undifferentiate into the dedifferentiated form, they exhibit an aggressive phenotype and are likely to metastasize.[6] The retroperitoneum and extremities are common primary sites, but they can also occur within the mediastinum and parates-

ticular region.[7] ALT/WDLS within the retroperitoneum, mediastinum, and spermatic cord are more likely to recur and result in significant morbidity and mortality from local disease.[6] Gene expression profiling when compared to normal fat has indicated overexpression of several genes in the 12q12–15 amplicon, including *CDK4* and *MDM2*.[7] MDM2 is a ubiquitin ligase that binds to the transactivation domain of p53 and promotes its degradation.

DEDIFFERENTIATED LIPOSARCOMA

Dedifferentiated liposarcoma (DDLS) is the second most common type of liposarcoma diagnosed. DDLS is cellular and consists of nonlipogenic sarcoma that transitions abruptly within an ALT.[4] DDLS has morphologic and molecular similarities to ALT/WDLS but behaves aggressively. DDLS has a higher rate of recurrence, with 20% to 30% distant metastasis, and a 6-fold higher risk of death compared to ALT/WDLS.[8,9] Many of the gene alterations found in WDLS are also found in DDLS.[7] For example, both *CDK4* and *MDM2* are overexpressed in both of these diseases. Genomic alterations of 207 STS, which included 50 DDLS specimens, confirmed the prior findings of amplifications within 12q12–15, including *CDK4* and *MDM2*.[10] WDLS and DDLS respond very poorly to chemotherapy and new treatment options are desperately needed.[11]

CDK4 and MDM2 Inhibitors

CDK4−Palbociclib. CDK4 is amplified in more than 90% of WDLS and DDLS cases, making it an opportune target in this disease subtypes. Preclinically, palbociclib (PD0332991), a CDK4/6 inhibitor, induces a G1 cell cycle arrest in liposarcoma cell lines that overexpress CDK4.[10] A phase I trial with palbociclib in patients with advanced solid malignancies identified one patient each with ATL/WDLS and DDLS who

had stable disease lasting several years at a dose of 200 mg daily for 14 consecutive days in 21-day cycles.[12] This led to an open-label phase II trial for patients with WDLS and DDLS. Patients' tumors were required to have CDK4 amplification and retinoblastoma protein (RB) expression, which is the downstream target for CDK4. Preclinically, RB expression was required for palbociclib activity.[10] Among the 30 patients enrolled (five with WDLS and 25 with DDLS), the trial reported a 12-week progression-free survival (PFS) rate of 66%, surpassing the primary endpoint criteria of 40%. Significant hematologic toxicities were observed, including grade 3 and 4 anemia (17%), thrombocytopenia (30%), neutropenia (50%), and febrile neutropenia (3%).[13] The results of a phase II study with a modified oral dose of 125 mg daily for 21 consecutive days in 28-day cycles (NCT01209598) were reported at the 2013 ASCO Annual Meeting, which indicated a comparable 12-week PFS but with reduced bone marrow toxicity.[14]

CDK4−LEE001 and LY2835219. Other CDK4 inhibitors are in clinical trials, including LEE001 and LY2835219. These agents exhibit a somewhat different toxicity profile, with neutropenia and QTc prolongation more common with LEE001 and gastrointestinal toxicity more common with LY2835219.[15,16] Stable disease was noted in patients with liposarcoma, although the complete results with these agents in this disease are pending publication.

One unresolved question is whether there exists a biomarker to predict clinical benefit. Rb expression appears to be necessary, but its presence is not predictive of benefit.

MDM2 targeting. Recently, it has been shown that CDK4 inhibition induces a G1 cell cycle arrest in all liposarcoma cells. However, only some of these cells undergo a process of cell death called cellular senescence. The proteolytic turnover of MDM2 appears critical for the induction of cellular senescence induced by palbociclib and by suppression of CDK4 by siRNA. Furthermore, the loss of MDM2 expression induced by CDK4 inhibition appears to be dependent on the baseline expression of ATRX. An examination of MDM2 loss in liposarcoma patients treated with palbociclib has been shown to correlate with prolonged stable disease; whereas patients with no change in MDM2 expression had rapid disease progression with this therapy. The importance of baseline ATRX expression, and the loss of MDM2 expression as a maker of clinical benefit to CDK4 inhibitors in liposarcoma (as well as other tumor types), will require validation in future clinical trials.[17]

MDM2 gene amplification or protein overexpression has been demonstrated in several cancer types, including DDLS.[18] Disruption of MDM2 and *p53* interaction in cancer types with wild-type *p53* and MDM2 overexpression has shown promise in vitro and in vivo. Nutlins are a class of imidazoline compounds that have been shown to have potent and selective activity against MDM2.[19] In preclinical studies, nutlin-3a was the first drug to show potent in vitro effects in liposarcoma cell lines with amplifications and overexpression of MDM2.[7] This drug induced both cell

---

KEY POINTS

- Sarcomas are rare malignancies of mesenchymal origin that represent a heterogeneous group of over 50 subtypes, of which liposarcomas are one of the most common subtype.
- Liposarcomas contain at least four distinct subtypes for which treatment has to be tailored.
- Well-differentiated liposarcoma is the least malignant form, does not respond to chemotherapy, and tends to recur locally.
- Dedifferentiated liposarcoma has some response to chemotherapy and, like well-differentiated liposarcoma, contains amplification/overexpression of murine double minute 2 and cyclin-dependent kinase 4, inhibition of which have shown promise in early-phase clinical trials.
- Retrospective data indicate trabectedin to have activity in myxoid (round cell) liposarcoma, which is currently under U.S. Food and Drug Administration review for this indication.

cycle arrest and apoptosis in these cells, which were also *p53* wild-type.[19]

MDM2−RG7112. RG7112 was the first nutlin inhibitor to be tested clinically. In a proof-of-concept study, 20 chemotherapy-naive patients with primary or relapsed WDLS (11 patients) or DDLS (9 patients) were enrolled in the neoadjuvant setting. Patients were treated with up to three cycles with 1,440 mg/m^2 of RG7112 for 10 days on a 28-day cycle schedule. Two of the 20 patients carried missense mutations in *TP53* and 14 of 17 had *MDM2* amplifications (three did not have adequate samples). Patients underwent paired biopsies before and on day 8 of treatment. *p21* expression, a marker of *p53* function, increased 3.48-fold in tumor tissue as measured by immunohistochemistry, while macrophage inhibitory cytokine-1 (MIC-1) levels, a marker of apoptosis and *p53* induction, increased in blood. *p53* expression and *MDM2* transcripts also increased by 4.86- and 3.03-fold compared to baseline, respectively. Nineteen patients received at least one cycle of RG7112, of which ten and five completed three and two cycles, respectively. One patient achieved a partial response, 14 had stable disease, and five experienced disease progression (all of whom had DDLS).[20] Ten patients underwent surgical resection at a median of 34.5 days after the last dose of RG7112, of which eight had a complete resection and two had partial resections.[20] Patients with partial resection received three cycles of adjuvant treatment and maintained stable disease.

Ten serious treatment-related adverse events (AEs) were observed in seven patients, all of which were hematologic in nature. Grade 3 or 4 AEs included neutropenia (30%), febrile neutropenia (5%), thrombocytopenia (15%), nausea (5%), emesis (10%), diarrhea (5%), and general deterioration (5%). One patient died of nontreatment-related postoperative hemorrhagic complications. Hematologic AEs, including thrombocytopenia, led to treatment delays in many patients; three had to discontinue treatment. All patients recovered from their hematologic AEs and there were no treatment-related bleeding complications.[20] RG7112 treatment in mice and monkeys also resulted in thrombocytopenia by promoting megakaryocyte progenitor cell destruction by apoptosis and inhibition of DNA synthesis during endomitosis, a key step for platelet production.[21]

MDM2−SAR405838. SAR405838 is an oral spirooxindole derivative antagonist that binds to MDM2 with a Ki of 0.88 nmol/L, has high specificity, and has a dissociation constant of 9.4 nmol/L. A cocrystal structure of SAR405838 and MDM2 indicates that SAR405838 mimics three key p53 amino acids and binds to the unstructured N-terminus of MDM2 to achieve high affinity.[22] SAR405838 activated wild-type *p53* function in vitro and in xenograft tumor tissue of solid tumors, leading to *p53*-dependent cell cycle arrest and/or apoptosis. SAR405838 resulted in transcriptional up-regulation of PUMA, a transcriptional target of p53, induction of apoptosis, and complete tumor regression in SJSA-1 osteosarcoma xenograft model.[22] A first-in-human phase I trial in patients with solid tumors evaluated once-daily and weekly schedules of SAR405838.[23] Only patients with DDLS were included in the maximum tolerated dose (MTD) expansion cohort. Sixty-eight patients were enrolled in the trial, of which 43% had liposarcoma. At the time of publication, 65 patients had discontinued study participation and three remained on study. Of the 65 patients, 47 discontinued participation because of disease progression, nine because of AEs, and nine for other reasons. Median duration of treatment was 42 days and MTD was established at 300 mg orally daily. Within the expansion cohort, 21 patients with DDLS were treated at 300 mg orally daily. The most common treatment-related AEs within this cohort included nausea (38%), fatigue (33%), diarrhea (24%), and thrombocytopenia (14%). Eight patients discontinued treatment because of AEs. Of note, no dose-limiting toxicities were observed on the weekly schedule of SAR405838.[23] Pharmacokinetic studies indicated a T_{max} of approximately 4 hours and half-life of nearly 16 hours. Plasma MIC-1 protein concentration correlated positively with SAR405838 exposure. Interestingly, a lower platelet count correlated with higher SAR405838 levels on a daily administered schedule, but a higher C_{max} achieved on the weekly schedule did not correlate with lower platelet counts. Overall, the best response was stable disease in 32 patients (47%), of which 13 patients (19.1%) had stable disease at 12 weeks. In the MTD expansion cohort with DDLS, 11 of 21 patients (52%) had stable disease as best response.[23]

MYXOID (ROUND CELL) LIPOSARCOMA

Myxoid (round cell) liposarcomas (MRCL) mostly arise in deep soft tissue of the extremities in patients who tend to be younger than those with other sarcoma subtypes. MRCL represents a single entity with variable round cell component and accounts for 30% to 35% of liposarcomas.[24] Round cell liposarcoma is considered a more aggressive subtype of myxoid liposarcoma, with greater than 5% round cell component carrying an unfavorable prognosis.[25,26] Unlike other tumors, MRCL tends to spread to serosal surfaces, bones, the abdominal cavity, and other soft tissues, even in the absence of lung disease.[27] Microscopic evaluation identifies tumors composed of uniform round-to-oval primitive nonmesenchymal cells and a variable number of monovacuolated lipoblasts. More than 90% of MRCL tumors contain the 12q13 and 16p11 translocation that leads to the *FUS-DDITR* (*TLS-CHOP*) fusion. Fused in sarcoma (FUS) protein, EWSR1, and TAF15 belong to the FET family of proteins and are involved in regulation of transcription and RNA splicing. DDIT3 is a leucine zipper containing transcription factor and is a member of the C/EBP family that plays a role in adipocyte differentiation and cell cycle control.[28] The fusion protein is thought to result in malignant transformation by favoring adipocyte differentiation over proliferation. These tumors are also characterized by mutations in *PIK3CA*, encoding the catalytic subunit of phosphatidylinositol 3-kinase (PI3K).[10] In a series of 71 patients with MRCL, 13 had point mutations in *PIK3CA*. These mutations were clustered in two domains, the helical domain (E542K and E545K) and the kinase domain (H1047L and H1047R). Interestingly, patients whose tumors harbored mutations in *PIK3CA* had a shorter duration of disease-specific survival than did those with wild-type *PIK3CA* (p = 0.036, log-rank test).[10]

Surgery alone or with radiation therapy is the mainstay of treatment, but despite appropriate treatment for local disease, nearly 40% of patients experience disease relapse.[29] Although MRCL is relatively more chemotherapy-sensitive compared to other STS, median survival is 2 years in the advanced disease setting.[30]

Trabectedin

Apart from chemotherapy, trabectedin (ET-743), a marine alkaloid, is approved in Europe as second-line treatment for advanced STS and is a promising agent, particularly in MRCL. Trabectedin has two known functions: 1) It binds to DNA within the minor grove of the double helix, causing a conformational change that likely changes its interactions with DNA-binding proteins, and 2) it causes double-stranded DNA breaks by interaction with transcription-coupled nucleotide excision repair complex. Owing to its ability to alter DNA–protein interaction, it is not surprising that trabectedin specifically inhibited type I and II *TLS-CHOP* transcripts from binding to their cognate target promoters in an MRCL xenograft model that impeded TLS-CHOP function.[31] Recent evidence has suggested that trabectedin also affects the tumor microenvironment by targeting monocytes and macrophages that have protumoral functions, including production of growth factors, neoangiogenesis, increased protease activity, and support in tumor cell dissemination.[32-35]

Fifty-one patients with advanced myxoid liposarcoma treated with trabectedin on a compassionate-use basis were analyzed retrospectively and found to have an overall response of 51%, including two patients who achieved a complete response. Median PFS was 14 months and PFS at 6 months was 88%.[24] In a single-center retrospective study of 21 patients treated with trabectedin for a median of four cycles, an objective partial response was achieved in three patients (14%) and eight patients (38%) achieved stable disease for a median duration of 4.5 months.[36] The benefit of trabectedin in other liposarcoma subtypes remains to be defined.

PLEOMORPHIC LIPOSARCOMA

Pleomorphic liposarcoma (PLS) represents approximately 5% to 15% of liposarcomas[37] and usually presents in adults within the lower extremity.[38] PLS pathologically exhibits large, multivacuolated pleomorphic lipoblasts.[39] PLS is associated with a poor prognosis, with high local recurrence and distant metastasis in the range of 30% to 35%.[40] Because of the rarity of the disease, treatment data within this particular subtype is limited. A retrospective study reviewed response to chemotherapy in 39 patients with unresectable or metastatic PLS.[41] Of the 32 patients assessable for response, one (3%) had a complete response, 11 (34.5%) had a partial response, and nine (28%) had stable disease, with a median follow-up of 62 months. The median PFS and OS were 4.3 and 14 months, respectively. The overall objective response rate was 37%. Interestingly, anthracycline-based regimens did not result in an improved response rate compared to nonanthracycline-based therapies.[41]

CHEMOTHERAPY AND LIPOSARCOMA SUBTYPE SENSITIVITY

Overall, liposarcomas do not respond well to systemic cytotoxic chemotherapy. The Royal Marsden study addressed the subtype-specific sensitivity to chemotherapy in a retrospective analysis of a prospectively maintained database of patients treated between August 1989 and June 2004. Of the 88 patients with liposarcoma treated, 94% of patients received first-line chemotherapy for metastatic disease or for local recurrence. Thirty percent received doxorubicin and 17% received ifosfamide as monotherapy, while 34% received the combination. Of the subtypes treated, the most response rates were observed in the myxoid subtype (48%), while PLS (33%), DDLS (25%), and round cell liposarcoma (17%) achieved some response, in contrast to WDLS which had none. Combination chemotherapy with doxorubicin and ifosfamide resulted in the greatest response rates across subtypes.

Another large retrospective study of 208 patients, which focused on patients with advanced WDLS and DDLS from 11 participating institutions, identified that 85 patients (41%)

received combination chemotherapy and 123 patients (59%) received single-agent chemotherapy.[43] The majority of patients (82%) received anthracycline-based therapy. Only 21 patients (12%) achieved an objective response, all of whom received anthracyclines. With a median follow-up of 28 months, median PFS and OS were 4.6 and 15.2 months, respectively. A trend toward a higher median PFS in WDLS (8.7 months) compared to DDLS (4 months) was noted. On multivariate analysis, age and performance status (PS) were the sole factors that independently associated with PFS, while grade and PS associated with OS.[43]

SUMMARY AND FUTURE DIRECTIONS

Although surgical resection remains the cornerstone for localized disease, treatment for unresectable or metastatic disease is highly dependent on the liposarcoma subtype. For patients with rapidly growing WDLS or DDLS, doxorubicin-based regimens can be considered as a treatment option, although response rates remain low. In contrast, for patients with MRCL, doxorubicin-based chemotherapy is the treatment of choice and trabectedin (where available) can also be considered as a treatment option. The role of *PIK3CA* inhibitors in this disease remains to be defined, but the opening of MATCH trials through the National Cancer Institute with agents targeting *PIK3CA* may soon answer this question. The importance of trabectedin and newer cytotoxic agents, such as eribulin in liposarcoma subtypes other than MRCL, continues to be defined. For PLS, chemotherapy remains the treatment of choice, although the prognosis in this setting is poor. Palbociclib, a CDK4/6 inhibitor, which was recently approved in combination with letrozole for patients with estrogen receptor (ER)–positive advanced breast cancer, is active in patients with WDLS/DDLS. With this agent, some patients achieve prolonged stable disease after disease progression on prior therapies. As no randomized trials are currently planned with this agent in WDLS/DDLS, and in the

absence of any other active agents, off-label use of this agent remains a consideration. It remains to be determined whether this agent will be added to National Comprehensive Cancer Network Drugs & Biologics Compendium now that it is approved for patients with ER-positive breast cancer. Although MDM2 inhibitors have been successful in stabilizing tumors in WDLS and DDLS, the hematologic side effects, especially thrombocytopenia, remain a major hurdle in drug development. The key to advancement of MDM2 inhibitors in the clinic is to balance efficacy with hematologic toxicity. This may be accomplished by optimizing scheduling such that efficacious pharmacokinetics are achieved without appreciable toxicity.

Although these subtype-specific treatments should be viewed as signs of progress in the treatment of patients with liposarcomas, key challenges remain. First, targeting MDM2 and CDK4 in patients with WDLS and DDLS generally does not result in responses, but rather in disease stabilization. Recent reports of proteolytic turnover of MDM2 protein in the setting of CDK4 inhibition and the role of ATRX in cellular senescence versus quiescence may shed more light on the key mechanisms involved in CDK4/6 inhibitor response. This may ultimately provide a means to identify which patients will respond best to this type of targeted therapy. Second, since both WDLS and DDLS contain MDM2 and CDK4 amplification/overexpression, these changes solely cannot explain the aggressiveness of DDLS. The molecular switch or switches that convert WDLS to DDLS require investigation. Third, the molecular pathways that drive this class of diseases, especially PLS, need to be further interrogated to identify actionable targets in these disease subtypes. Owing to their heterogeneity and diverse underlying molecular mechanisms that drive growth, it is not surprising that liposarcoma subtypes respond differently to distinct treatments. This genetic diversity provides unique opportunities in drug development and has provided patients with liposarcoma new hope in treatment of their disease.

Clonal Evolution Models of Tumor Heterogeneity

Liran I. Shlush, MD, PhD, and Dov Hershkovitz

OVERVIEW

Somatic/clonal evolution is the process of sequential acquisition of vertically transmittable genetic/epigenetic elements in multicellular organisms. Cancer is the result of somatic evolution. Understanding the processes that shape the evolution of individual tumors might help us to treat cancer more efficiently. The initiating genetic/epigenetic events occur in functional cells and provide the cell of origin a selective advantage under a changing environment. The initiating genetic events tend to be enriched in specific tissues (and are sometimes specific for those tissues), as different tissues undergo different changes in the environment that will activate selective forces on different cells of origin. For the initial clonal expansion to occur premalignant clones need to have a relative fitness advantage over their competitors. It is estimated that the premalignant phase can take several years. Once the premalignant clonal expansion is established, the premalignant cells will contribute to the changing environment and will start competing among themselves. In late stages of cancer evolution the environmental changes might be similar across different tissues, including a lack of physical space, a shortage of energy, and activation of the immune system, and more and more of the hallmarks of cancer will evolve. In this review we will explore the possible clinical relevance of the heterogeneity that evolves during this long somatic evolution. Above all, it should be stressed that the earlier the clonal expansion is recognized, the less diverse and less fit for survival the cells in the population are.

Cancer evolutionary biology is the study of the history of a tumor and the processes that have shaped its diversity. The major aim of this review is to build a meaningful link between evolutionary concepts and practical applications in cancer medicine. To eliminate all cancer cells without destroying the host (human or tissue) one should understand the branching processes that separated the cancerous clones from their normal cell of origin. Much like penicillin targeting a critical speciation event (the bacteria cell wall), an anticancer drug such as imatinib targets a critical event in the somatic evolution of myeloid progenitor survival.

Cancer evolutionary biology seeks to explain all the characteristics of a single tumor in a single individual; however, in this short review we will focus on the clinical relevance of tumor heterogeneity. As human cancers can evolve over many years with prolonged clinically latent periods,[1] relatively short generation times, ongoing mutation, and ever-changing environments, it is expected that the genotypic and phenotypic intratumor diversity will be substantial. However, key questions in cancer evolution need to be addressed before a clinician will be able to decide whether the treatment or diagnosis should be changed based on the presence of multiple sub-populations within a single tumor. For example, it is not clear in all cancers whether the ancestral clones of a tumor disappear (linear model) or whether several phenotypically distinct clones evolve in parallel (branching evolution).[1]

Regardless of the evolutionary model involved, the order of phenotype appearance is unclear. Another unresolved question in cancer evolutionary biology deals with the use of appropriate tools to describe intratumoral heterogeneity. Although the coding regions of the genomes of humans and chimpanzees are almost identical (99.4%) any child can tell the difference between the two species. Interestingly, RNA expression from different tissues demonstrates substantial differences between humans and chimpanzees (31.4% different).[2] Similarly, different clones from the same colon carcinoma showed phenotypically distinct behavior whereas the coding region sequence was almost identical.[3] Unlike germ-line evolution, somatic evolution (the driving force of cancer) can include a higher complexity of epigenetic transmittable information in the form of methylation, a chromatin modulation that can be stably vertically transmitted from cell to cell and defines unique phenotypes. Recent technologic advances in modern pathology have made it possible to analyze DNA, RNA, and protein from different portions of a single human tumor. Such an approach, combined with functional studies, kinetic assays, and the description of the environment that shapes evolution, hold promise for a better understanding of cancer mechanisms and their relevance to diagnosis, prognosis, and treatment.

SAMPLING ISSUES IN CANCER DIAGNOSIS

Accurate diagnosis is the first step in cancer therapy. In some cases, decisions regarding the most appropriate therapy are

Corresponding author: Liran I Shlush, MD, PhD, Princess Margaret Cancer Centre, 620 University Ave., Toronto, ON M5G 2M9, Canada; email: liranshlush3@gmail.com.

based on genetic testing of the tumor tissue and identification of specific targetable mutations. For example, studies in EGFR-mutant lung adenocarcinoma demonstrated a marked improvement in response rate, progression-free survival, and quality of life using EGFR tyrosine kinase inhibitors compared to chemotherapy, whereas in EGFR wild-type tumors the opposite was true.[4,5] With increasing evidence for intratumoral heterogeneity, one should wonder whether a small biopsy specimen actually represents the entire tumor mass. This issue was addressed in two recent studies that applied whole-exome or whole-genome sequencing to multiple regions of non-small cell lung cancer. Interestingly, the results of these studies were conflicting; one group identified known driver mutations in different samples of individual tumors, suggesting that sequencing of a single region well represents the tumor,[6] whereas the other group found regionally separated driver mutations, which obviously complicates targeted treatment selection.[1] Similar discrepancies in mutation status between primary tumors and metastases for common oncogenes have been described and reviewed.[7] For example, in a metastatic breast carcinoma the discordance in estrogen receptor, progesterone receptor, and HER2 receptor status between confirmed primary and recurrent breast cancer metastasis was 12.6%, 31.2%, and 5.5%, respectively.[8] Additionally, in lung adenocarcinoma the primary-metastasis discrepancy ranged from 0% to 34% for activating EGFR mutations in different series.[7] In colon carcinoma, despite some discordance in KRAS mutation status between adenomas and carcinomas,[9] there are very high concordance rates between primary tumor and metastasis,[10,11] indicating that, at least for colon carcinoma, the primary tumor and metastasis are equally suitable for diagnosis. In population genetics, different sampling approaches are used depending on the scientific question. Random sampling from limited locations (as used in most instances of cancer diagnosis) can underestimate population diversity if migration is low.[12] Direct sampling based on phenotypes can miss recent population expansions. Taking into account sampling issues and adapting knowledge from population genetics might lead to a better estimation of cancer diversity and its relevance to outcome.

KEY POINTS

- Cancer evolutionary biology aims to understand the processes shaping genotype–phenotype correlations in cancer.
- Cancer evolution is a long process, usually occurring over years, with a premalignant phase occurring in functioning cells.
- During evolution, heterogeneity is created not only at the DNA level.
- Early cancer events are tissue specific and can be used for targeted therapies; however, if diagnosed late they might be irrelevant to tumor survival.
- The earlier a cancer is diagnosed, the lower the tumor heterogeneity and the better the prognosis.

QUANTITATIVE CANCER GENETICS

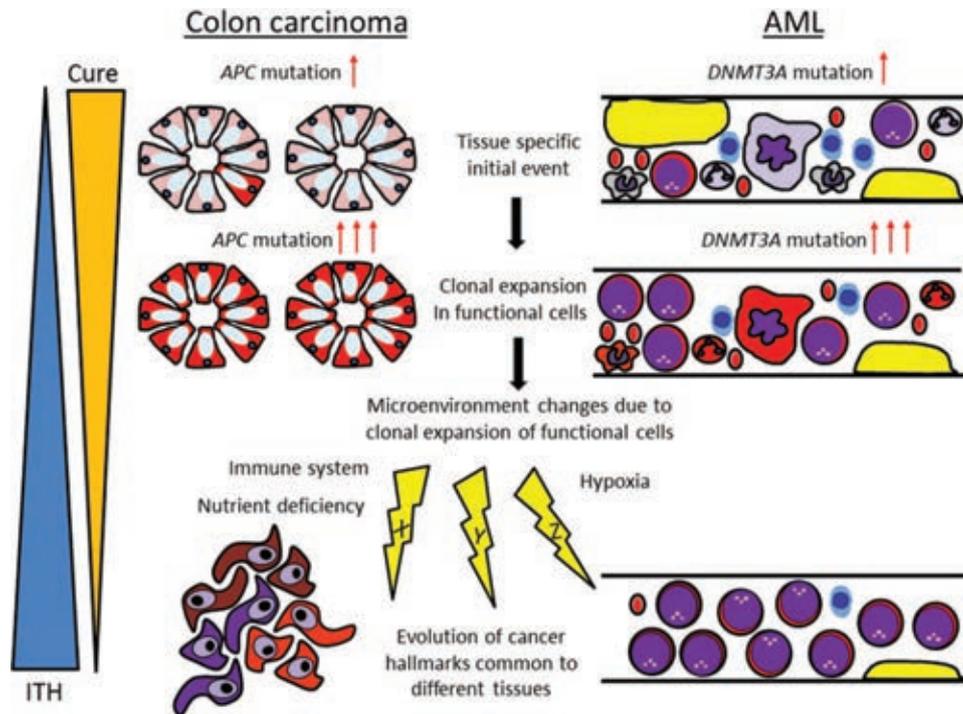
Evolutionary biology is a quantitative methodology in which defined allele frequencies are monitored on a time scale. Current pathologic reports of cancer mutation analysis are in most instances binary and thus qualitative. For example, a patient harboring a "druggable" mutation in 5% of his/her tumor tissue would screen positive using sensitive testing modalities and would be treated with targeted therapy even though 95% of the tumor cells should respond better to classic chemotherapy. Overall, such a patient might benefit from a combination therapy. Incorporating quantitative genetic and epigenetic analysis to the decision-making algorithms of a clinical trial is a cumbersome task as the heterogeneity in the studied groups will increase; however, efforts should be made by oncologists to pursue such approaches.

EARLY AND LATE EVENTS IN CANCER EVOLUTION AND THEIR RELEVANCE TO TREATMENT

Cancer therapy approaches can be broadly divided into two categories: (1) treatments targeting general cancer mechanisms that are not tumor/tissue specific; such therapies are referred to as hallmark therapies.[13] (2) Treatments targeting tumor/tissue specific mechanisms/phenotypes that can be grouped under the umbrella of targeted therapies.

The hallmarks of cancer have evolved to increase the fitness of any cell in any tissue regardless of the environment or the cell of origin. Targeted therapies are often (but not always) tissue specific, and in most cases target mechanisms that have increased the fitness of a cell in a specific cell type or environment. It is important to realize that cancer is not a random process or a "bad cell" aiming to take over the tissue. Under the evolutionary theory, in any living system changes in allele frequencies and clonal expansions in populations are the result of a selective pressure introduced by the environment. There is a reason why most of the driver mutations described in cancers are somatic and not germ line: somatic mutations provide a selective advantage only to specific cells in a specific tissue under a specific environment that enabled their selection.

The early events in cancer evolution increase the fitness of a normal cell, as the very first mutation occurred in a functional cell that most probably expanded as a non cancerous functional cell with improved fitness[14,15] (reviewed by Shlush and Minden[16]). Therefore, it is predicted that early events will be tissue specific and therefore will be sensitive to targeted therapy. As the initiating cell gradually expands in an environment with limited resources, it is now the malignant cell population that introduces changes into the environment and in most tissues this will occur in a similar manner. Now, the selection will be for cells that are better able to replicate, migrate, and utilize energy, and the hallmarks of cancer will evolve together with increasing intratumoral heterogeneity (Fig. 1). For these reasons, the hallmarks of cancer are common to different tissues. Accordingly, the hallmarks of cancer can be later events in the evolution process and not shared

FIGURE 1. Tissue-specific Early Evolutionary Events versus Common Late Hallmarks of Cancer Events


Early mutations are tissue specific and increase the fitness of the cell of origin under a changing environment. Initial clonal expansion of functional cells will eventually lead to changes in the environment that will in turn lead to selective pressure for the various hallmarks of cancer. Mutations (X,Y,Z) that have accumulated in the premalignant clones will be selected and gradually reduce the functionality of the cell of origin.

Abbreviations: AML, acute myeloid leukemia; ITH, intratumoral heterogeneity.

by all of the tumor cells. Unfortunately, it is not necessarily sufficient to target the tissue-specific phenotypes, because at the time of diagnosis (usually late in the evolution process) they might be unnecessary for survival. On a practical level, oncologists need to know what the major evolutionary events are in their tumor of interest, and in what order they occurred. This knowledge can be used in the planning of clinical trials and combination therapies. It is important to understand that a tumor presenting with the hallmarks of cancer has most probably evolved over a long period and might have lost some of the initial phenotypes that subsequently became superfluous for survival. Many cancers are diagnosed late in their evolution and if identified earlier they might have been targetable through their tissue-specific genotype/phenotypes.

INTRATUMORAL GENETIC HETEROGENEITY AND CANCER PROGNOSIS

Intratumoral heterogeneity has been demonstrated to be a predictive marker for cancer mortality. In Barrett's esophagus, the higher the diversity in a single biopsy the worse the prognosis.[17] Heterogeneity in HER2 amplification is associated with a higher cancer-specific death rate.[18] Similar findings were noted in breast carcinoma.[19] In head and neck cancer, intratumoral heterogeneity at the whole genomic level was significantly associated with shorter survival.[20] Additionally, the presence of sub-clonal driver mutations was

associated with reduced survival in chronic lymphocytic leukemia,[21] and patients with localized resected lung carcinoma that had a higher fraction of sub-clonal mutations were more likely to relapse.[6] These recent findings suggest that the degree of sub-clonality might serve as a cancer marker per se. Higher diversity is related to a higher mutation rate or longer tumor evolution with more replications. However, as discussed above, the survival of multiple clones suggests that multiple phenotypes were selected under different environments (branched evolution), all of which tell us something about the tumor biology and history.

FUTURE DIRECTIONS

The study of evolution, like the study of history, involves looking at the past to create a better future. Recent studies[14,15] suggest that early mutations in leukemia occur in cells capable of mainlining their functionality. These early events lead to clonal expansion of cells trying to maintain function. Clonal expansion is relatively common in the general population.[22-24] The early clonal expansion, which can last for years, will eventually progress to uncontrolled cell growth and the emergence of dysfunctional cells. From these studies we learn that cancer in adults is a longstanding state, with precancerous lesions most likely evolving as a result of the aging environment. Accordingly, we suggest that changing the environment and targeting early events might change the evolutionary trajectory of cancer.

Disclosures of Potential Conflicts of Interest

"Lassie," "Toto," and Fellow Pet Dogs: Poised to Lead the Way for Advances in Cancer Prevention

Deborah W. Knapp, DVM, Deepika Dhawan, PhD, and Elaine Ostrander, PhD

OVERVIEW

Cancer causes substantial morbidity and takes the lives of over 8 million people worldwide each year. Advances in cancer prevention research are crucial, and animal models are key to this. There are many valuable experimentally induced cancer models, but these do not fully meet the needs for cancer prevention studies. Pet dogs with risks for naturally occurring cancer can fill important gaps in cancer prevention research. Using invasive urothelial carcinoma (iUC) as an example, the advantages of utilizing pet dogs include: (1) close similarities between dogs and humans in carcinogenesis, molecular and cellular features, invasive and metastatic behavior, and response to treatment, thus providing high relevance for comparative studies, (2) shared environment between dogs and humans to help identify not-yet-known environmental iUC risks, (3) strong breed-associated risk (5- to 21-fold increased risk compared with mixed breeds) that facilitates investigation of gene-environment interactions, screening, and early intervention, (4) large size of dogs (versus rodents) that allows collection of fluids and tissues via cystoscopy, and detailed imaging at multiple time points, and (5) acceptance for studies in which each participating dog can benefit while enjoying life in their family environment, and in which findings will help other dogs and humans. An ongoing 3-year study in Scottish Terriers (comparable to a 15- to 20-year study in humans) is aimed at defining genetic and environmental risk factors for iUC, effective methods for screening/early detection, and a successful secondary cancer prevention approach with very promising results to date. Pet dogs can indeed propel cancer prevention research.

There is a need for improved cancer prevention research. More than 580,000 people in the United States and over 8 million people worldwide are expected to die from cancer, including all cancer types, yearly.[1,2] Although it is accepted that cancer prevention should offer the most cost-effective and appealing long-term strategy to control cancer, cancer prevention research has not kept up with the need, especially for an aging population.[3] One of the challenges in cancer prevention research is the identification and use of relevant animal models in which findings in the model will actually translate into improved prevention and treatment strategies for humans. Unfortunately, many preclinical models fail to reflect the disease in humans.[4-7] Other published concerns with experimentally induced models include: (1) the induction of cancer in animals that are young and otherwise healthy, whereas humans with cancer are often older with comorbid conditions, (2) the assessment of response in animals with homogeneous tumors versus that in humans with heterogeneous cancer, (3) timing of an intervention in animals that is unrealistic in humans, and (4) the use of toxic doses of treatment agents to achieve a desired outcome in animals when these doses would not be tolerated by humans.[6]

CANCER PREVENTION RESEARCH AND THE VALUE OF PET DOGS
Strong Potential Value for Pet Dogs in Cancer Research

There is growing evidence that pet dogs with specific forms of naturally occurring cancer can serve as highly relevant models for those cancers in humans.[8-12] There are an estimated 83 million pet dogs in the United States,[13] and a quarter of older pet dogs are expected to die from cancer.[8-12] For specific types of naturally occurring cancer, including, but not limited to, invasive urinary bladder cancer,[8] osteosarcoma,[14] subsets of squamous cell carcinoma,[9] and lymphoma,[15,16] considerable similarities have been noted between the cancer in dogs and humans in regards to histopathology, molecular features, and biologic behavior. Importantly, these cancers develop in the context of an intact immune system, and are characterized by considerable heterogeneity within and between individuals, similar to human cancer.[10] Studies to date indicate that the genes and pathways involved in cancer development in dogs are similar to those in humans.[17,18] Dogs develop cancer in an environment shared with their owners, and this has enabled dogs to serve as sentinels for specific carcinogens such as asbestos exposure and mesothelioma risk.[19] Studies

in dogs can help identify not yet known exposures that have the potential to contribute to understanding of human cancer.[20-22] The compressed life span of dogs compared with humans facilitates cancer prevention research in that a 15 to 20 year period in human life can be studied in dogs in 2 to 3 years. In an intriguing example, a 7-month study in older dogs (physiologically equivalent to human age 62 to 69) demonstrated a U-shaped dose-response relationship between selenium status (toenail selenium concentration) and provided target concentrations to prevent DNA damage and induce apoptosis within the prostate.[23-24] Midrange concentrations were associated with protective effects, whereas DNA damage was most pronounced at the lowest and highest selenium concentrations along the curve. This study offered a possible explanation for the failure of the 7-year Selenium and Vitamin E Cancer Prevention Trial (SELECT) of 35,000 men, which had begun before the dog study; the concentrations achieved in men in the SELECT study were not in the beneficial range as defined by the dog study.

Study Opportunities Afforded by Strong Breed-Associated Risk for Cancer in Dogs

Another intriguing aspect of cancer research in pet dogs is the tremendous opportunities offered by strong breed-associated risk for certain types of cancer. Examples include the 23-fold increased risk for squamous cell carcinoma of the digit in Giant Schnauzers[9] and the 21-fold increased risk for invasive bladder cancer in Scottish Terriers[8] compared with mixed breed dogs. These findings, along with the sequencing of the dog genome,[25] offer unparalleled opportunities to uncover complex traits leading to cancer development, including gene-gene and gene-environment analyses. For a specific cancer type, the number of deleterious alleles segregating in a single dog breed is expected to be limited because of essentially closed breeding in the establishment and maintenance of the breed.[9] Dog breeds are genetically far more simple compared with dog or human populations as a whole.[26] This

allows researchers to circumvent small family size, outbred population structure, and locus heterogeneity that limit human cancer gene mapping.[27,28] Detailed records of dog breeding by breed clubs add to the value of the model.[9] When taking advantage of breed-associated cancer risk, including genome wide association studies (GWAS), analyses can be performed with much fewer subjects than would be required for a human GWAS study. For example, an initial GWAS performed on 31 Standard Poodle cases and 34 controls allowed identification of a locus on canine chromosome 15 for squamous cell carcinoma of the digit with high significance that spanned approximately 1 million base pairs. Additional mapping and sequencing with less than 100 additional dogs revealed a founder mutation—a copy number variant affecting *KITL* expression.[9,29] The expectation is that there are shared genetic factors that drive cancer development in both dogs and humans; however, many of these factors are difficult to elucidate in humans, but dog studies can allow the identification and understanding of complex traits important in human cancer.

One example of this involves mutations leading to a renal cancer syndrome in German Shepherd Dogs that mimics that in Birt-Hogg-Dubé syndrome in people.[30] The locus was initially found using one large family, characterized by a single male that had been crossed to a number of females. Analysis of the progeny of the crosses allowed the locus to be reduced to a small size, and the underlying causative gene, folliculin, to be identified. Of note, the locus was mapped first in dogs, then in humans. Yet mutations in the same gene produce very similar cancer syndromes in humans and dogs.

NEEDS AND OPPORTUNITIES IN INVASIVE BLADDER CANCER RESEARCH
Current Challenges in Human Invasive Bladder Cancer
One of the best examples of a canine cancer with high translational potential and value is invasive urinary bladder cancer, specifically iUC, also referred to as invasive transitional cell carcinoma. There is a clear need to improve the outlook for people who have or who are at risk for developing this cancer. More than 16,000 people in the United States[31] and over 160,000 people worldwide[32] die from iUC each year. Clinical consequences include urinary obstruction as a result of progression of the primary tumor and major organ failure from metastasis. Both can cause substantial morbidity and lead to death. The mainstay of front-line treatment for bladder-confined iUC is cystectomy.[33] Many patients, however, are not candidates for this involved surgery because of comorbid conditions. Of those who undergo surgery, approximately 50% develop distant metastases.[34] Despite initial favorable response to chemotherapy, drug resistance develops in almost all patients with metastases, ultimately leading to death. The median survival time for patients with metastatic disease (approximately 14 months) has not improved to any extent in more than 20 years.[35] In addition, there is a huge economic burden associated with bladder cancer. Lifetime health care costs for patients with muscle invasive blad-

der cancer are estimated to average $150,000 per patient.[36] In the United States alone, $4 billion is spent on the medical costs of bladder cancer (including all forms of the cancer), and the lost life costs are estimated at $17 billion per year from premature death from bladder cancer.[36] There is a clear need to develop and implement strategies to prevent the development and progression of iUC.

To make progress against iUC, research involving animal models is crucial. Experimentally induced models of bladder neoplasia include chemically induced tumors, transgenic mouse models, and orthotopic xenograft models.[37,38] Although these experimental animal models are informative and are extensively used in bladder cancer research, there is still a need for complementary animal models in which the cancer is naturally occurring, invades and metastasizes consistently, and more closely mimics iUC in humans. Pet dogs with naturally occurring invasive iUC provide an ideal animal model to address this need.[8]

Pet Dogs Contributing to Invasive Bladder Cancer Research

Bladder cancer makes up 2% of all naturally occurring cancers in dogs, similar to the frequency in humans.[39,40] By conservative estimates, iUC occurs in at least 20,000 pet dogs per year, although the cancer in many of these dogs goes undiagnosed.[39] Most dogs with bladder cancer have high grade iUC, with superficial low grade tumors being rare in dogs.[8,41] There are marked similarities between the histopathology of iUC in dogs and humans, and reported cellular and molecular features are also similar across the two species.[8] Gene expression array analyses also demonstrate considerable similarities between iUC in dogs and humans (D. Dhawan, D.W. Knapp, C. Khanna, unpublished data 2015).

The locally invasive and metastatic behavior of iUC in dogs mimics that in humans. Nodal and distant metastasis are common, with up to 20% of dogs having metastases at diagnosis and 67% having metastases at death including distant metastases confirmed at necropsy in almost 60% of dogs.[8] Common distant sites of metastasis include lung, liver, and bone.[8]

Invasive UC is typically a disease of older dogs with median ages at diagnosis ranging from 9 to 11. In contrast to iUC in humans, female dogs have a higher risk of the cancer than male dogs (female-male ratios 1.7:1 to 1.9:1), and interestingly, neutered dogs have a higher risk than sexually intact dogs.[8] Hematuria and stranguria are the most common presenting signs. Cystectomy is rarely performed in pet dogs because of the expense and morbidity, and the frequent extension of the cancer down the urethra.[8] Radiation therapy is infrequently applied, and the mainstay for treatment of iUC in dogs is chemotherapy, cyclooxygenase inhibitors, and combinations of these. Platinum agents appear to be the most active, especially when combined with a cyclooxygenase inhibitor, which substantially enhances the activity of the platinums.[8] Medical therapy can allow excellent quality of life in most dogs for several months to over a year, but unfortu-

nately the development of drug resistance is common and most dogs ultimately die from the cancer.

There are multiple ongoing clinical trials for pet dogs with iUC. Similar to human studies, the pet dogs live at home, and come into the Veterinary Teaching Hospital periodically for evaluation. Canine trials are performed with institutional approval and informed pet owner consent. Clinical trials are well accepted as a win-win-win scenario in pet dogs with iUC. Each participating dog is expected to benefit as they gain access to a promising new treatment that is expected to be well tolerated and that is usually less expensive than other treatments. Additionally, crucial new knowledge is gained, which can improve the outlook for other dogs and, ultimately, for humans with the cancer.[8] In fact, at the Purdue University College of Veterinary Medicine, where two of the authors (Knapp and Dhawan) are employed, more than 90% of owners of dogs with iUC elect to enroll their pet in a clinical trial. Parallel mechanism studies are feasible in dogs with samples of blood, urine, and in some cases tumor tissues collected via cystoscopy before and during therapy. Most pet owners will also allow a necropsy of the dog when it dies or is euthanized (as a result of declining quality of life from cancer that progression or other conditions). Treatment trials in dogs that have been translated, or are poised to be translated because of the success in dogs and applicability to humans, include cyclooxygenase inhibitor treatment, folate-targeted therapy, and demethylating treatments.[8,42,43]

Not only can dogs with iUC facilitate the development of better treatment, dogs at risk for iUC may hold equal or more value in cancer prevention research. Understanding the causes of a particular type of cancer would undoubtedly aid in the development of prevention strategies. The greatest risk factor for iUC in humans is exposure to cigarette smoke. Exposure to other chemicals also increases risk, but 50% of patients with iUC have no known risk factors for the cancer. Although cigarette exposure has not yet been linked to iUC risk in dogs, other chemicals can have a profound effect on cancer risk. Exposure to older generation flea control products, which in some instances contained benzene and toluene (known carcinogens in humans), resulted in more than a 20-fold increased risk in iUC in dogs across many breeds, especially in female and obese dogs (other risk factors). In Scottish Terriers, who have a strong breed-associated risk for iUC, exposure to lawn chemicals resulted in an additional 7-fold increased risk compared with that in unexposed dogs. A follow-up study revealed widespread uptake of lawn chemicals into the urine of dogs exposed to treated lawns and untreated lawns contaminated by chemical drift. Some, but not all, studies suggest a link between exposure to herbicides, pesticides, and contaminants in agricultural chemical mixtures and iUC risk in humans.[44-46] In humans, genetic factors, especially in relation to chemical exposures, are associated with increased iUC risk, although the understanding of these gene-environment interactions is limited.[47-49] Studies are needed to further identify these factors and gene-environment interactions that increase iUC risk, and dog studies could prove crucial in this regard.

TABLE 1. Breed-Associated Risk for iUC in Dogs Identified in Analyses of Veterinary Medical Data Base Records

Breed	OR Compared with Mixed Breed	95% CI
Mixed Breed Dog (Reference Category)	1.0	NA
Scottish Terrier	21.12	16.23-27.49
Eskimo Dog	6.58	3.34-12.96
Shetland Sheepdog	6.05	4.76-7.69
West Highland White Terrier	5.84	4.23-8.08
Keeshond	4.26	2.25-8.07
Samoyed	3.43	1.81-6.49
Beagle	3.09	2.34-4.08

Abbreviations: OR, odds ratio; NA, not applicable.
Records from Participating Veterinary Colleges in the United States and Canada of dogs with iUC and dogs in the same breed without iUC (SNOMED search, 1999-2010).

One of the most powerful aspects of the naturally occurring dog model for iUC is the strong breed-associated risk for the cancer in dogs. There are at least seven breeds of dogs in which the risks of iUC is over 3 times that of mixed breed dogs, with the most impressive risk being in Scottish Terriers (odds ratio [OR] 21.1; 95% CI, 16.23 to 27.49; Table 1). GWAS have been used to identify two loci with strong significance for iUC risk in dogs, and steps to elucidate the specific genes involved are underway (E. Ostrander, H.G. Parker, D.W. Knapp, unpublished data 2015).

The strong breed-associated risk can be used to select groups of dogs for the study of iUC screening, early detection, and early intervention. A study is underway in Scottish Terriers in which a minimum of 100 dogs over the age of 7 who have no current evidence of bladder disease and no history of bladder cancer will be monitored for at least 3 years. The study calls for evaluation at 6-month intervals with medical history, physical exam, ultrasound exam of the urinary tract, urine sediment exam, and multiple emerging urine-based assays to detect iUC. The goals of the study are to determine the percentage of dogs in which cancer or precancer (urothelial dysplasia, carcinoma in situ, and early-stage iUC) can be found before the onset of any clinical signs of disease, and to determine the appropriate screening interval, screening test, and age to begin screening. Dogs with evidence of cancer or precancer will undergo cystoscopy and biopsy. Those with precancer or early-stage cancer will be eligible to enroll in a secondary cancer prevention trial, with secondary prevention being an intervention implemented at the early-stage of cancer development to cause regression or to prevent progression. In this particular study, the secondary prevention agent being evaluated is a cyclooxygenase inhibiting drug. With the compressed aging in dogs, this 3-year study in dogs would be expected to be equivalent to an approximately 20-year study in humans. The expectation was that over a period of 3 years, precancer or cancer would be found in approximately 30% of the dogs. With the study still in its first year, however, the frequency of precancer and cancer detec-

tion is much higher than expected at this time point. And, with the cancer being found early, the antitumor effects of the cyclooxygenase inhibitor are also exceeding that typically observed in more advanced disease. It is anticipated that the treatment response with nontargeted approaches such as cyclooxygenase inhibitors, and to perhaps a greater extent with targeted agents, will be better in early cancer that has not acquired as many genetic changes leading to drug resistance. This is encouraging evidence that this approach is one that can be used to test current and future strategies for detection and early intervention of iUC. It is exciting to consider that dog studies, which are much quicker and much less expensive to perform compared with human studies, could be used to help design the approach with the highest likelihood of success for the lengthier and far more costly human trials.

CHALLENGES TO ADVANCING CANCER RESEARCH IN PET DOGS

Although there is substantial evidence for the value of pet dog studies in cancer prevention and treatment research that could positively effect human patients with cancer, there are challenges that need to be met to make the most use of this approach. There are at least three main areas where challenges must be met: (1) funding, (2) critical mass of veterinary scientists doing translational research, and (3) access to appropriate numbers of dogs for clinical studies. Regarding clinical research costs, dog trials are far less expensive than human trials. For example, an appropriately powered, randomized three-arm treatment trial in dogs, depending on the intervention being tested and numbers of dogs needed, could cost $1 million, whereas a similar study in humans would cost $10s of millions to over $100 million. Thus, one could clearly argue that if the dog study yielded results that were then used to markedly increase the odds of success in the human trial, that the dog study would be a very sound financial investment. All too often, however, when funding agencies and industry see that in some instances an entire mouse study could be done for the costs of one to two of the dogs in a trial, then the funding decisions go to the more traditional rodent experiments rather than the dog study. Part of this is because there has not been a "walk-off home run" in comparative oncology research in the last 20 years, in which the dog study was done first and the results clearly informed the design of a follow-up human study that was successful because of the dog work. There are numerous areas where translational researchers are on the brink for work that should have this high level of effect, but until that happens, funding agencies continue to opt for more traditional animal studies, even if those studies lack relevance to the human condition. Without funding for dog studies, however, the "walk-off home run" study is difficult, if not impossible, to achieve.

Another essential component of valuable translational research utilizing pet dogs is the scientists that will drive the work. The number of veterinary scientists with the knowledge, experience, translational mindset, willingness to conduct prospective clinical trials, and that make comparative

oncology research a main emphasis of their career is very limited. A unique set of skills and capabilities is needed, including knowledge of veterinary oncology, the human cancer focused in the research, and basic science that can be applied to improve the clinical condition, as well as excellent communication and people skills to build multidisciplinary teams (DVM, MD, PhD) to develop and accomplish the work, writing skills for successful grants and manuscripts, and the passion and drive to make the work happen. Forward thinking institutions are also key. Institutions need to build infrastructure and support, and allow individual faculty that have high potential to be the "research engines" to move away from the typical "triple-threat" position (equal time spent on clinical service, teaching, and research) of an academic veterinary oncologist. Some of the more successful veterinarians that have worked in translation research have spent time at a medical school or have had MD mentors. This enables them to better understand the most critical needs in human oncology and to network for collaborative research. The veterinary scientists must also have sufficient understanding of basic science to know how it could be applied to answer key clinical questions and to communicate with basic scientists for successful collaborations. Even with these skills and talents though, valuable translational research is going to require multidisciplinary teams.

Access to adequate numbers of dogs for clinical studies is obviously important. Currently, there is marked underutilization of dogs for clinical studies. In iUC for example, of the estimated 20,000 dogs that develop this cancer yearly, less than 5% of those dogs enter prospective clinical trials each year. There are programs in place, however, to accomplish canine clinical trials in which the numbers needed exceed that of a single institution. The best example is the Comparative Oncology Trials Consortium implemented by the Comparative Oncology Program at the National Cancer Institute.[50] This consortium includes academic veterinary oncologists at 20 veterinary colleges across the United States and Canada. Another consortium, the Canine Comparative Oncology Genomics Consortium (CCOGC)[50] sponsored by the National Cancer Institute, the American Kennel Club Canine Health Foundation, the Morris Animal Foundation, and Pfizer, is facilitating access to tumor and normal tissues and other samples from dogs through a biospecimen repository. Although this is an excellent starting point, this or similar repositories will need to expand to meet research needs in academia, nonprofit organizations, and industry/pharmaceutical companies, and to offer the possibility of a canine version of The Cancer Genome Atlas.[51]

In summary, clinical studies of pet dogs who have naturally occurring cancer or who are at risk for developing naturally occurring cancer can provide an unparalleled opportunity to make progress that will benefit humans, as well as pet dogs. Fortunately, there are solutions to overcome the challenges summarized above. This will allow pet dogs such as Lassie to "save the day" again, this time for cancer research!

Metabolism and Oxidative Stress Response Pathways in Kidney Cancer: A Tale of Chance and Necessity

Carole Sourbier, PhD, Ramaprasad Srinivasan, MD, PhD, and W. Marston Linehan, MD

OVERVIEW

Over 270,000 patients are affected with kidney cancer worldwide and 120,000 died from this disease in 2014. Over the last few decades, important progress has been made in our understanding of the genetic and molecular mechanisms underlying the growth of these tumors, which has led to improvement in patient care. Some of the most significant recent advances came from the increasing number of large datasets generated by bioinformatics (genomics, proteomics, etc.) and their integration to characterize the genetic and molecular factors responsible for kidney tumor development and survival. Interestingly, deregulated metabolism and oxidative stress pathways are commonly found in advanced-stage kidney tumors and are important factors to consider and potentially target when developing therapeutic approaches.

Patients with small and localized kidney tumors (known as renal cell carcinoma;RCC) who are treated with surgical resection or surveillance have a very high 5- and 10-year survival rate (over 95%). However, less than 15% of patients with advanced disease (T4 or M1) will survive longer than 5 years.[1,2] RCC is not a single disease; it is made up of a number of different types of cancer that occur in the kidney. Each type is characterized by different histology, a distinctive clinical course, disparate genetic changes, and requires distinct clinical approaches. The most common type of RCC is clear cell renal cell carcinoma (ccRCC). ccRCC represents 75% of all RCC and is characterized in 90% of cases by mutation of the *von Hippel-Lindau (VHL)* gene.[3,4] The second most common type of RCC is papillary RCC, representing approximately 15% of cases. Papillary tumors can be subcategorized into two distinct histologic subtypes: papillary type I and papillary type II. Papillary type I includes tumors with *MET* mutations and chromosome-7 amplification. Papillary type II, a heterogeneous group of tumors, includes tumors with tricarboxylic acid cycle (TCA) enzyme mutations, such as *fumarate hydratase* (*FH*), leading to a highly aerobic glycolytic phenotype and upregulation of the Nrf2-antioxidant response pathway. There are few therapeutic strategies specifically tailored to papillary tumors, and agents commonly used in ccRCC have only limited effectiveness in advanced papillary RCC.

It is known that dysregulation of cellular energetics and a metabolic shift to aerobic glycolysis is a hallmark of many types of cancer.[5-7] Initially described by Otto Warburg in 1924, cancers characterized by aerobic glycolysis undergo a metabolic shift to increased glycolysis despite the presence of oxygen and functioning mitochondria. Currently recognized as one of the "12 hallmarks of cancer,"[7] dysregulation of cellular energetic needs is supported by multiple genetic and molecular events. Some examples include the activation of the phosphatidylinositol-3 kinase (PI3K)/protein kinase B (Akt)/mammalian target of rapamycin (mTOR) pathway or the VHL/hypoxia-inducible factor (HIF) pathway, which would affect different aspects of cellular metabolism and also the activation of "coping" pathways, such as the Nrf2 pathway, which allows cells to survive the oxidative stress linked with an aberrant metabolism.[8] Regardless of whether metabolic alterations of tumor cells are an initiating event leading to tumorigenesis or are an adaptation associated with an aggressive phenotype, identifying the metabolic events associated with RCC survival is an important step toward the development of effective forms of therapy for this group of tumors.

CLEAR CELL RENAL CELL CARCINOMA TUMORS
Targeting the VHL/HIF Pathway
Current therapies for patients affected with advanced ccRCC mostly target the VHL/HIF pathway. The VHL protein binds other proteins, such as elongin B, elongin C, and CUL2, to target the HIF for ubiquitin-mediated degradation. This is an oxygen-sensing mechanism.[9-11] The VHL complex targets hydroxylated proteins, such as the HIF1-alpha and HIF2-alpha, for proteasomal degradation. In normoxic conditions, HIF prolyl hydroxylase hydroxylates two proline res-

---

idues on HIF-alpha. Under hypoxia, HIF is not hydroxylated, is not recognized by the VHL complex, and is stabilized. HIF1-alpha and HIF2-alpha are transcription factors that have downstream targets that are important for cell survival under hypoxic conditions and that regulate multiple biologic functions such as angiogenesis, energy metabolism, cell proliferation, erythropoiesis, and iron metabolism. Transforming growth factor alpha, vascular endothelial growth factor and its receptor, as well as the glucose transporters GLUT1 and GLUT4, and lactate dehydrogenase A (LDHA) are among HIF's downstream transcriptional targets. Since the identification of *VHL* gene mutations in ccRCC and elucidation of the role played by VHL in regulating the HIF pathway, numerous therapeutic approaches targeting this pathway have been developed.[10,12] However, although response rates can be substantial (in some cases as high as 40%), most disease eventually become resistant to therapy and progress. It has been shown in preclinical studies that HIF2-alpha is a critical pathway in VHL-deficient tumors.[13-15] Several strategies to inhibit HIF2-alpha have shown promising results in vitro in VHL-deficient tumor cell lines, and further studies are being conducted to facilitate evaluating this strategy in the clinic.[16-18] To improve the current clinical outcomes for patients with advanced ccRCC, development of more selective and potent agents targeting the vasculature might be necessary as well as a better understanding of how and why tumor cells are becoming resistant.

## UNDERSTANDING THE METABOLIC ADAPTATION OF CLEAR CELL RENAL CELL CARCINOMA TUMORS

Deciphering the molecular basis of ccRCC is critical for the development of effective targeted therapies. In report on ccRCC by The Cancer Genome Atlas, 19 substantially mutated genes were identified, including *VHL*, chromatin remodeling genes (*PBRM1, SETD2*, and *BAP1*), genes of the

<div style="background:#eee">

KEY POINTS

- Genetic and molecular mechanisms underlying renal cell carcinomas' developments drive metabolic changes in tumor cells.
- Advanced clear cell RCC and hereditary leiomyomatosis and RCC tumors share a similar metabolic profile consisting of a shift to aerobic glycolysis, enhanced glutamine metabolism, and increased fatty acid synthesis.
- Improvement in outcomes for patients with clear cell RCC has been made over the last 10 years by strategically targeting the VHL/HIF pathway.
- Targeting metabolic changes supporting tumor cells' survival might have a therapeutic value for clear cell RCC and papillary tumors.
- Imbalances in redox status are symptomatic of aggressive tumors and should be considered when developing a targeted therapeutic approach for RCC.

</div>

PI3K/Akt pathway (*PTEN, PI3KCA*), the mTOR pathway (*MTOR*), and *P53*. By integrating genomic, proteomic, and transcriptomic data, this study reported findings in high-grade, high-stage ccRCC that were consistent with a metabolic shift toward aerobic glycolysis and decreased oxidative phosphorylation. These data provide the basis for the development of additional therapeutic approaches in patients with advanced ccRCC.

Over the last few decades, signaling pathways, such as PI3k/Akt/mTOR, AMPK, or PKC-theta, have been shown to be promising therapeutic targets for ccRCC in clinical or preclinical studies.[19-22] Many of these signaling pathways are implicated directly or indirectly in regulating cell metabolism (Fig. 1). For example, two agents targeting mTOR, a key node in cell metabolism, have been approved for the treatment of ccRCC (everolimus and temsirolimus).[23] mTOR is a serine/threonine protein kinase that interacts with several proteins to form two distinct mTOR complexes (mTORC1 and mTOCR2) that have different metabolic and biologic functions, different regulators, but share the same catalytic mTOR subunit (for review see Laplante M and Sabatini DM).[24] mTORC1 stimulates glucose metabolism and fatty acid synthesis via regulation of HIF1-alpha and SREBP1/2 activation respectively, while inhibiting autophagy and supporting macromolecule biosynthesis. mTORC2 activates Akt and supports cell survival and cytoskeleton dynamics.[24] It is thought that resistance to mTOR inhibitors such as rapamycin is at least partly due to the fact that rapamycin only inhibits mTORC1, and mTORC2 is able to overcome this inhibition by phosphorylating and activating Akt (and glucose uptake). Thus, novel mTOR inhibitors targeting the catalytic subunit (i.e., dual TORC1/2 inhibitors) as well as approaches combining PI3K/Akt inhibitors with mTORC1 inhibitors and dual PI3K/mTOR inhibitors are being developed. The PI3K/Akt signaling pathway is involved in the insulin response pathway and promotes glucose uptake via regulation of GLUT1/4.[25] Identified about 9 years ago as aberrantly activated in ccRCC and a potent preclinical therapeutic target,[19,20] it was shown to be associated with ccRCC tumor progression, partially because of its role in supporting glycolysis.[26] Several agents targeting the PI3K/Akt pathway are currently in development for ccRCC. Studies are underway to determine if targeting glucose uptake combined with inhibition of glutamine metabolism might be therapeutically beneficial in ccRCC. Since both glucose metabolism and reductive glutamine metabolism have been shown to be upregulated. Since glutamine uptake also promotes lipids biosynthesis via reductive carboxylation, thus both glutamine uptake and lipids biosynthesis might be potential therapeutic targets. Inhibition of fatty acid synthase has been shown to have a potent effect in vitro in ccRCC cell lines; however, more work will be needed before this is translated into clinical trials. Preclinical studies have shown that cancer cells shift their metabolism to glutamine metabolism to support anabolism and growth.[27] In *VHL*-deficient tumor cells, HIF2-alpha expression is sufficient to induce reductive carboxylation because of reduced intracellular citrate levels.[28-31]

FIGURE 1. Clear Cell Renal Cell Carcinoma

High-grade, high-stage ccRCC present a metabolic shift toward aerobic glycolysis, decreased oxidative phosphorylation, and increased glutamine metabolism. This metabolic adaptation is supported in part by activation of the PI3K/Akt, mTOR, and HIF pathways.

Glutamine starvation and glutaminase inhibitors were both lethal to *VHL*-deficient tumor cells in vitro and in preclinical animal models suggesting that glutamine metabolism may be a therapeutic target for *VHL*-deficient ccRCC, alone or combined with other approaches. The development of glutaminase inhibitors for ccRCC therapy is currently being evaluated in early phase clinical trials.

OXIDATIVE STRESS RESPONSE IN CLEAR CELL RENAL CELL CARCINOMA

The high-energetic needs of tumor cells, aerobic glycolysis, inhibition of autophagy, and rapid cell proliferation, all lead to an increased oxidative stress.[32,33] Oxidative stress caused by unbalanced accumulation of reactive oxygen species (ROS), has been shown to promote tumor growth by inducing DNA damage and gene mutations or by activating signaling pathways promoting cell proliferation.[32] However, how to therapeutically target or manage tumors' oxidative stress response is still under study and it is unclear whether ROS scavengers or inducers might be beneficial. In ccRCC, both approaches have been evaluated in preclinical models. Agents affecting glutathione metabolism (glutaminase inhibitors), for example, or inducing endoplasmic reticulum stress (proteasome inhibitors and Hsp90 inhibitors) have been shown to be effective in preclinical models.[30,34]

TYPE II PAPILLARY RENAL CELL CARCINOMA

Type II papillary RCC can occur in both a sporadic (nonhereditary) and inherited form. Hereditary leiomyomatosis

and renal cell carcinoma (HLRCC) is a hereditary cancer syndrome in which affected individuals are at risk for the development of cutaneous and uterine leiomyomas and an aggressive form of type II papillary RCC.[35] The most prevalent gene mutation(s) responsible for sporadic papillary type II tumors are still unknown; however, studies have reported mutations of genes in the Nrf2 complex (Nrf2, KEAP1, CUL3).[36]

UNDERSTANDING THE METABOLIC ADAPTATION OF HEREDITARY LEIOMYOMATOSIS AND RENAL CELL CARCINOMATUMORS

In 2002 Tomlinson et al determined that *FH*, a gene encoding the TCA enzyme fumarate hydratase, was responsible for HLRCC.[37] It is estimated that approximately 15% to 20% of patients bearing a *FH* germ-line mutation will develop kidney tumors. Loss of FH enzyme function leads to impaired oxidative phosphorylation, a metabolic shift to aerobic glycolysis, and accumulation of the metabolite fumarate.[38-40] In patients with HLRCC-associated kidney tumors, HIF1-alpha and GLUT1 are overexpressed and tumors are highly [18F]fluorodeoxyglucose-avid on PET imaging.[39,40] FH-deficient tumor cells are notably dependent on glucose for ATP production as well as on glutamine for citrate, glutathione, and lipid biosynthesis. Increased amounts of the metabolite fumarate accumulate because FH-deficiency drives multiple biologic processes including inhibition of prolyl hydroxylase and stabilization of HIF1-alpha, supporting both

aerobic glycolysis (GLUT1/4, LDHA) as well as angiogenesis (e.g., vascular endothelial growth factor).[39] Aerobic glycolysis in HLRCC-associated FH-deficient papillary RCC cells produces increased ATP, leading to downregulation of the energy-sensing master regulator, AMPK.[22] Therapeutic strategies targeting aerobic glycolysis with silencing of LDHA or activators of AMPK have shown promising preclinical effects.[22,41]

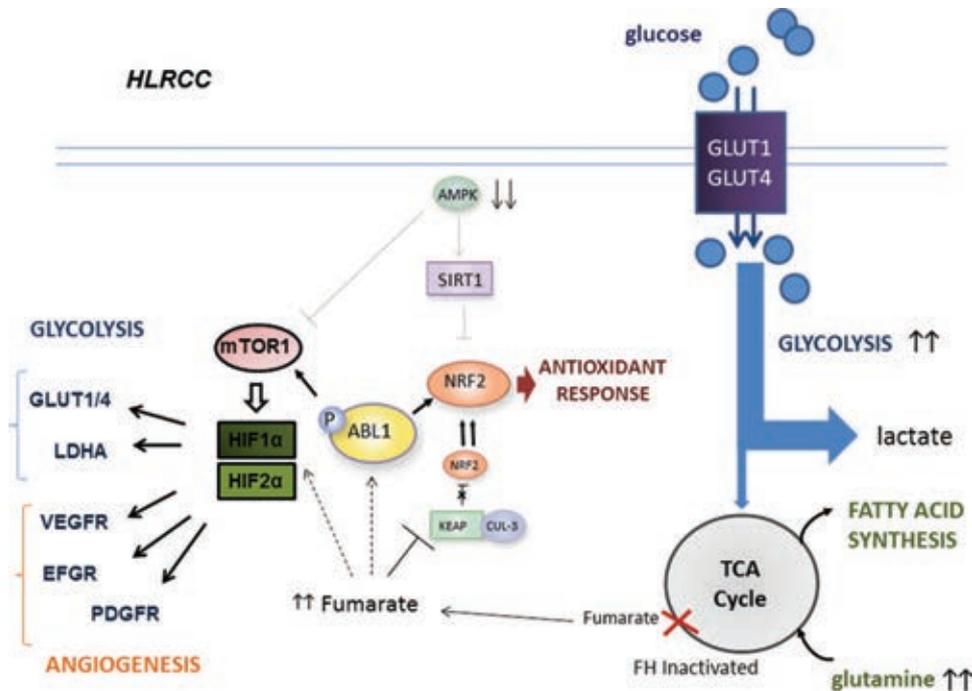
OXIDATIVE STRESS RESPONSE IN HEREDITARY LEIOMYOMATOSIS AND RENAL CELL CARCINOMA

FH-deficient tumor cells are characterized by oxidative stress due to elevated aerobic glycolysis and fumarate accumulation.[42,43] Targeting this redox imbalance by further increasing ROS has shown promise in preclinical studies.[44] In addition to its role on inducing ROS, fumarate accumulation is also critical in supporting the antioxidant response via the inhibitory succination of the Kelch-like ECH-associated protein 1 (KEAP1).[45,46] KEAP1 is the endogenous Nrf2 inhibitor and promotes targeting Nrf2 for proteosomal degradation. Nrf2 is a transcription factor critical for the antioxidant response by transcriptionally activating genes with antioxidant response element sequences, including NQO1 and HMOX.[47] The antioxidant signature of Nrf2 pathway activation has been found in both sporadic papillary type II tumors as well as HLRCC-associated kidney tumors, providing a potential therapeutic approach targeting this pathway.[46]

In studies conducted to develop a therapeutic approach targeting the Nrf2 pathway in FH-deficient type II papillary RCC, we recently showed that the activity of tyrosine kinase ABL1 was critical for Nrf2 nuclear translocation opening a new perspective on how to target this pathway[21] (Fig. 2). Based on current understanding of the mechanisms supporting HLRCC tumor cell survival with aerobic glycolysis needed to provide ATP and NRF2 antioxidant response pathway needed to cope with this extreme metabolism, it is reasonable to speculate that targeting both pathways simultaneously might have a promising effect. A phase II trial for patients with advanced papillary type II tumors (NCT01130519) using bevacizumab to inhibit angiogenesis and erlotinib to inhibit EGFR and modulate glucose and lipid metabolism via regulation of the PI3K/Akt pathway is currently underway.[48] In addition, we have also developed a therapeutic strategy targeting glycolysis and Nrf2 transcriptional activity via ABL1 inhibition.[21] We showed that ABL1 supports glycolysis in an mTOR-dependent manner and promotes Nrf2 transcriptional activity by indirectly allowing its nuclear translocation. Promising results were found in in vivo experiments in HLRCC xenograft models using vandetanib (a potent ABL1 inhibitor) as a single agent and when combined with the AMPK-activator metformin. A clinical trial evaluating the effect of vandetanib and metformin in patients with sporadic as well as HLRCC-associated type II papillary RCC is under development.

CONCLUSION

Over the past two decades significant progress has been made in our understanding of the molecular mechanisms of RCC.

FIGURE 2. Hereditary Leiomyomatosis and Renal Cell Carcinoma


FH-deficient tumor cells are characterized by elevated aerobic glycolysis and oxidative stress. Accumulation of the oncometabolite fumarate promotes Nrf2 antioxidant response transcriptional activity via KEAP1 inhibition and ABL1 activation. ABL1 also regulates aerobic glycolysis by activating the mTOR/HIF pathway.

Ten years ago we had very limited options for the treatment of patients with advanced RCC. We currently have seven approved agents for patients with advanced RCC and have some potential approaches that could represent a new era of targeted therapies and precision medicine designed to target metabolic and stress response pathways critical to tumor survival. The development of new bioinformatic tools will certainly further improve our understanding of the metabolic basis of kidney cancer and will hopefully provide the basis for the development of effective forms of therapy for patients with this disease.
